At a Glance Commentary.

Scientific Knowledge on the Subject: New therapies for asthma exacerbations remain a significant unmet medical need. Development of human relevant preclinical models are needed to further elucidate the complex mechanisms underlying asthma exacerbation and investigate new therapeutic strategies.

What This Study Adds to the Field: Using a human Airway Lung-Chip model, we show here for the first time a live human rhinovirus (HRV) infection of the asthmatic epithelium that recapitulates complex features of viral-induced asthma exacerbation. The dynamic microenvironment of the chip enables the real-time study of virus infection, epithelial response, and immune cell recruitment under healthy and asthmatic conditions. The model reproduces key endpoints that have been observed in asthmatics and individuals infected with rhinovirus including the ciliated cell sloughing, altered cilia beating frequency, goblet cell hyperplasia, increased expression of adhesion molecules in microvascular endothelial cells, and inflammatory mediator release. High-resolution temporal analysis of secreted inflammatory markers enabled by dynamic sampling revealed alteration of IL-6, IFN-λ1 and CXCL10 secretory phases after rhinovirus infection in an IL-13 high environment. Leveraging high-content imaging and analysis of circulating inflammatory cells, we demonstrated the efficacy of a CXCR2 antagonist to reduce adhesion, motility, and transmigration of perfused human neutrophils. Thus, this micro-engineered chip may offer a powerful addition to preclinical models for understanding mechanisms underlying asthma exacerbation pathology and developing new therapeutic strategies.

Abstract

Rationale: Viral-induced exacerbation of asthma remain a major cause of hospitalization and mortality. New human relevant models of the airways are urgently needed to understand how respiratory infections may trigger asthma attacks, and to advance treatment development.

Objectives: To develop a new human relevant model of rhinovirus-induced asthma exacerbation that recapitulates viral infection of asthmatic airway epithelium, neutrophil transepithelial migration, and enables evaluation of immunomodulatory therapy.

Methods: A micro-engineered model of fully differentiated human mucociliary airway epithelium was stimulated with IL-13 to induce a Th2-type asthmatic phenotype and infected with live human rhinovirus 16 (HRV16) to reproduce key features of viral-induced asthma exacerbation.

Measurements and Main Results: Infection with HRV16 replicated key hallmarks of the cytopathology and inflammatory responses observed in human airways. Generation of a Th2 microenvironment through exogenous IL-13 stimulation induced features of asthmatics airways, including goblet cell hyperplasia, reduction of cilia beating frequency, and endothelial activation, but did not alter rhinovirus infectivity or replication. High resolution kinetic analysis of secreted inflammatory markers revealed that IL-13 treatment altered the IL-6, IFN-λ1, and CXCL10 secretion in response to HRV16. Neutrophil transepithelial migration was greatest when viral infection was combined with IL-13 treatment, while treatment with MK-7123, a CXCR2 antagonist, reduced neutrophil diapedesis in all conditions.

65 **Conclusions:** This micro-engineered Airway Lung-Chip provides a novel human-relevant

66 platform for exploring the complex mechanisms underlying viral-induced asthma

67 exacerbation. Our data suggest that IL-13 may impair the hosts' ability to mount an

68 appropriate and coordinated immune response to rhinovirus infection. We also show that

69 the Airway Lung-Chip can be used to assess the efficacy of modulators of the immune

70 response.

81 **Introduction.**

82 Asthma is a chronic inflammatory disease of the respiratory tract defined by shortness of

83 breath, wheezing, and chest tightness that affects 300 million people worldwide[1]. In most

84 cases the disease can be managed with inhaled corticosteroids and bronchodilators;

85 however, up to 1/8 of patients experience asthma exacerbations that can lead to

86 emergency hospitalizations and death[2]. Asthma exacerbations are characterized by

87 acute episodes of decreased lung function and result in significant morbidity, mortality

88 and economic costs[3,4]. Prevention and treatment of asthma attacks hence remain an area

89 of considerable unmet medical need[5]. A major trigger of asthma attacks is human

90 rhinovirus (HRV) infection of asthmatic airways[6–8]. New human-relevant models are

91 critically needed to study how a respiratory infection may provoke asthma attacks, and to

92 advance the development of therapeutics[9]. To address this challenge, we leveraged a

93 human Airway Lung-Chip featuring mucociliary airway epithelium and hemodynamic

94 perfusion[10] to model key elements of viral-induced exacerbation of asthma. Our platform

95 recapitulates (1) the asthmatic remodeling of human mucociliary airway epithelium, such

96 as goblet cell hyperplasia[11], (2) cytopathic effects and epithelial inflammation in response

97 to HRV infection[12], and (3) recruitment of immune cells to the epithelium[13]. We show that

98 in conjunction with innovative high-content imaging, microfluidic sampling, and compound

99 testing, the Airway Lung-Chip helps to elucidate and probe the pathological mechanisms

100 that arise from the interaction of HRV infections with asthmatic airways, including

101 impaired interferon responses and altered immune cell transmigration. Taken together,

102 we demonstrate that our human Airway Lung-Chip provides a powerful new platform for

103   studying the time course, mechanisms and potential treatments of viral-induced asthma

104   exacerbations.

105

106   **Methods.**

107   Complete methods can be found in the online supplement.

108   **Cell differentiation and HRV infection on-chip.**

109   Cells were cultured and differentiated as previously described [10]. Briefly, human primary

110   airway epithelial cells (hAECs) from 4 healthy donors (Supplementary Table 1) were

111   seeded in the Airway Lung-Chips on a human placenta collagen IV-coated 3-μm pore

112   polyester membrane at a density of 3 x 10^6 cells/mL and left to attach for 2h. Five days

113   post seeding, air liquid interface (ALI) was introduced and Airway Lung-Chips were

114   perfused basally at 60μL/h for 3 weeks until full differentiation. Epithelium integrity,

115   ciliation, and apical mucus secretion were monitored for quality control. Upon full epithelial

116   differentiation, hMVECs or HUVECs were seeded onto the opposite side of the

117   membrane, in the vascular channel at a density of 1 x 10^7 cells/mL and cultured under

118   flow for 3-4 days in endothelial growth media. Rhinovirus strain 16 (HRV-16) (ATCC® VR-

119   283) was inoculated into the epithelial channel of fully differentiated Airway Lung-Chips

120   and incubated for 3h at 33˚C while control chips received DMEM only. Following

121   incubation, the epithelial channel of each chip was gently rinsed 5 x with DMEM. After the

122   final wash, and every 24h thereafter, the epithelial surface was washed with 50 μL of

123   DMEM to determine virus growth kinetics and the basolateral effluent was collected for

124   cytokine/chemokine responses. HRV16 titers were determined by infecting H1-HeLa cells

125   (CRL-1958) with serially diluted virus samples, recording the number of wells positive for

126   viral cytopathic effect (CPE) at each dilution after 5 days post infection and calculating

127   the $TCID_{50}$/mL. A Th2 microenvironment was induced by perfusing the vascular channel

128   of the Airway Lung-Chips with 100 ng/mL of IL-13 (Peprotech, USA) for 7 days. High-

129   content imaging was performed in live and fixed tissues and followed by quantitative

130   analysis to extract structural and kinematic endpoints, including ciliary beat frequency and

131   neutrophil recruitment dynamics. Anti-dsRNA antibody J2 (mabJ2, scicons, CZR) was

132   utilized to detect replicating intracellular HRV16 by immunofluorescence staining.

133   **Results.**

134   Here, we describe the development of a human Airway Lung-Chip suitable for the study

135   of viral-induced asthma exacerbation and the effect of immunomodulatory compounds on

136   immune cell dynamics (**Supplementary Fig. 1A**).

137   **Adapting the Airway Lung-Chip design to enable immune cell transmigration.**

138   We adapted our recently developed micro-engineered "small-airway-on-a-chip" model [10]

139   by increasing the membrane pore size (3.0 μm vs 0.4 μm) to allow immune cells to

140   transmigrate from the vascular microchannel to the epithelial lumen (**Supplementary Fig.**

141   **1B**). As substrate pore size can greatly influence tissue differentiation[14], we validated the

142   new chip design for airway tissue culture. hAECs were seeded in the top channel and

143   human primary endothelial cells were seeded in the bottom channel to create a tissue-

144   tissue interface. We confirmed establishment of a well-differentiated mucociliary

145   bronchiolar epithelium by the presence of robust ZO-1-containing tight junctions,

146   characteristic epithelial cobblestone-like morphology, mucus producing goblet cells, and

147   dense coverage with ciliated cells (**Supplementary Fig. 1C-E)**. Formation of an intact

148   microvascular endothelium was validated by staining for endothelial junctional protein VE-

149   Cadherin (**Supplementary Fig. 1F)**. Mucociliary function was assessed by high-speed

150   video microscopy and quantitative analysis[15]. We measured a ciliary beat frequency of

151   16.35 (± 2.6) Hz (**Supplementary Fig. 1G-H, Supplementary movie 1**). Microbead

152   trajectories revealed locally unidirectional mucociliary transport (**Supplementary Fig. 1I**)

153   with a typical velocity of ~ 100 μm/sec, which is similar to mucociliary transport velocities

154   in intact human airways [16]. In sum, the Airway Lung-Chip was functionally augmented

155   with a 3-μm pore membrane to enable immune cell transmigration, and we validated that

156   it supports the viability and function of normal human bronchiolar tissue.

157

158   **HRV16 readily infects the Airway Lung-Chip and induces cytopathic effects.**

159   We next investigated HRV infection of the Airway Lung-Chip (**Fig. 1A**). We infected the

160   chip apically with HRV16, a rhinovirus serotype commonly used in clinical challenge

161   studies, and analyzed viral infectivity and replication, cell tropism and induced cytopathic

162   effects (CPE). Infection a multiplicity of infection (MOI) of 1 resulted in a rapid apical

163   release of infectious virus particles that peaked between 24 and 48 hours post infection

164   (hpi) followed by a steady decline of released virions until no virus was detected 144 hpi

165   (**Fig. 1B**). This timeframe is consistent with viral shedding and symptom score profiles of

166   individuals experimentally infected with HRV [17–19].

167   HRV16 readily infected the intact epithelium and induced apical cell sloughing by 24 hpi

168   (**Fig. 1C**). Real time imaging and immunofluorescence (IF) characterization identified that

169 the majority of detached cells were infected multiciliated cells (**Fig. 1D, Supplementary**

170 **movie 2**), similar to what has been observed in respiratory tissue biopsies of human

171 volunteers experimentally infected with HRV[20,21]. Many of the detached cells were

172 TUNEL-positive, indicating apoptosis (**Supplementary Fig. 2A**). IF imaging of infected

173 chips revealed that HRV16 infection was restricted to ciliated cells and induced the

174 protrusion and extrusion of infected cells from the epithelial lining, while mucus producing

175 cells remained non-infected (**Fig.1E, Supplementary movie 2**). By day 6 post infection,

176 few ciliated cells remained on the epithelial surface (13-fold decrease in cilia coverage;

177 p<0.001) (**Fig. 1F, Supplementary Fig. 2B**) and they displayed significantly shorter cilia

178 (**Supplementary Fig 2C-D**). Additionally, consistent with HRV16 ciliated cell tropism, we

179 observed a 60% reduction in ciliary beat frequency following infection (p<0.001) (**Fig. 1G**

180 and **Supplementary movie 3**). The acute damage to ciliated cells was accompanied by

181 a 2-fold increase in the area covered by MUC5AC positive cells by day 6 post infection

182 compared to non-infected chips (p<0.001) (**Fig. 1H, Supplementary Fig. 2E**), in line with

183 clinical observations[22].

184

185 **Modeling viral-induced asthma exacerbation on-chip.**

186 We used interleukin-13 (IL-13) stimulation to induce features of type 2 inflammation in

187 asthma (**Fig. 1I**). IL-13 plays a central role in allergic asthma and, together with IL-5, is

188 an important mediator of viral-induced exacerbations in asthma [23]. When we perfused the

189 vascular channel of the Airway Lung-Chip with IL-13 (100 ng/mL) for 7 days preceding

190 virus infection we detected a significant increase in the number of goblet cells (rising from

191 16.5% to 50.3% total area; p<0.01) (**Fig. 1K, Supplementary Fig. 3**) and a decrease in

192   cilia beating frequency (14.4% reduction; p<0.001) (**Fig. 1K,L and Supplementary**

193   **movie 4**), which is consistent with observations made in airway mucosa of asthmatic

194   patients [24,25].

195   To recapitulate HRV-induced asthma exacerbation, we combined IL-13 treatment with

196   HRV16 infection to induce exacerbation (**Fig. 2A**). Infection of the IL-13 stimulated Airway

197   Lung-Chip with HRV16 did not result in significant changes in viral loads in apical washes

198   nor in the duration of infection when compared with non-stimulated chips (**Fig. 2B**). This

199   finding is consistent with recent studies in asthmatics experimentally infected with HRV16

200   [26–28], although another study found a higher viral load in asthmatics on day 3 of infection[29].

201   Type 2 inflammation has been suggested to increase asthmatics susceptibility to

202   exacerbations through airway remodeling and modulation of the antiviral response [30]. To

203   gain insight into the effect of IL-13 on HRV16-induced inflammatory responses we first

204   measured the levels of pro-inflammatory cytokines and chemokines released apically and

205   basolaterally at 24, 48 and 72 h post HRV16 infection, in the presence or absence of IL-

206   13 (**Fig.2C-E and Supplementary Fig. 4**). Apical and basolateral secretion of CCL11

207   (Eotaxin-1), a potent eosinophil chemoattractant and marker of Th2 asthma in human [31],

208   was increased following HRV16 infection (**Fig. 2C**), consistent with literature[32]. This was

209   not significantly altered by IL-13 treatment. In contrast and consistent with literature[33],

210   apical secretion of CCL26 (Eotaxin-3), another chemokine associated with eosinophil

211   recruitment and persistence in patients with asthma[34], was increased at all time points

212   following stimulation with IL-13 alone, while HRV16 infection had no effect on CCL26

213   release. Analysis of the interferon (IFN) type III responses revealed that apical and basal

214   release of IFN-λ1 at 48 hpi, and of the IFN-induced lymphocyte chemoattractant CXCL10

215 at 48 and 72 hpi were increased following HRV16 infection (**Fig. 2D**). IL-13 treatment

216 significantly reduced the measured IFN response in HRV16 infected chips. This is

217 consistent with other in vitro studies showing that IL-13 impairs IFN-λ production[35], and

218 with clinical reports intimating that individuals with asthma or cells from asthmatics

219 infected with HRV have a deficient IFN response [36–39], although this remains

220 controversial[40]. Basal secretion of IL-8, a potent attractant of neutrophils[41], was increased

221 48 h post HRV16 infection, with little impact of IL-13 treatment (**Fig. 2E**). In contrast, we

222 found that induction of IL-6 secretion following HRV16 infection was greatly reduced in

223 IL-13 treated samples at 48 h post infection (**Fig. 2E)**. Notably, we did not detect any IFN-

224 β secretion at any time point with and without IL-13 stimulation.

225 To elucidate the kinetics of inflammatory mediator release during viral-induced asthma

226 exacerbations and thereby gain additional insight into the pathophysiological process[42,43],

227 we exploited the microperfusion of the Airway Lung-Chip for high resolution temporal

228 profiling of IFN-λ1, CXCL10 and IL-6 secretion. By collecting basal medium outflow every

229 2h for 74h, we revealed the temporal dynamics of cytokine secretion after HRV infection

230 (**Fig. 2F**). In untreated chips, both IFN-λ1 and IL-6 increased quickly and reached

231 maximal, or near maximal, values at approximately 22 h post HRV16 infection. CXCL10

232 rose more slowly and peaked at 34 h post infection, in line with direct interferon-

233 dependent regulation of CXCL10. In contrast, the IL-13 treated chips exhibited markedly

234 suppressed secretion profiles. The high-resolution profiling plots reveal this difference in

235 the first 24h, whereas it remains masked in the accumulated medium collected after 24

236 hpi (**Fig. 2D,E**). This demonstrates that high resolution profiling is a sensitive method for

237   detecting onset and dynamics of cytokines release, determining sensitive time windows,

238   and identifying the best sampling strategy.

239   We also investigated the effect of the IL-13 stimulation of human endothelial cells, which

240   contributes to leukocyte recruitment in the pathogenesis of asthma[44]. Within 48h of the

241   IL-13 treatment, we observed progressive endothelium morphological changes leading to

242   the formation of cell aggregates throughout the vascular wall (**Supplementary Fig. 5A**)

243   accompanied by a doubling of endothelial cell density ($p < 0.0001$) (**Supplementary Fig.**

244   **5B**). Further analysis revealed increased gene expression of P-Selectin ($p = 0.036$) and

245   E-Selectin ($p = 0.06$), two adhesion molecules involved in inflammatory cell recruitment,

246   compared to control (**Supplementary Fig. 5C, Supplementary Table 2**). IF staining of

247   intercellular adhesion molecule 1 (ICAM-1) and vascular cell adhesion protein 1 (VCAM-

248   1) was also increased in IL-13 treated cultures (**Supplementary Fig. 5E)**, indicating that

249   IL-13 promotes activation of the lung microvascular endothelium. Indeed, bronchial

250   biopsies from subjects with asthma revealed increased adhesion molecule expression in

251   endothelial cells[45].Although we cannot rule out that the IL-13 treatment stimulated the

252   epithelial cells to release additional chemokines, our findings align with previous studies

253   on the effects of IL-13 on human endothelial cells[46].

254

255   **Pharmacological modulation of neutrophil recruitment and transmigration by a**

256   **CXCR2 antagonist on-chip.**

257   Airway neutrophilia is frequently observed in acute exacerbations of asthma[13,47,48], and is

258   associated with asthma severity[49]. HRV infections in asthmatics may also promote

259 selective recruitment of neutrophils[50]. Since neutrophils can contribute to asthma

260 exacerbation through the release of tissue-damaging compounds[51], neutrophil

261 recruitment constitutes a potential drug target. We sought to show feasibility of probing

262 the real-time dynamics of neutrophil recruitment on the Airway Lung-Chip, where the

263 endothelial vascular channel supports the live observation of circulating and

264 transmigrating neutrophils. In a proof-of-concept study, we investigated neutrophil

265 recruitment in exacerbated conditions and in response to a CXCR2 antagonist, which

266 blocks neutrophil sensing of IL-8[41]. Here, we perfused freshly isolated human neutrophils

267 stained with a live dye through the vascular channel of exacerbated asthma chips under

268 physiological flow (i.e., with fluid shear stresses of ca. 1 dyn/cm^2 [52], an important factor

269 for physiological neutrophil recruitment[53]). We observed neutrophil adhesion and crawling

270 at the surface of the microvascular endothelium, rapidly followed by neutrophil

271 transendothelial migration through a combination of transcellular and paracellular

272 migratory events (**Fig. 3A, B**). Treatment with either IL-13 or HRV16 significantly

273 increased neutrophil adhesion, and combined treatment almost doubled recruitment

274 compared to each condition alone (**Fig. 3C, D**). Pre-treatment of neutrophils with 10 µM

275 MK-7123, a CXCR2 antagonist, at 24 hpi significantly reduced neutrophil adhesion to the

276 endothelium in all treatment groups (**Fig. 3C, D**), and also reduced neutrophil crawling

277 velocity (**Fig. 3E, F and Supplementary movies 5 and 6**). Real time imaging revealed

278 that many endothelium bound neutrophils transmigrated from the vascular channel

279 through the 3-µm pores of the membrane (which frequently merge into even larger pores

280 in track-etched membranes) into the epithelium channel where they adhered to the

281 epithelial surface (**Fig. 3G and Supplementary movie 7**) and treatment with MK-7123

282   reduced the proportion of transmigrating neutrophils (**Fig. 3H**). Furthermore,

283   characterization of fully migrated neutrophils revealed expression of myeloperoxidase

284   (**Fig. 3I**), a marker of neutrophil activation found in lungs of asthmatics [54] that contributes

285   to inflammation *in vivo* [55]. Thus, our on-chip disease model of asthma exacerbation not

286   only enabled efficacy testing of an immunomodulatory compound but also elucidated the

287   multi-step dynamics of neutrophil recruitment in a human-relevant context.

288

289   **Discussion**

290   We still incompletely understand why asthmatics are at higher risk of developing life-

291   threatening exacerbation following rhinovirus infection. Previous *in vitro* studies have

292   suggested that prior damage to the asthmatic airway epithelium facilitates HRV infection

293   by exposing more permissive, ICAM-1-expressing basal cells, explaining the

294   susceptibility of asthmatic airways to infection [56,57]. The corollary is the perception that

295   intact epithelial layers of healthy subjects are somewhat resistant to HRV infection[58].

296   Contrasting with this view, our findings demonstrate that HRV can readily infect the intact

297   well-differentiated mucociliary epithelium and induce significant airway remodeling

298   leading to almost complete loss of ciliated cells and goblet cell hyperplasia by day 7 post

299   infection. Our observations are consistent with studies showing induction of mucin

300   production by rhinovirus infection of human bronchial epithelia in vitro and in vivo [22,59],

301   the induction of goblet cell metaplasia by rhinovirus-mediated foxa3 activation[60], high viral

302   load and cell shedding the airways of individuals infected with HRV[20,26–28], as well as

303   HRV-induced CPEs[61,62] and apoptotic events[63] in *in vitro* human bronchial epithelia. This

304   suggests that RV infections have considerable potential for cytopathic and remodeling

305   effects in the airways, and that HRV-induced CPE might contribute to exacerbations in

306   asthmatic individuals by directly damaging mucociliary clearance and increasing mucus

307   secretion.

308   Several groups have investigated the effect of IL-13-induced mucous metaplasia on the

309   susceptibility of human airway epithelium to HRV infection and come to discordant

310   conclusions, such as increased versus reduced susceptibility to HRV infection [64] [65]. In

311   contrast, we did not detect any significant difference in viral load or infection persistence

312   in IL-13 treated versus non-treated chips. Donor to donor variability and differences in

313   experimental design might explain the different outcomes. Clinical studies are also in

314   disagreement, with some reporting higher viral loads in asthmatics[29] while others align

315   with our results in showing no difference in viral titer of asthmatics compared to non-

316   asthmatics [26–28,66]. In sum, there are clearly many remaining unknowns in HRV-induced

317   asthma exacerbation, and our findings show that the Airway Lung-Chip is a valuable new

318   tool for their investigation.

319   We found that HRV-induced type III IFN response was ablated in a type 2

320   microenvironment, which is consistent with studies showing impaired IFN responses in

321   cells from asthmatic individuals challenged with HRV [36,67]. However, several recent *in*

322   *vitro* and *in vivo* studies contradict these results [26,28,40,68,69], suggesting that an impaired

323   IFN responses may not be the only factor contributing to exacerbation. Asthma phenotype

324   heterogeneity and differences in the study designs may further confound the picture. An

325   impaired IFN response might be specific to asthmatics with a Th2-dominant inflammatory

326   profile [23,36], in line with the downregulation of IFN-λ1 by a Th2 microenvironment on our

327   chip.

328 Effective orchestration and resolution of the immune response rely on both magnitude

329 and kinetics of secreted cytokines. IL-6 is a prime example as its pro- or anti-inflammatory

330 nature depends on secretion timing [43]. Here, we have leveraged the microscale perfusion

331 of the Airway Lung-Chip to conduct high resolution temporal profiling of secreted

332 cytokines. We found that the IL-6 secretory profile was markedly disrupted by IL-13

333 stimulation. This could be due to the altered epithelial architecture and cell type

334 composition of the asthmatic microenvironment[70], which may alter cytokine

335 responses[71,72]. The central role of IL-6 in infection and inflammation has been extensively

336 described [73] and though it is usually considered a pro-inflammatory mediator in asthma

337 exacerbations, its protective role in the lung was highlighted in several studies [42 74 75 76],

338 which together with our results may suggest a more nuanced role for IL-6 in exacerbation

339 pathogenesis.

340 We also demonstrated the utility of the Airway Lung-Chip for testing the efficacy of

341 immunomodulatory compounds on neutrophil recruitment. Though the first generation of

342 CXCR2 inhibitors has failed to deliver in the clinic, it is now appreciated that neutrophils

343 are extremely heterogeneous and display different responses depending on subtype and

344 environmental factors[77]. Because of this, more than ever new platforms like the Airway

345 Lung-Chip are needed to enable the phenotypic and functional profiling of neutrophils in

346 the context of disease and drug treatment.

347 In summary, we developed a new on-chip human disease model of viral-induced asthma

348 exacerbations that recapitulates hallmarks of rhinovirus-induced responses of the

349 asthmatic airway. Owing to its unique fluidic design and accessibility to optical imaging,

350 the Airway Lung-Chip also enables the high-resolution profiling of cytokine release,

351 phenotypic changes and dynamic immune cell responses to immunomodulatory

352 therapies in a human-relevant context, thus adding a powerful pre-clinical platform for

353 probing complex disease mechanisms and developing new treatments for asthma

354 exacerbations.

355

Fig 1. **Modeling HRV infection and Th2 asthma phenotype on the Airway Lung-Chip**. (**A**) HRV-16 was apically delivered to the chip at an MOI~1. (**B**) Viral growth kinetic of HRV-16 following infection. HRV16 was titrated in apical washes and data represent mean ± SD log10 $TCID_{50}$/ml from 3 different donors with two to five biological replicates per donor. The dashed line indicate the limit of detection of the titration assay. (**C**) Phase contrast micrographs of differentiated airway epithelium cultured in the airway chip for 3 weeks at air liquid interface infected with HRV16 for 24h (right) or non infected (left) showing epithelial cells sloughed off infected cultures while non infected epithelium remains intact. Scale bar, 50 μm. (**D**) IF image of apical washes from cultures infected with HRV16 for 24h showing detached cells stained for β-tubulin (green), mAbJ2 (red) and DAPI (blue). Scale bar, 10 μm. (**E**) IF image of the differentiated mucociliary epithelium on-chip infected with HRV16 for 24h and stained for β-tubulin (left) or MUC5AC (right) (green) and mAbJ2 (red). Orthogonal views show a ciliated infected cells protruding from the epithelial lining (white arrow). Scale bar, 20 μm. (**F**) Total culture area covered by ciliated cells in non infected chips and 6 days post HRV16 infection. (**G**) Cilia beating frequency in non infected chips and 72 hpi. (**H**) Total culture area covered by goblet cells in non infected control and HRV16 infected chips 6 dpi. (**I**) A Th2 asthma environment was generated through vascular perfusion of IL-13 (100 ng/mL) over 7 days. (**J**) Total culture area covered by goblet cells in absence or presence of IL-13 (100 ng/mL) for 7 days. (**K**) Heat map of cilia beating frequency (CBF) on-chip generated from a high speed recording of cilia beating in a representative field of view in absence or presence of IL-13 (100 ng/mL). Scale shows color coded CBF values in Hz. Scale bar, 20 μm. (**L**) Graph showing ciliary beat frequency in absence or presence of IL-13 (100 ng/mL). Data are from chips with cells from three healthy donors, with one or two biological replicates (chips) per donor. Data represent mean ±SEM and significance was determined by unpaired Student's; ****P < 0.0001.

Figure 2. Modeling HRV-induced asthma exacerbation on chip and measuring inflammatory responses. (**A**) The severe asthma chip was generated by inducing features of Th2 asthma through vascular perfusion of IL-13 (100 ng/mL) and exacerbation through HRV16 epithelial infection (MOI 1). (**B**) Viral growth kinetic of HRV-16 following infection of the airway chip at an MOI~1 in the absence or presence of IL-13. HRV-16 was titrated in apical washes and data represent mean ± SEM log10 TCID$_{50}$/ml from 3 different donors with two to five biological replicates per donor. **(C-E)** The graphs show the effect of on polarized apical and basal release of CC chemokines (**C**), interferon and interferon-induced chemokines (**D**), and pro-inflammatory interleukins (E) by the combination of IL-13 treatment and HRV-16 infection in the exacerbated asthma chip at 24h, 48h and 72h post infection. (**F**) The graphs show a high resolution, kinetic profiles of insert IFN-λ1, IP-10/CXCL10and IL-6 response following HRV16 infection, with and without IL-13 treatment over 72 h. Data represent mean ±SEM of cells from three to four different donors, with one or two biological replicates (chips) per donor. Significance was determined by multiple comparison two-way ANOVA followed by Tukey's post-hoc correction; *P < 0.05, **P < 0.01, ***P < 0.001, ****P < 0.0001.

Fig 3. Assessing and modulating IL-13- and HRV-induced neutrophil recruitment and infiltration on chip. (**A**) Schematic diagram of the severe asthma chip depicting the neutrophil recruitment assay. (**B**) Micrographs showing paracellular and transcellular transmigration of neutrophil live-stained (red) through GFP-expressing endothelial cells (green). Obvious transcellular diapedesis events are indicated by the pink arrows while the blue arrow points at a paracellular migration. Scale bar, 10 μm. (**C**) Fluorescence microscopic imaging of chips perfused through the microvascular channel under physiological conditions (shear stress, 1 dyn/cm²) for 5 min with freshly isolated CellTracker red−labeled human neutrophils showing recruitment to the endothelium stimulated or not with a combination of IL-13, HRV-16 and a CXCR2 antagonist (MK-7123 - 10μM). Scale bar, 50 μm. (**D**) Quantification of neutrophil recruitment from (**C**). (**E**) Schematic diagram of neutrophil diapedesis taking place in the severe asthma chip. (**F**) Fluorescence imaging tracking neutrophil velocity at the endothelial surface in HRV-16 infected chips, in absence (left) or presence (right) of the CXCR2 antagonist. Scale shows color coded velocity values in μm/sec; Scale bar, 50 μm. (**G**) Quantification of neutrophil velocity in HRV16 infected chips with or without MK-7123 (10μM). (**H**) The graph shows the disappearance of neutrophils (expressed in % of starting count) due to transmigration from the vascular wall to the epithelial lumen in HRV16 infected chips in absence or presence of MK-7123 (10μM). (**I**) Immunofluorescence micrograph of an HRV16 infected chip showing human neutrophil stained for myeloperoxidase (green) that have migrated to the epithelial lumen among HRV16 infected epithelial cells (red). Scale bar, 20 μm. Data represent mean ± SEM from three different donors with two biological replicates (chips) per donor.

A

Adapt human Airway Lung-Chip design	Develop disease model components	Model viral-induced asthma exacerbation
○ Enable immune cell transmigration	○ Th2 asthma phenotype: IL-13 stimulation ○ Exacerbator: Human rhinovirus (HRV16) infection	○ Th-2 asthma phenotype + viral exacerbator ○ Test modulator of immune cell recruitment

Supplementary figure 1. The human Airway chip. **A**) Overview of approach taken in this study to model asthma exacerbation and demonstrate feasibility of compound testing. (**B**) Functionally augmented Airway Lung-Chip design has 3-µm pore membrane for enabling neutrophil transmigration between the endothelial and epithelial channel. (**C**) The differentiated airway epithelium on the top channel exhibits continuous tight junctional connections on-chip, as demonstrated by Zo-1 staining (red). Scale bar, 20 µm. (**D-E**) The well-differentiated human airway epithelium generated on-chip also contains goblet cells stained for MUC5AC (green) and demonstrates extensive coverage of ciliated cells labelled for β-tubulin (green). Scale bar, 20 µm. (**F**) The human (lung blood microvascular) endothelial monolayer formed in the bottom channel of the chip features continuous adherens junctions between adjacent cells, as indicated by VE-Cadherin staining (green). Scale bar, 10 µm. All images are representative of two to five independent experiments performed with cells from three different donors. (**G**) Graphic representation of cilia beating frequency (CBF) on-chip generated from a high speed recording of cilia beating in a representative field of view. Scale shows color coded CBF values in Hz. Scale bar, 20 µm. (**H**) The graph shows the cilia beating frequency measured in 5-10 random on-chip fields of view and each dot represents regions of ciliary beating. Data have been recorded in cells from three different donors and are presented as mean ± SD. (**I**) Time lapse composite image of a 5 sec recording of 1-µm fluorescent microbeads suspended in PBS and introduced in the top channel. The path lines reveal the mucociliary transport of the differentiated hAECs. Scale bar, 20 µm.
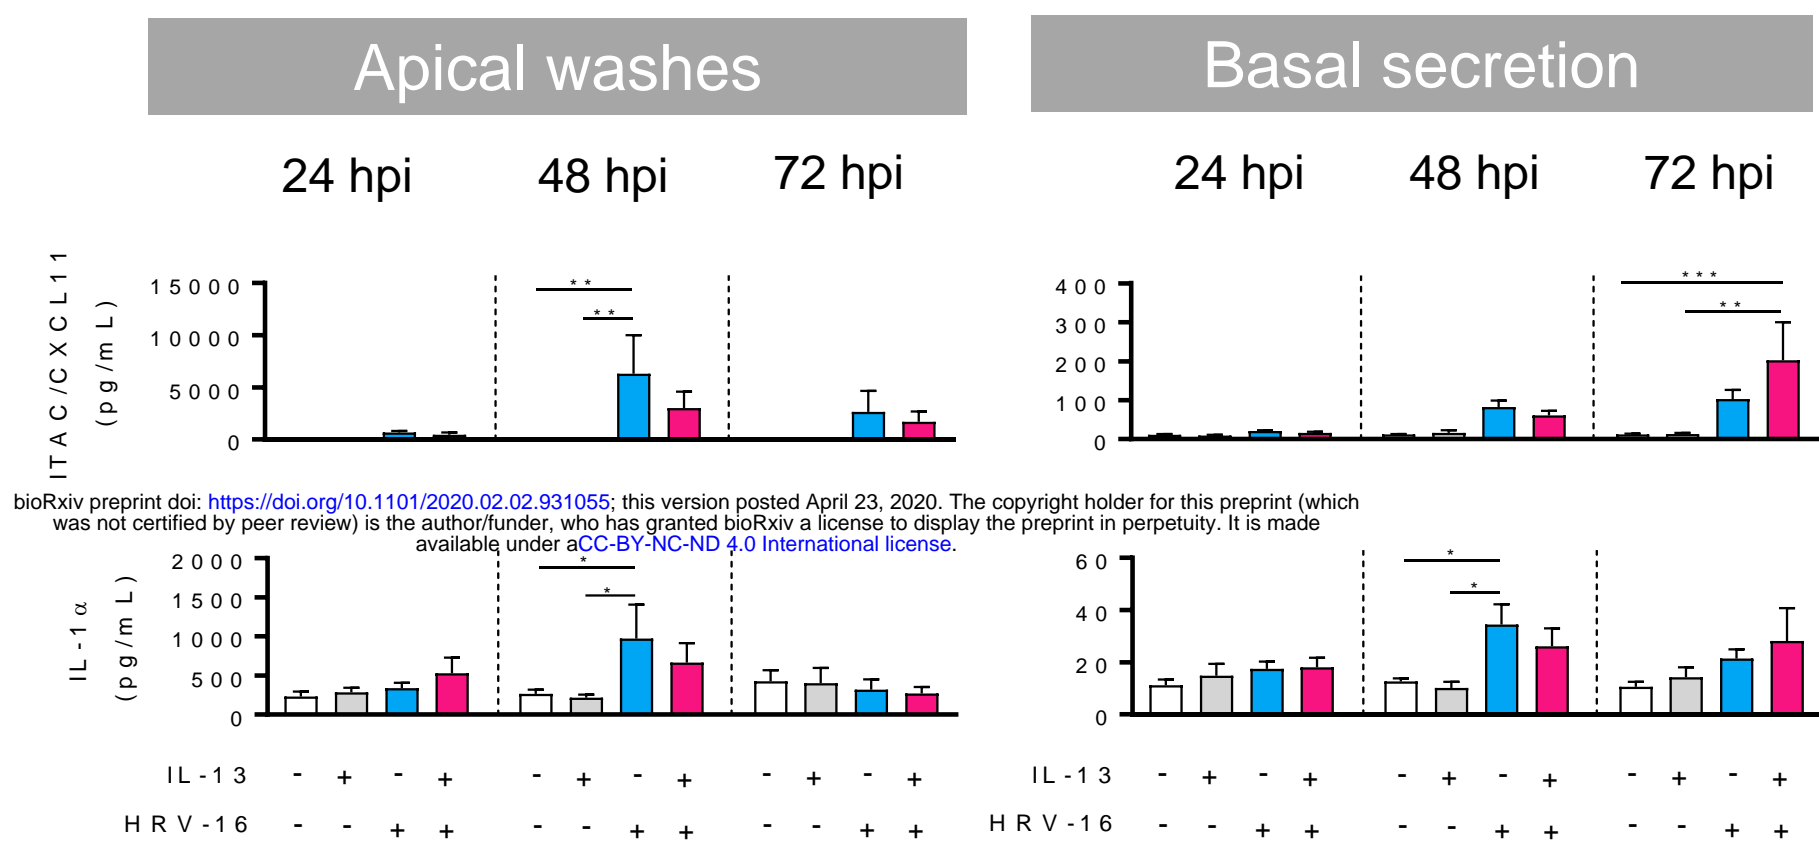

**Supplementary figure 2. HRV infection causes cytopathic effects and epithelial remodeling.** (**A**) Fluorescence confocal micrograph of detached epithelial cells stained using the TUNEL assay showing nuclei of apoptotic (green) and non apoptotic (blue) cells. Scale bar, 20 μm. (**B**) Immunofluorescence images of the differentiated epithelium non infected (left) or fixed at 6 days post HRV16 infection (right) and stained for β-tubulin (green) and DAPI (blue). Scale bar, 20 μm. (**D**) Confocal image of the cells collected in an apical wash 24 h following HRV16 infection of an airway chip showing the extend of ciliated cells destruction. Note the presence of individual cilia (green) in the apical wash. Scale bar, 20 μm. (**D**) Quantification of the length of cilia on multiciliated cells 6 d post HRV16 infection. Data represent mean ± SEM; Significance was determined by unpaired Student's t-test; ****P < 0.0001. (**E**) Immunofluorescence images of the differentiated epithelium non infected (left) or 6 days post HRV16 infection (right) and stained for MUC5AC (red) and DAPI (blue). Scale bar, 20 μm.

FIGURE 3

| No treatment | IL-13 (100 ng/mL) |

MUC5AC/DAPI

Supplementary Figure 3 . IL-13 induces goblet cell hyperplasia. Immunofluorescence confocal views of differentiated airway epithelium cultured at air-liquid interface for 3 weeks on-chip in the absence (left) or presence (right) of IL-13 (100 ng/mL) for 7 days showing epithelium stained for the goblet cell marker MUC5AC (green) and nuclei (blue). Scale bar, 20 µm (applies to both views); images are representative of two independent experiments performed on cells from three different donors.

Supplementary figure 4. The graphs show the effect on polarized apical and basal release of CXCL11 and IL-1α by the combination of IL-13 treatment and HRV-16 infection in the severe asthma-on-a-chip at 24h, 48h and 72h post infection. Data represent mean ±SEM of cells from three to four different donors, with one or two biological replicates (chips) per donor. Significance was determined by multiple comparison two-way ANOVA followed by Tukey's post-hoc correction; *P < 0.05, **P < 0.01, ***P < 0.001.
Supplementary figure 5. IL-13 induces aggregation and activation of endothelial cells. (**A**) Fluorescence micrographs of GFP-expressing endothelial cells co-cultured with well differentiated airway epithelial cells on chip, in absence (left) or presence (right) of IL-13 (100ng/mL) for 48h. Scale bar, 50 μm. (**B**) Quantification of endothelial cell density in absence or presence of IL-13 (100 ng/mL) for 48h. (**C**) Volcano plot showing gene expression of IL-13 (100ng/mL) treated endothelial cells compared to untreated group. Data were analyzed using a two-stage step-up method of Benjamini, Krieger and Yekutieli. (**D**) Effect of IL-13 (100ng/mL) on endothelial cell adhesion molecules ICAM-1 and VCAM-1 expression, as measured using fluorescence measurement. Data represent mean ±SEM of n=3 replicates. Significance was determined by unpaired Student's t-test; *P < 0.05, ****P < 0.0001. (**E**) Fluorescent micrograph of human pulmonary microvascular endothelial cells in presence and absence of IL-13 (100 ng/mL) for 48h and stained for adhesion molecules ICAM-1 and VCAM-1 (red), and VE-Cadherin (green). Nuclei were counter stained with DAPI (blue). Scale bar, 20 μm.

| Donor #	AGE	SEX	SMOKING
1	5 yo	F	N
2	21 yo	M	N
3	18 yo	M	Y
4	18 yo	F	N

**Supplementary table 1**. Age and sex of donors used in this study.

Supplementary movie 1. Real time phase contrast microscopic imaging of well differentiated human airway epithelial cells cultured inside the airway chip for 21 days on a 3 um pore membrane showing extensive coverage of synchronized cilia beating. Scale bar, 20 μm.
Supplementary movie 2. Real time phase contrast microscopic imaging of HRV16-infected airway chips (24hpi) showing rounded ciliated detaching from the epithelium (white arrows). Scale bar, 20 μm.
Supplementary movie 3. A movie showing phase contrast microscopic imaging of well differentiated human airway epithelial cells cultured inside the airway chip for 21 days on a 3 µm pore membrane and infected with HRV16 for 72 h. Scale bar, 20 µm.
Supplementary movie 4. A movie showing phase contrast microscopic imaging of well differentiated human airway epithelial cells cultured inside the airway chip for 21 days on a 3 µm pore membrane and treated with IL-13 (100 ng/mL) for 7 d. Scale bar, 20 µm.

Supplementary movie 5. A movie showing movement tracking of fluorescently labelled human neutrophils recruited to the surface of the microvascular endothelium 24 post HRV16 infection on chip. Scale bar, 50 µm.

Supplementary movie 6. A movie showing movement tracking of fluorescently labelled human neutrophils recruited to the surface of the microvascular endothelium 24 post HRV16 infection and treated with the CXCR2 inhibitor, MK-7123 (10µM) on chip. Scale bar, 50 µm.

Endothelial side

50 µm

Supplementary movie 7. A movie of an orthogonal sectioning of a chip from the vascular to the epithelial compartment showing labelled neutrophil (white) at the surface of the microvascular endothelium and neutrophil that have crossed the membrane and transmigrated towards the epithelium. Scale bar, 50 µm.
