20 Abstract

21

22 Cigarette smoking has multiple serious negative health consequences. However, the  
23 epidemiological relationship between cigarette smoking and SARS-CoV-2 infection is  
24 controversial; and the interaction between cigarette smoking, airway expression of the ACE2  
25 receptor and the susceptibility of airway cells to infection is unclear. We exposed

26 differentiated air-liquid interface cultures derived from primary human airway stem cells to  
 27 cigarette smoke extract (CSE) and infected them with SARS-CoV-2. We found that CSE  
 28 increased expression of full-length ACE2 (fACE2) but did not alter the expression of a Type  
 29 I-interferon sensitive truncated ACE2 that lacks the capacity to bind SARS-CoV-2 or a panel  
 30 of interferon-sensitive genes. Importantly, exposure to CSE did not increase viral infectivity  
 31 despite the increase in fACE2. Our data are consistent with epidemiological data suggesting  
 32 current smokers are not at excess risk of SARS-CoV-2 infection. This does not detract from  
 33 public health messaging emphasising the excess risk of severe COVID-19 associated with  
 34 smoking-related cardiopulmonary disease.

## 37 Introduction

38 SARS-CoV-2 is the causative agent of coronavirus disease 2019 (COVID-19). The SARS-CoV-2  
39 envelope spike (S) protein is essential for virus attachment and cell entry via the main  
40 cellular receptor - angiotensin converting enzyme 2 (ACE2) (Kuba et al. 2005; Wang et al.  
41 2020; Daly et al. 2020; Li et al. 2003). Entry is further dependent on S-protein priming by  
42 TMPRSS2 facilitating fusion of viral and cellular membranes (Hoffmann et al. 2020; Walls et  
43 al. 2020; Shang et al. 2020).

44 ACE2 is a membrane-associated aminopeptidase expressed in a range of tissues including  
45 vascular endothelia, ureteric epithelia and the small intestine (Harmer et al. 2002; Hamming  
46 et al. 2004; Zou et al. 2020; Hikmet et al. 2020). In the renin-angiotensin-aldosterone system  
47 (RAAS), it converts the vasoconstrictive hormone angiotensin-II to the vasodilator Ang 1-7  
48 but has other physiological roles in glucose homeostasis and beta cell function (Jiang et al.  
49 2014) (Niu et al. 2008; Bindom et al. 2010).

50

51 The physiological role for ACE2 at homeostasis in airway epithelial cells is unknown. In  
52 preclinical murine models ACE2 was confirmed as the epithelial receptor for SARS-CoV-1  
53 and was shown to confer protection against SARS-CoV-1 associated acute lung injury (Imai  
54 et al. 2005; Kuba et al. 2005; Ren et al. 2006). However, the mechanism by which ACE2  
55 mediates protection is unclear and may relate to its role in the pulmonary vascular  
56 endothelium rather than the airway epithelium (Imai et al. 2005). In transcriptomic studies  
57 of the human respiratory tract and lung, there is a proximal-distal ACE2 mRNA expression  
58 gradient; expression is highest in the nasal epithelium and lower distally in the alveolar  
59 epithelium, mirroring the permissiveness to SARS-CoV-2 infection (Sungnak et al. 2020;

60 Lukassen et al. 2020; Ziegler et al. 2020; Hou et al. 2020) (Zamorano Cuervo and Grandvaux  
61 2020). The distribution of ACE2 protein expression is less well characterised due to the  
62 paucity of validated reagents but is consistent with the proximal-distal graded expression  
63 pattern (Ortiz et al. 2020; Hikmet et al. 2020). Notably, ACE2 expression in the lung is not  
64 altered by ACE inhibitors or angiotensin receptor blockers (Lee et al. 2020).

65

66 In addition, an N-terminally truncated (dACE2) isoform that is sensitive to interferon  
67 stimulation or viral infection has been detected (Onabajo et al. 2020; Ng et al. 2020; Blume  
68 et al. 2021; Shajahan et al. 2020). Importantly, dACE2 does not express the SARS-CoV-2  
69 spike-protein binding domain and its relevance in SARS-CoV-2 infection and normal  
70 physiology remains unclear (Onabajo et al. 2020; Blume et al. 2021).

71

72 The impact of ACE2 expression on COVID-19 incidence and severity is unclear (Chung et al.  
73 2020). Much of the available information on ACE2 expression is from scRNA databases and  
74 has not reported the relative expression of the two isoforms. Given the differential isoform  
75 binding to SARS-CoV-2, this is likely to be an important issue.

76

77 Smoking has been associated with increased ACE2 expression in rodent models and in  
78 studies on human subjects (Gebel et al. 2010; Hung et al. 2016; Yilin, Yandong, and Faguang  
79 2015; Cai et al. 2020; Brake et al. 2020; Leung et al. 2020; Smith et al. 2020). Consistent with  
80 this, higher ACE2 transcripts have been detected in the lungs of COPD patients (Cai et al.  
81 2020; Jacobs et al. 2020; Leung et al. 2020; Smith et al. 2020) and in airway cells from  
82 occasional or “social” smokers exposed to 3 cigarettes over a 24hr period (Aliee et al. 2020).

83 Importantly, studies to date have not linked RNASeq data with protein and isoform  
84 expression.

85

86 The epidemiological data regarding the association of smoking with COVID-19 is conflicting  
87 and controversial (Farsalinos et al. 2020; Simons et al. 2020; Rossato et al. 2020; Hopkinson  
88 et al. 2021; Grundy et al. 2020; Patanavanich and Glantz 2020). However, an extensive and  
89 ‘living’ meta-analysis undergoing regular updates as the evidence improves, suggests that  
90 current smoking is not associated with an increased risk of SARS-CoV-2 infection (Simons et  
91 al. 2020). Large surveys have suggested that chronic respiratory disease including COPD  
92 (mainly a smoking-related disease in the UK) may be associated with an increased risk of  
93 severe COVID-19 (Docherty et al. 2020; Williamson et al. 2020) . This may be consistent with  
94 the observation in the living meta-analysis that former smokers were at an increased risk of  
95 severe COVID-19 (Simons et al. 2020; Zhao et al. 2020).

96

97 Differentiated human airway epithelial cells grown at the air-liquid-interface (ALI) are the  
98 optimal laboratory system in which to model the impact of smoking on the early stages of  
99 SARS-CoV-2 infection (Blume et al. 2021; Purkayastha et al. 2020; Sachs, Finkbeiner, and  
100 Widdicombe 2003). Purkayastha and colleagues recently reported brief exposure of  
101 primary airway cultures (3 minute/day for four days) to “headspace” cigarette smoke (CS),  
102 that is CS in a closed environment, to investigate the impact of CS on ACE2 expression and  
103 SARS-CoV-2 infection (Purkayastha et al. 2020). A significant increase in ACE2 expression  
104 was not detected in response to CS, in contrast to the available molecular epidemiological  
105 data detailed above. However, they reported that CS exposure did increase viral infection at  
106 48 hours.

107

108 We now report our observations from experiments in which we exposed primary human  
 109 bronchial epithelial cells (HBECs) at ALI to cigarette smoke extract (CSE). We find that HBECs  
 110 upregulate ACE2 expression in response to CSE – consistent with the molecular  
 111 epidemiological evidence (Cai et al. 2020; Brake et al. 2020). However, this did not lead to  
 112 an increase in infection by SARS-CoV-2 despite preferential upregulation of full-length ACE2  
 113 receptor (flACE2) rather than the N-terminal truncated isoform in response to CSE exposure.  
 114 This suggests that in normal human bronchial epithelial cells physiological expression of  
 115 flACE2 does not limit viral infectivity. We go on to show that dACE2 is a Type I interferon-  
 116 sensitive gene in primary HBECs, and define the impact of CSE, nicotine and NRF2 agonists  
 117 on ACE2 isoform expression.

118

119 This study directly addresses one of the controversies in the link between smoking and  
 120 SARS-CoV-2. Our results are consistent with epidemiological evidence suggesting that  
 121 current smoking is not associated with a higher incidence of SARS-CoV-2 infection.

122

123

## 124 **Results**

125

### 126 **ACE2 is expressed on differentiated ciliated cells at homeostasis**

127 Previous studies have shown ACE2 expression increases following differentiation at the air-  
 128 liquid interface (ALI), but could be reversed if cultures were resubmerged (Jia et al. 2005).  
 129 We grew HBECs from Donor 1 at the air-liquid interface (ALI) for a minimum of 4 weeks to  
 130 produce a well-differentiated, pseudostratified mucociliary epithelium (**Figure 1a**). ACE2  
 131 mRNA expression was increased on differentiation, as was TMPRSS2, the main cellular  
 132 protease implicated in SARS-CoV-2 spike protein cleavage and FOXJ1, a key transcription  
 133 factor regulating airway ciliation. Full length ACE2 protein was not detectable in submerged  
 134 HBEC cultures but was readily detectable on differentiation (**Figure 1b-d**) emphasising the  
 135 importance of using differentiated HBECs to model airway infection. Confocal imaging  
 136 demonstrated apical ACE2 expression colocalising with markers of ciliated cells but not  
 137 goblet cells (**Figure 1 e,f**) (Sims et al. 2005).

138

### 139 **Cigarette smoke extract increases ACE2 expression in differentiated HBECs**

140

141 We then exposed differentiated ALI cultures from Donor 1 to 10% cigarette smoke extract  
 142 (CSE) for 48 h before harvesting cells (**Figure 2a**). CSE exposure induced a significant  
 143 increase in ACE2 (mRNA) and marked induction at the protein level relative to controls  
 144 (**Figures 2b and 2c**). We evaluated ACE2 immunofluorescence after CSE exposure which was  
 145 consistent with increased apical ACE2 expression relative to control wells (**Supp Figure 1**).

Increased ACE2 levels were also detected from differentiated ALI cultures derived from Donor 2, a former smoker (61 pack-years) with COPD (**Supplementary Figure 2**). Of note, there was no evidence of cytotoxicity in response to CSE, as exposure did not cause an increase in apoptosis or necrosis as shown by flow cytometric analysis (**Figure 2d**; **Supplementary Figure 3**) or an obvious cytopathic effect on histology (**Figure 2e**). Importantly, given prior data on the impact of nicotine on ACE2 expression in submerged undifferentiated bronchial epithelial cells, (Russo et al. 2020), we found that nicotine did not significantly alter the expression (mRNA) of either ACE2 or lead to a consistent change in ACE2 protein expression (**Supplementary Figure 4**). CSE had a negligible effect on the expression of the predominant nicotinic acetylcholine receptor expressed on airway epithelial cells – CHRNA7 (**Figure 2f,g**).

#### **HBECS exposed to CSE are not more susceptible to infection by SARS-CoV-2**

To determine whether CSE exposure would render the cells more susceptible to SARS-CoV-2 infection, differentiated ALI cultures (Donor1) were pre-treated with CSE for 48 h, then inoculated with SARS-CoV2 for 3 h and harvested after 72 hours for flow cytometric quantitation of infection or immunofluorescence (IF) (**Figure 3a**).

ACE2 colocalised with spike protein in infected wells (**Figure 3b**) consistent with ciliated cells being more susceptible to infection and with prior reports (Sims et al. 2005; Schaefer et al. 2020). On some specimens infected cells appeared to be extruded from the epithelial surface – as previously reported for SARS-CoV-1 and 2 (Sims et al. 2005).

Importantly, despite the increased ACE2 levels following CSE exposure, there was no significant difference in the total infected fraction or infected ciliated cell fraction between control or CSE exposed cells (**Figure 3c**). Therefore, in this model CSE exposure did not increase SARS-CoV-2 infection.

### **Regulation of ACE2 isoform expression – impact of cigarette smoke**

The relationship between cigarette smoke exposure and viral infections has previously been investigated using primary cells – for example cigarette smoke was associated with increased rhinovirus infection in submerged cultures (Eddleston et al. 2011) or influenza A infection in differentiated ALI cultures (Duffney et al. 2018). However, SARS-CoV-2, in contrast to typical respiratory viruses, is associated with an attenuated cellular interferon response (Blanco-Melo et al. 2020). Of note, a truncated isoform of ACE2 denoted as dACE2 was recently implicated as an interferon-sensitive gene (ISG), but importantly predicted to not act as a receptor for SARS-CoV-2 based on the reported ACE2-Spike receptor binding domain interaction (Blume et al. 2021; Onabajo et al. 2020; Ng et al. 2020; Li et al. 2005; Lan et al. 2020).

We therefore explored the impact of cigarette smoke exposure on ACE2 isoform expression using recently described tools (**Figure 4a**) (Onabajo et al. 2020). We first assessed the relative expression of fACE2 and dACE2 in submerged primary HBECs compared to differentiated HBECs at ALI. dACE2 was upregulated on differentiation but modestly compared to the full-length receptor (**Figure 4b**).

We next tested isoform-specific expression of ACE2 exposed HBECs to Type I and Type II interferons and CSE. IFN- $\alpha$  (Type I) but not IFN- $\gamma$  (Type II) led to a transcriptional upregulation of dACE2 (mRNA). Neither interferon significantly altered the expression of the full-length transcript (**Figure 4c**). This extends the recently published data from immortalised airway cells (Blume et al. 2021) and confirms that the N-terminus truncated transcript (dACE2) is an interferon-sensitive isoform. Further, CSE did not significantly alter the expression of a panel of interferon-sensitive genes (**Suppl Figure 5**). Therefore, differentiated airway epithelial cells have the capacity to respond to Type I interferon and CSE does not mimic that response.

CSE did not significantly alter the expression of dACE2 mRNA (**Figure 4d**). In agreement with the transcriptional data, both N & C-terminus ACE2 antibodies (**Figure 4a**) showed that CSE consistently upregulated fACE2 protein but had no impact on an ACE2 band migrating at 52kd - the predicted molecular weight of dACE2 (**Figure 4e and Suppl Figure 6**) (Blume et al. 2021). We conclude from these experiments that cigarette smoke does not activate interferon signalling or ISGs in normal human bronchial epithelial cells and preferentially upregulates fACE2 rather than dACE2.

## **Antioxidants upregulate ACE2 in differentiated airway epithelial cells**

Nuclear factor erythroid 2-related factor 2 (NRF2) is the master transcriptional regulator of the cellular antioxidant response and already a focus of therapeutic efforts to counteract epithelial oxidative stress in COPD. NRF2 agonists have also been proposed as therapeutics for COVID-19 (Olagnier et al. 2020). In our experiments, CSE treatment of ALI cultures led to

the expected increase in NRF2 as well as ACE2 upregulation (**Figure 5a**). Further, oltipraz, a KEAP1 inhibitor and NRF2 agonist already in Phase III clinical trials, increased both ACE2 mRNA expression and fACE2 protein (**Figure 5b-d**). This was a consistent finding in two donors – a non-smoker (Donor 1) and an individual with COPD (Donor 2), (**Supplementary Figure 7a**). Despite elevating fACE2 levels (**Supplementary Figure 7a**), oltipraz pre-treatment did not increase SARS-CoV2 infection (**Figure 5e, Supplementary Figure 7b**). Of note, infection for these experiments was undertaken with the B.1.1.7 variant. As others have shown there is considerable inter-experiment variation when using SARS-CoV-2 to infect in primary HBECs (Hou et al. 2020; Ravindra et al. 2021). (However, in three experiments with multiple technical replicates from two donors (**Figure 5e, Supplementary Figure 7b**), there was no increase in infection with either CSE (consistent with **Figure 3C**) or oltipraz. We also assessed the impact of combined treatment with oltipraz and CSE. Again, despite induction of ACE2 (**Supplementary Figure 7a**), there was no increase in SARS CoV-2 infectivity. Therefore, smoking and KEAP1 inhibition both increase fACE2 expression but this does not lead to an increase in SARS-CoV-2 infectivity measure using either flow cytometry or in situ immunofluorescence of differentiated bronchial epithelial cells at the air-liquid interface.

## Discussion

The severity of COVID-19 is associated with increasing age and comorbidities including obesity, diabetes mellitus and chronic respiratory disease. Separately, there is a long established and direct link between smoking and serious adverse health outcomes, including chronic respiratory diseases, cardiovascular disease and cancer.

During the pandemic, there has been intense interest in the link between cigarette smoking and COVID-19. In terms of chronic respiratory disease, smoking is a major global cause of COPD, and current smokers or individuals with COPD are more at risk of severe COVID-19 infections and death (Alqahtani et al. 2020; Leung et al. 2020; Zhao et al. 2020; Guo 2020; Hopkinson et al. 2021; Simons et al. 2020). Molecular epidemiological studies have linked COPD with an increased expression of ACE2, the main receptor for SARS-Co-V2 (Smith et al. 2020; Jacobs et al. 2020; Brake et al. 2020). Further, bulk and single cell RNA-Seq datasets comparing smokers and never-smokers has consistently shown that cigarette smoking (acute and chronic) leads to an increase in ACE2 expression, although these studies have not discriminated between the two ACE2 isoforms that are now known to be expressed in the airway (Cai et al. 2020; Zhang, Yue, et al. 2020; Aliee et al. 2020; Leung et al. 2020).

The elevated ACE2 expression in smokers has been linked with increased susceptibility to infection (Purkayastha et al. 2020; Cai et al. 2020). However, the available clinical epidemiological data suggests that smokers and non-smokers have similar risks of infection, but that those smokers or ex-smokers with cardiorespiratory end-organ damage (COPD,

cardiovascular disease) are more likely to have severe infections or die from COVID-19 (Williamson et al. 2020; Docherty et al. 2020; Simons et al. 2020; Grundy et al. 2020).

Although increased ACE2 in the conducting airways was suggested to increase susceptibility to SARS-CoV-2 infection (Cai et al, 2020); others have suggested elevated ACE2 in the distal airways or the pulmonary vasculature could be beneficial during the later stages of COVID-19 and mooted upregulation of ACE2 as a rational therapeutic goal (Chaudhry et al. 2020; Vaduganathan et al. 2020; Kuba et al. 2005; Monteil et al. 2020; Verdecchia et al. 2020).

We have now explored the link between smoking, ACE2 and SARS-CoV-2 infection *in vitro* using differentiated primary human bronchial airway epithelial cells (HBECs) at the air-liquid interface (ALI). Since these and similar nasal cells are the putative first sites of entry for SARS-CoV-2, we sought to expose these *in vitro* human “airways” to SARS-CoV-2 with and without cigarette smoke extract to understand the impact of smoking on the earliest stage of *in vivo* infection.

We demonstrate that cigarette smoke induces ACE2 expression in HBECs using multiple approaches – quantitative PCR, immunofluorescence and western blotting. This is consistent with the molecular epidemiology data linking ACE2 expression and smoking. Given the difficulties reproducing detection of ACE2 protein in clinical specimens (Aguiar et al. 2020; Hikmet et al. 2020; Ortiz et al. 2020), it is particularly important to have demonstrated expression of ACE2 protein and its localisation at the cell surface – where it has the capacity to act as a receptor for SARS-CoV-2. Importantly, in our experiments, increased expression of ACE2 in response to CSE does not significantly alter the percentage of cells infected. This

is consistent with the epidemiological data suggesting smoking is not a major risk factor for infection.

One explanation for the lack of impact of CSE on HBEC infection despite elevation of ACE2 was that it upregulates the truncated isoform of ACE2 – dACE2 - lacking the SARS-CoV-2 binding domain. However, we demonstrate that CSE mainly induces expression of the full-length isoform, despite the cells retaining the potential to upregulate dACE2 in response to IFN $\alpha$ .

Our results differ from recently published data that did not detect an increase in ACE2 mRNA/protein in response to cigarette smoke but nevertheless suggested that smoking increases viral infection (Purkayastha et al. 2020). This discrepancy may reflect differences in the smoking exposure protocols used. In our experiments we added cigarette smoke extract to the basal chamber of the transwell while cells are maintained at ALI. This is a well-established technique and has been used extensively in respiratory and cardiovascular research (Schamberger et al. 2015; Ito, Ishimori, and Ishikawa 2018). Further, it recapitulated the increase in ACE2 reported in clinical specimens. Purkayastha *et al* took an alternative approach – exposure of the entire differentiated cell culture to smoke for a brief period of 3 minutes/day for 4 days. This protocol was modelled on a study by Gindele et al who adapted a customised, bespoke aerosol toxin exposure system to expose small airway epithelial cells to relatively higher cigarette smoke doses for longer duration and at repeated time-points during differentiation at ALI (Gindele et al. 2020). Their results demonstrated a clear induction of ACE2 (**Supplementary Figure 8**) also reported by Smith et al (Smith et al. 2020). In contrast, Purkayastha et al used a standard vacuum chamber with

modest exposure doses and did not demonstrate ACE2 induction (Purkayastha et al. 2020).

Of note, neither exposure model led to CSE-associated toxicity.

There has been a keen interest in modulating ACE2 expression to influence the course of COVID-19. This is a complex area, as noted by others (Michaud et al. 2020; Verdecchia et al. 2020; Zhang, Penninger, et al. 2020). One hypothesis is that reducing ACE2 expression in the upper airways may protect against SARS-CoV-2 infection. This is consistent with observations that transduction with ACE2 increases cellular susceptibility to infection albeit in models where the overexpression of ACE2 is at unrepresentative supraphysiological levels (McCray et al. 2007; Yang et al. 2007). It is critical to distinguish between the conducting and distal airways (alveolar units) when considering the impact of ACE2 expression. These cell types have different stem cell precursors, different functions and distinct responses to specific stimuli (Stripp and Shapiro 2006). Any potential enthusiasm for reducing ACE2 in the conducting airway where SARS-CoV-2 first infects cells must be tempered by a significant body of evidence suggesting higher ACE2 may have a protective impact in the distal airway and protect against acute lung injury/adult respiratory distress syndrome (Michaud et al. 2020; Verdecchia et al. 2020; Imai et al. 2005). Therefore, an ideal therapeutic in severe COVID-19 may reduce ACE2 in the conducting airways but increase its expression in the alveolar units. Although this is unlikely to be an achievable goal, our data demonstrating that an elevation of fACE2 has no impact on cellular infection is consistent with the notion that expression of fACE2 is not the key factor limiting SARS-CoV-2 infection of conducting airway cells.

In COPD, NRF2 agonists would be a theoretically attractive way to induce the key antioxidant response as well as modulate ACE2 expression. We show that oltipraz, an NRF2 agonist already in Phase 3 clinical trial for other indications, increased rather than decreased ACE2 in the HBECs. Nicotine, a component of cigarette smoke, is also being actively assessed in clinical trials as a potential protective agent in COVID-19 infection (ClinicalTrials.gov Identifier NCT04583410), (Farsalinos et al. 2020). This was based on early epidemiological observations suggesting smokers may be protected against SARS-CoV-2 infection as well as preclinical studies on submerged bronchial epithelial cells suggesting nicotine may increase ACE2 mRNA expression (Russo et al. 2020). It is uncertain how to translate observations on ACE2 mRNA in undifferentiated airway cells into a clear understanding of the receptor expression at the apical surface of airway epithelial cells. Our data show that nicotine does not significantly alter ACE2 or CHRNA7 mRNA expression in differentiated HBECs after 48 hours treatment.

Our studies are limited by the focus on the conducting airways and therefore address the initial phases of infection rather than the later stage at which individuals are admitted to hospital and which are important for COVID-19 morbidity and mortality. Further, smoking has important systemic impacts that cannot be modelled in ALI epithelial cultures. In that context it is possible that CSE in the basal media more closely mimics the sustained systemic effects of smoking. In terms of assaying cellular infection, differentiated airway ALI models have profound advantages but it is possible that subtle changes in susceptibility to infection are not detected because of the well-to-well variation typical of experiments using primary cells.

Overall, our data are entirely consistent with the documented epidemiology of SARS-CoV-2 infection. Individuals with chronic respiratory or cardiovascular disease associated are more vulnerable to severe COVID-19. However, current smokers have a similar susceptibility to SARS-CoV-2 infection as the general population. We show that the airway epithelial response to cigarette smoke is associated with an increase in full length ACE2 – the key SARS-CoV-2 receptor - but not an increased susceptibility to cellular infection. Therapeutic strategies that increase ACE2 receptor expression in the conducting airways are unlikely to increase cellular infection.

## Methods

### Primary human bronchial epithelial cell (HBEC) culture and other cell line culture

Primary human bronchial epithelial cells (HBECs) derived from a non-smoking donor (Cat# CC-2540, male; Lonza; Donor 1) or derived directly from a patient at Cambridge University Hospitals NHS Trust (Research Ethics Committee Reference 19/SW/0152; Donor 2) were expanded using PneumaCult™-Ex Plus Medium (Cat# 05040; Stemcell) supplemented with Penicillin (100 I.U./ml)-Streptomycin (100 µg/ml). All experiments were performed using cells at passage 3. All experiments in used cells expanded from Donor 1 except when stated otherwise.

Cell lines including A549 (ATCC; Cat# CCL-185, male), Calu3 (ATCC; Cat# HTB-55, male) HEK293T (ATCC; Cat# CRL-3216, female) (A549-ACE2, HEK293T-ACE2) have been used as negative or positive controls. HEK293T lines were maintained in RPMI supplemented with 10% FBS, 2 mM L-glutamine, pH 7.5, and 1 mM sodium pyruvate at 37°C in a 5% CO<sub>2</sub>. A549 and Calu-3 cell lines were cultured in Dulbecco's Modified Eagle's Medium (DMEM) and Eagle's Minimal Essential Medium (EMEM) respectively, supplemented as specified above.

### Air-Liquid Interface (ALI) Culture

Briefly,  $1 \times 10^5$  of expanded primary HBECs at passage 3 in 200 µl of supplemented PneumaCult™-Ex Plus Media were seeded in the apical chamber of a 24-well Transwell®

insert with 0.4µM pore (Cat# 353095, Falcon) pre-coated with Rat tail Type I collagen (Cat# 354236, Corning) with 500 µl of PneumaCult™-Ex Plus Media in the basolateral chamber. The following day, both apical and basolateral chambers underwent a media change (200 µl and 500 µl, respectively). After two days of submerged culture, media from the apical chamber was removed to establish the air-liquid interface (ALI day 0) whilst media in the basolateral chamber was replaced with 500 µl HBEC ALI differentiation medium (PneumaCult™-ALI Medium, Cat# 05021; Stemcell). Basolateral media was changed every 2-3 days and apical surface washed with warm PBS twice a week to remove any build-up of mucous and secretions. Cultures were allowed to differentiate for at least 28 days before being used for any experiments.

#### **Cigarette Smoke Extract (CSE) Generation and Treatment**

Cigarette smoke extract (CSE) was prepared, filter sterilised using 0.20µm filter and used within 30 mins of generation. CSE was generated by smoking two Kentucky reference cigarettes and bubbling the generated smoke through 25 ml ALI media at a rate of 100 ml/min. Each cigarette took roughly 6 mins to burn. This solution is regarded as “100% CSE” and was diluted with ALI media to generate a 10% working solution. Cells were treated with 10% CSE for 48 hours before being treated with SARS-CoV-2, harvested or fixed for further analysis.

## **SARS-CoV-2 infection**

The clinical isolate of SARS-CoV-2 viruses used in this study were SARS-CoV-2/human/Liverpool/REMRQ0001/2020(Lineage B.29) (Chu et al. 2020) (Patterson et al. 2020) and SARS-CoV-2 England/ATACCC 174/2020 (Lineage B.1.1.7). Stocks were sequenced before use and the consensus matched the expected sequence exactly. Viral titre was determined by 50% tissue culture infectious dose (TCID<sub>50</sub>) in Huh7-ACE2 cells.

For infection, the indicated dose of virus was diluted in PBS to a final volume of 50 µL and added to the apical chamber of the transwell of differentiated HBEC-ALI cultures for 2-3 hours prior to removal. At 72 hours post-infection HBEC-ALI apical surfaces were washed once with PBS, dissociated with TrypLE, and fixed in 4% formaldehyde for 15 minutes. Fixed cells were washed and incubated for 15 minutes at room temperature in Perm/Wash buffer (BD #554723). Permeabilised cells were pelleted, stained for 15 minutes at room temperature in 100 µL of sheep anti-SARS-CoV-2 nucleocapsid antibody (MRC-PPU, DA114) at a concentration of 0.7 µg/mL, washed and incubated in 100 µL AF488 donkey anti-sheep (Jackson ImmunoResearch #713-545-147) at a concentration of 2 µg/mL for 15 minutes at room temperature. Stained cells were pelleted and fluorescence staining analysed on a BD Fortessa flow cytometer.

## **Immunofluorescence**

ALI cultures were washed three times with PBS and fixed using 4% paraformaldehyde (PFA) for 15 minutes at room temperature before permeabilization with 0.3% Triton-X for 15

minutes. Cells were blocked for 1 hour in 5% Normal goat serum/1% Bovine serum albumin (BSA) at room temperature. Primary antibodies; anti-ACE2 antibody was initially Abcam 228349 but was discontinued part-way through this study and was then replaced with 21115-1-AP (Proteintech); Acetylated tubulin (T7451; Sigma); Muc5AC (MA5-12178; Invitrogen), SARS-CoV / SARS-CoV-2 (COVID-19) spike antibody [1A9] (GTX632604; Genetex), SARS-CoV-2 (COVID-19) Nucleocapsid antibody DA114 (MRC PPU) were added and incubated at 4 degrees overnight. Following several washes with Phosphate Buffered Saline and Tween-20 (PBS-T), cultures were incubated with secondary antibodies for 1 hour in the dark at room temperature before being washed a further three times before Hoechst staining (100 µg/ml) and mounting. Confocal images were captured using a Nikon C2 Confocal Microscope, magnification ×40 oil. Composite images were generated and analysed using Fiji. Immunofluorescent images were also captured using a Cellomics Arrayscan (ThermoFisher Scientific VTI) using 64 fields of view/transwell at x10 magnification and analysed using HCS. Studio 2.0 Client Software. Results are expressed as percent of infected cells according to AF488 positive staining. For Figure 5E (Donor 1 only) the controls were shared with a published experiment ( )

#### **qRT-PCR**

RNA was extracted using RNeasy Mini Kit (Qiagen) according to manufacturer's instructions and quantified using a NanoDrop Spectrophotometer (ThermoFisher). cDNA synthesis was performed using a High-Capacity cDNA Reverse Transcription Kit (ThermoFisher). qRT-PCR

was performed using Fast SYBR® Green Mix (ThermoFisher) alongside the following primers used for detecting expression of genes of interest: ACE2 Forward (5'-3'): CGAAGCCGAAGACCTGTTCTA, Reverse (5'-3'): GGGCAAGTGTGGACTGTTCC; dACE2 Forward (5'-3'): GGAAGCAGGCTGGGACAAA, Reverse(5'-3'): AGCTGTCAGGAAGTCGTCCATT; TBP (House keeper) Forward (5'-3'): AGTGAAGAACAGTCCAGACTG, Reverse (5'-3'): CCAGGAAATAACTCTGGCTCAT; TMPRSS2 Forward (5'-3'): CTGCTGGATTTCGGGTG, Reverse (5'-3') TTCTGAGGTCTTCCCTTTCCT; FOXJ1 Forward (5'-3'): TGGATCACGGACAACTTCTGCTA, Reverse (5'-3') CACTTGTTCCAGAGACAGGTTGTGG; MUC5B Forward (5'-3'): CCTGAAGTCTTCCCCAGCAG, Reverse (5'-3') GCATAGAATTGGCAGCCAGC. Samples were run in technical triplicates on a StepOne machine and relative differences in expression were determined using the comparative  $\Delta C_T$  method and TBP used as the endogenous house-keeping control.

### Western Blotting

Recombinant Anti-ACE2 antibodies (Cat# ab108209; Abcam: N-terminal) and (Cat# ab15348; Abcam: C-terminal), alpha-tubulin (Cat# sc-32293; Santa-Cruz) and beta-actin (Cat# sc-69879; Santa-Cruz) were used for ACE2/dACE2, alpha-tubulin detection and beta-actin, respectively.

### Apoptosis detection

ALI cultures exposed to CSE or control media were washed three times with PBS and detached from the transwell membrane with accutase. Apoptotic cells was detected by concurrent staining with annexin V–APC and PI (Cat# 88-8007-72, eBioscience) and their far-red and red fluorescence was measured by flow cytometry (Fortessa LSR, BD).

## Quantification and Statistical Analysis

Statistical analyses of mRNA expression assays and infection quantification data were performed using Prism 8 software (GraphPad Software). P values were calculated using a two-tailed, Mann Whitney *U*-test unless stated otherwise. P values were noted as follows: ns, not significant; \*,  $P < 0.05$ ; \*\*,  $P < 0.01$ ; \*\*\*,  $P < 0.001$ . Error bars represent the mean  $\pm$  standard error of the mean unless stated otherwise.

## 494 Acknowledgements

495 SARS-CoV-2/human/Liverpool/REMRQ0001/2020 was a kind gift from Lance Turtle  
 496 (University of Liverpool) and David Matthews and Andrew Davidson (University of Bristol).  
 497 SARS-CoV-2 England/ATACCC 174/2020 was a kind gift from Greg Towers (University College  
 498 London), and we are also grateful to Ajit Lalvani, Jake Dunning, Maria Zambon and  
 499 colleagues at Public Health England and Giada Mattiuzzo at the National Institute for  
 500 Biological Standards and Controls and Wendy Barclay and Jonathan Brown and all  
 501 colleagues in the United Kingdom Research Institute funded collaboration Genotype to  
 502 Phenotype. Sheep anti-SARS-CoV-2 nucleoprotein antibody (DA114) was a kind gift from  
 503 Paul Davies (obtained from MRC PPU Reagents and Services, University of Dundee). We  
 504 gratefully acknowledge the support from Ms Jacqui Galloway in establishing the primary  
 505 cells from patients. We also gratefully acknowledge advice and discussions from Dr Stephen  
 506 White, Department of Life Sciences, Manchester Metropolitan University regarding  
 507 generation and use of cigarette smoke extract.

508 We are grateful for the generous support of the UKRI COVID Immunology Consortium,  
 509 Addenbrooke's Charitable Trust (15/20A) and the NIHR Cambridge Biomedical Research  
 510 Centre. This work was supported by a Wellcome Trust Principal Research Fellowship  
 511 (084957/Z/08/Z) and MRC research grant MR/V011561/1 to P.J.L. This work was supported  
 512 by the NC3Rs NC/S001204/1 project grant and the Roy Castle Lung Cancer Foundation grant  
 513 (2015/10/McCaughan) to FM.

## Figure Legends

### **Figure 1. ACE2 expression increases upon differentiation in HBECs cultured at the air-liquid interface (ALI).**

**A.** Schematic representation of ALI experimental set-up using HBECs. Cell type specific markers are shown in parentheses. **B.** HBEC *TMPRSS2* and *ACE2* expression (RNA) both increase when cultured for 28 days at the ALI compared to submerged, non-differentiated cell culture. Expression of the transcription factor required for ciliation, *FOXJ1* is also significantly upregulated. RT-qPCR data presented as log<sub>2</sub> relative fold-change in expression compared to submerged HBECs from n=5 independent experiments (Mann Whitney, \*\*, P < 0.01). Error bars represent mean and the standard error of the mean. **C.** ACE2 protein is also increased during differentiation. A549 cells overexpressing ACE2 are used as a positive control. Representative western blot from 3 independent experiments. ACE2 antibody Ab228349 was used. **D.** ACE2 expression (red fluorescence, antibody Ab228349) is upregulated on differentiation. **E)** ACE2 (red, Antibody used 21115AP) is expressed apically on the epithelial cell surface, predominantly colocalising with ciliated cells (acetylated tubulin, green fluorescence). **F)** ACE2 (red, antibody 21115AP) does not colocalise with goblet cells (MUC5AC, green fluorescence). Scale bars on fluorescent images = 100µm. All experiments in Figure 1 used cells expanded from Donor 1.

### **Figure 2. Exposure to cigarette smoke extract (CSE) increases ACE2 expression at both the RNA and protein level**

**A.** Schematic showing ALI culture experimental set-up with CSE. **B.** CSE exposure (10%) for 48 h increases *ACE2* expression in differentiated HBECs relative to untreated controls. RT-qPCR data presented as log<sub>2</sub> relative fold-change in expression from n=8 independent experiments (Mann-Whitney, \*\*\*, P < 0.001). **C.** CSE exposure (10%) for 48 h also

increases ACE2 protein expression relative to untreated control. Calu-3 are presented as the positive control. Representative western blot from 3 independent experiments. ACE2 antibody – ab15348. **D.** CSE exposure does not induce apoptosis in differentiated HBECs at ALI relative to control samples as analysed by flow cytometric analysis using AnnexinV (AnV) and Propidium iodide (PI) staining see also Supplementary Figure 3. Data represents 2 independent experiments using cells from Donor 1. **E.** H&E staining of sectioned differentiated ALI HBEC cultures from Donor 1 with and without CSE exposure (x20 magnification). **F.** Treatment of differentiated HBECs at ALI with 1 uM Nicotine for 48 h does not induce *ACE2* expression. **G.** CSE exposure does not significantly alter *CHRNA7* expression. **G.** RT-PCR data for **F** and **G** is presented as log2 relative fold-change in expression from n=3-8 independent experiments (Mann-Whitney, ns).

### **Figure 3. HBECs exposed to CSE are not more susceptible to infection by SARS CoV2**

**A.** Schematic representation of SARS-CoV-2 infection of CSE exposed HBEC ALI cultures. **B.** SARS-CoV-2 infection was detected using an antibody specific to the viral spike protein (S2 domain). Representative immunofluorescent images showing 72 h post SARS-CoV-2 infection; expression of viral spike protein (green) primarily co-localised with ACE2 (red) expressing cells. White arrowheads indicate co-localisation of markers in merged images. **C.** Flow cytometry quantification of ciliated and non-ciliated cells infected with  $8 \times 10^3$  TCID<sub>50</sub> of B.29 lineage SARS-CoV-2 following control/CSE exposure (n=12); each dot represents an individual transwell from 2 independent experiments, bars represent mean values (Mann Whitney; ns, non-significant).

### **Figure 4. A short isoform of ACE2 is upregulated during HBEC differentiation and interferon-alpha stimulation but not CSE exposure at ALI.**

**A.** Schematic of full-length ACE2 (fACE2) and the truncated isoform (dACE2) detailing position of antibody binding epitopes for immunofluorescence and western blot analysis. The location of primers used to distinguish ACE2 and dACE are also shown. **B.** HBECs differentiated at ALI upregulate a short isoform of ACE2 (dACE2) as well as the full length ACE2. RT-PCR data shows log<sub>2</sub> relative fold-change in expression from n=7 independent experiments (Mann-Whitney \*\*, P < 0.01). **C.** dACE2 is specifically sensitive to interferon-alpha stimulation (24 h) but not interferon-gamma at 24 h. Full-length ACE2 shows no modulation with interferon treatment at 24 h. RT-PCR data shows log<sub>2</sub> relative fold-change in expression from n=3-6 independent experiments (Mann-Whitney, \* p<0.05). **D.** 48 h exposure of CSE does not promote an increase in dACE2 mRNA. RT-PCR data shows log<sub>2</sub> relative fold-change in expression from n=7 independent experiments (Mann-Whitney, ns). **E.** Western blot is representative of 5 independent experiments and shows the impact of 48 h exposure of CSE on fACE2/dACE2 expression. Also see Supplementary Figure 6. ACE2 antibody used ab15348.

**Figure 5. CSE and oltipraz increase ACE2 and NRF2 expression but not SARS-CoV-2 infection.**

**A.** CSE exposure induces NRF2 mRNA expression at 48 h. **B.** The NRF2 agonist Oltipraz increases NRF2 mRNA. **C.** Oltipraz increases fACE2 mRNA expression. **D.** Oltipraz increases fACE2 protein expression (ACE2 antibody Ab15348). RT-PCR data shows log<sub>2</sub> relative fold-change in expression from n=7 independent experiments (Mann-Whitney, \*\* P < 0.01, \* p<0.05). Representative western blot from 3 independent experiments. **E.** Fluorescent image analysis of whole transwell ALI cultures show that for Donors 1 and 2, CSE or NRF2 agonists, alone or in combination, did not result in increased infection. Each datapoint represents a single well and infection was with 1x10<sup>4</sup> TCID<sub>50</sub> of B.1.1.7 SARS-

599 CoV-2. Representative microscopy montages show the entire ALI transwell. Scale bar: 500  
600  $\mu\text{m}$ . Infection was quantitated and presented as percentage of cells infected for each  
601 condition.
