Thalamic inputs of layer 4 (L4) cells in sensory cortices are outnumbered by local connections. Thus, it was suggested that robust sensory response in L4 emerges due to synchronized thalamic activity. In order to investigate the role of both inputs in generation of cortical synchronization, we isolated the thalamic excitatory inputs of cortical cells by optogenetically silencing cortical firing. In anesthetized mice, we measured the correlation between isolated thalamic synaptic inputs of simultaneously patched nearby L4 cells of the barrel cortex. In contrast to correlated activity of excitatory synaptic inputs in the intact cortex, isolated thalamic inputs exhibit lower variability and asynchronous spontaneous and sensory evoked inputs. These results were further supported in awake mice when we recorded the excitatory inputs of individual cortical cells simultaneously with the local field potential (LFP) in a nearby site. Our results therefore indicate that cortical synchronization emerges by intracortical coupling.

The response of cortical cells to repeated stimuli is highly variable from trial to trial, and it is often correlated among nearby cells¹⁻⁷. Trial to trial correlation of sensory responses, also known as noise correlation, can promote the saliency of neuronal responses⁸⁻¹⁰. However, it may reduce the capacity to carry information¹¹⁻¹⁴. Thus, a cortical mechanism that actively decorrelates synaptic inputs could improve coding^{14,15}. Since spiking mechanisms of cortical cells are thought to be highly reliable^{16,17}, noise correlations in spiking are likely to reflect correlated membrane potential fluctuations. Indeed, ongoing and sensory evoked synaptic activities in nearby cortical cells are correlated both in time and magnitude^{7,6,18-20}. In primary sensory cortices, layer 4 (L4) cells receive the majority of their synaptic inputs from neighboring cortical cells^{21,22}. However, they are also strongly driven by feedforward thalamic inputs^{23,24}. Therefore, correlated activities between cells in L4 could either arise from common cortical noise or inherited directly from shared thalamic inputs.

In support of the first view, several studies reported that trial to trial variability of sensory evoked cortical response strongly depends on the instantaneous state of cortical activity at the time of stimulation^{25-28,9,5}. It was also shown that both ongoing and evoked activities can be modulated by the animal's behavior and neuromodulators^{18,19,29-31}. State dependent modulation of noise correlation was revealed both when using paired intracellular recordings¹⁸, or when the membrane potential was simultaneously recorded with nearby local field potential (LFP)^{32,33}.

Furthermore, the cortex shows slow ongoing oscillations in membrane potential after isolation from adjacent tissue³⁴ and when thalamus was pharmacologically inactivated³⁵. Another study showed that a large component of the covarying response in the thalamus and cortex of the somatosensory system is independent of stimulus properties³⁶. Taken together, these studies strongly suggest that noise correlation results from variation in cortical activity.

Alternatively, L4 variability could be inherited directly from thalamic inputs. In line with this view, it was shown that silencing cortical firing had a negligible effect on the variability of membrane potential response of L4 cells to repeated visual stimuli⁴. Additionally, Bruno and Sakmann³⁷ proposed that the convergence of inputs from a large number of synchronous thalamic cells strongly drive L4 cells, obviating the need for cortical mechanisms such as recurrent cortical amplification to explain noise correlations.

In this study, we optogenetically silenced the cortex^{38–40} while simultaneously performing whole cell and LFP recordings in awake mice and dual intracellular recordings in anesthetized mice. This enabled us to study the contribution of thalamic and cortical excitatory synaptic inputs to the subthreshold correlated ongoing and sensory evoked activities in the barrel cortex. Our experiments show that cortical synchrony is not inherited from thalamic inputs but rather depends on recurrent cortical activity.

Results

Barrel cortex amplifies thalamic inputs

Layer 4 (L4) cells in sensory cortices are strongly driven by feedforward thalamic inputs^{23,24}. Yet the role of these inputs in the generation of correlated cortical activity was never directly tested. In order to determine the contribution of thalamic inputs to subthreshold correlation between L4 cells, we used an optogenetic approach to silence cortical firing while recording isolated thalamic synaptic inputs of cortical cells. To this end we employed Gad/PV Cre transgenic mice crossed with a ChR2 reporter strain (Fig. 1a and see Methods). Surface illumination of the somatosensory cortex (S1) with a blue LED (470 nm, ~7mW, LED-ON condition) activated GABAergic cells (Fig. 1b, example cell and population data below, 0.6 ± 0.4 vs.

80±33hz for LED OFF and LED ON respectively, n=7 cells, z=-2.3664, p=0.015, Wilcoxon signed rank test). This, in turn, inhibited the local circuitry and almost completely blocked whisker evoked firing of excitatory cells (i.e., non-ChR2 expressing cells) at all depths. Cells in upper layers were silenced by almost 100% (example cell in upper panel of Figure 1c is shown during repetitive whisker stimulation; L4 population data below 0.4±0.1 vs. 0.002±0.002 spikes/stim LED OFF and LED ON; n=7 cells, z=-2.3664, p=0.015 Wilcoxon signed rank test) and cells in deeper layers (L5 and L6, below 500-μm,) by 92% (Fig. 1c 0.84±0.5 vs 0.04±0.06 spikes/stim LED OFF and LED ON; n=6 cells, z=-1.862, p=0.0313 Wilcoxon signed rank test). During cortical silencing (LED ON), the recorded excitatory currents (as measured when clamping the cells at the reversal potential of inhibition, measured for each cell from the response to light) reflected remote thalamic inputs to L4 and L5 cells^{38–41}. The latter also receives remote inputs from higher cortical areas^{41–45}. This allowed us to estimate the amplification of these inputs by recurrent cortical circuits. For each cell we averaged the whisker evoked excitatory synaptic current (EPSC), both during intact cortical activity and when the cortex was silenced (Fig. 1d). Thalamic contribution in response to principal whisker (PW) stimulation varied considerably in individually recorded L4 and L5 cells (Figs. 1d and 1e). The mean relative thalamic contribution was larger in L4 than in L5 cells (0.46±0.06 and 0.19±0.07, respectively, p=0.0198 Mann Whitney test, see the depth profile in Figure 1e and the right traces in Figure 1d), probably reflecting the greater innervation of L4 compared to L5 by thalamic fibers⁴¹. Importantly, the relative contribution of thalamic inputs were indistinguishable when we stimulated either the PW or the adjacent whisker (AW, Fig. 1f p=0.55, n=18, Wilcoxon signed rank test). Hence, thalamic contribution to total response is unrelated to the optimality of the stimulus, similar to findings in the visual and auditory cortices^{39,40}.

We next verified that our manipulation allowed us to correctly isolate thalamic inputs. We first ruled out the possibility that the reduction in synaptic response was caused by shunting inhibition. Indeed, in contrast to a shunting effect, in some cells a prominent reduction in the response was recorded while no change in input resistance was measured (Fig. 1g, left example), whereas in others the response was unaffected although input resistance was reduced (Fig. 1g, right example). No significant correlation was found between the thalamic fraction and the measured change in input resistance (Fig. 1h, population data. A small trend exists, but it cannot explain the

reduction of the response by shunting, as it shows minimal attenuation for cells in which input resistance was clearly reduced). In addition, by recording thalamic single units we also ruled out the possibility that our manipulation altered the firing of VPM cells due to cortico-thalamic feedback connections (Figs. 1h). Finally, illumination of the cortex 100 ms before whisker stimulation had no effect on the evoked currents (Supplementary Fig. 1), excluding the possibility that the reduction in EPSC is due to slow extrasynaptic activation of GABA(B) receptors^{46,47}. These results indicate that the isolated thalamic synaptic inputs were not affected by cortical inactivation.

In order to study the contribution of thalamic inputs to the correlations between individual cells in thalamic recipient cortical layers, we performed simultaneous *in-vivo* whole-cell recordings from pairs of nearby excitatory neurons in L4 (Euclidean distance <200μm; Fig. 2a) of anesthetized mice (some of the cells presented in Fig. 1e were recorded as pairs). We analyzed only pairs of cells for which both cells received direct thalamic inputs, as evident from the reduction but not full loss of their response to whisker stimulation (Fig. 2b). We found that thalamic inputs could be substantially different for simultaneously recorded nearby cells (example in Fig. 2b). This was quantified by calculating the similarity index (SI) of their mean thalamic contributions ($SI = 1 - \frac{|TC1-TC2|}{TC1+TC2}$, where *TC1* and *TC2* are the relative thalamic contributions of the two cells). The SI for the recorded pairs was only marginally higher than expected from individually recorded cells (Fig. 2c, computed using a bootstrap analysis, see Methods), indicating that the large diversity in thalamic contribution in individual cells (Fig. 1e) was not the result of different experimental conditions.

Cortical synchronized ongoing activity does not emerge from thalamic inputs

During ongoing activity, a prominent correlation in synaptic inputs of simultaneously recorded cells was measured. The correlation coefficient (CC) between nearby L4 cortical cells during ongoing activity was comparable between current clamp and voltage clamp modes within the same pair (see example in Fig. 3a; mean CC=0.5±0.05 and 0.55±0.04, respectively, p=0.6875, n = 7 pairs). This implies that measurements under voltage clamp are a good estimate of the functional correlations between cells.

To reveal the contributions of thalamic inputs to cortical synchronized ongoing activity in L4, we compared the correlations between the excitatory synaptic currents in each pair when cortical firing was intact (LED OFF) to that calculated when cortical firing was silenced (LED ON). Whereas excitatory currents were highly synchronized in the intact cortex (Fig. 3b and Supplementary Fig. 2 and 3; population mean $CC=0.39\pm0.04$, $n=10$ pairs, Fig. 3c, upper panel, LED OFF), the correlation between the cells dropped substantially when we silenced cortical firing (Fig. 3b and Supplementary Fig. 2 and 3; population mean $CC=0.11\pm0.02$, Fig. 3c, upper panel, LED ON, $z=-2.8031$, $p=0.002$, Wilcoxon signed rank test). We extended our database by recording from mixed pairs, where one cell was located in L4 and the other in L5 (Supplementary Fig. 4). Similar to L4-L4 pairs, CC of excitatory synaptic currents in L4-L5 pairs during ongoing activity (mean $CC=0.27\pm0.08$, $n=6$ pairs, Fig. 3c, lower panel, LED OFF) dropped significantly when cortical firing was silenced (mean $CC=0.07\pm0.02$, Fig. 3c, lower panel, LED ON, $z=-1.862$, $p=0.0313$, Wilcoxon signed rank test). The synaptic activity during LED ON decreased by $33\pm4.5\%$ ($p=6e^{-6}$, Wilcoxon signed rank test, measured from the total excitatory charge Q , the time integral of the EPSCs) and in an equivalent manner in both cells (Supplementary Fig. 5 shows $\frac{Q_{LED\ on}}{Q_{LED\ off}}$ in each pair), indicating that reduced CC was not due to unequal light effects. Hence, synchronized ongoing activity in cortical neurons, within and across different thalamic recipient layers, depends on recurrent cortical activity and does not reflect the correlation between the cell's feedforward thalamic inputs.

Trial to trial correlation between layer 4 cells of whisker evoked activity is not determined by thalamic inputs

We next examined the cortical and thalamic contributions to trial to trial variability of whisker evoked EPSCs of L4 cells. In the visual system, inactivation of cortical firing had a negligible effect on trial to trial membrane potential variability⁴, suggesting that cortical variability is dominated by thalamic inputs. In contrast, we found that in the barrel cortex, optogenetic silencing of local firing profoundly reduced the variability of the whisker evoked EPSCs (Figure 4a-c). This was evident both in the standard deviation and in the coefficient of variation (CV). On average the standard deviation of peak EPSPs was reduced by $62\pm22\%$ following cortical silencing (Fig. 4b, $p=0.0003$, $n=17$, $z=-3.6$, Wilcoxon signed rank test). This trend

remained even after normalization by the mean (Fig. 4c, reduction of $14\pm 29\%$ in CV, $p=0.029$, $n=17$, $z=-2.2$, Wilcoxon signed rank test).

The larger trial to trial variability of intact cortex compared to inactivated cortex suggests that it is strongly influenced by recurrent cortical circuits. Therefore, we examined the cortical and thalamic origins of the sensory evoked excitatory trial to trial correlation (TTC_{EE} , noise correlation) between pairs of cells that received direct thalamic inputs. Figure 4d shows two representative pairs in which 10 sequential whisker evoked responses of one cell (orange traces) are sorted from the smallest to the largest, with the corresponding responses of the second cell (blue traces) during LED OFF (left) and LED ON (right) conditions (for illustration purposes traces of the cell with the larger responses, on average, was placed below the second cell). Across the population, the change in TTC_{EE} for the recorded pairs was not consistent between the two conditions. In 5 pairs TTC_{EE} was reduced, in 3 it roughly remained the same and in two pairs it was increased (Fig. 4e). No significant difference was found between the mean TTC_{EE} values. For the 7 L4-L4 pairs the TTC_{EE} dropped from 0.38 ± 0.14 to 0.16 ± 0.09 (Fig. 4e, dark blue circles, $z=-1.0142$, $p=0.219$, Wilcoxon signed rank test), and for 4 L4-L5 pairs it changed from 0.16 ± 0.05 to 0.29 ± 0.06 (Fig. 4e, light blue circles $p=0.375$, Wilcoxon signed rank test). Notably, as the lines connecting the two conditions crossed each other, the TTC_{EE} during LED OFF condition could not be predicted from the one measured during cortical silencing; that is, the distributions across the conditions were not correlated with each other ($r^2=0.07$, $p=0.557$ and $r^2=0.16$, $p=0.596$ for L4-L4 and L4-L5 pairs, respectively). Furthermore, noise correlation when cortex was intact, or during silencing, was not related to the ongoing correlations under the same conditions (Supplementary Fig. 6). Thus, similar to ongoing activity, we can conclude that the TTC_{EE} of sensory response between cortical cells is not determined by direct thalamic inputs but rather depends on recurrent cortical activity.

Ongoing and sensory evoked correlated cortical activities in awake animals do not emerge from thalamic inputs

Both ongoing and evoked activities in cortical cells are regulated by animal behavior^{18,19,29,30,48}. As so, we wished to confirm our result in awake mice. Naïve animals were head-fixed, and were not trained to perform a task. Similar to our

recordings in anesthetized animals, surface illumination of the cortex activated GABAergic cells (Fig. 5a, example cell and population data below, 1.3 ± 0.7 vs. 47 ± 16 Hz for LED OFF and LED ON; $n=7$ cells, $z = -2.63$, $p=0.015$, Wilcoxon signed rank test). This in turn inhibited the local circuitry and blocked almost completely (98%) whisker evoked firing of the non-ChR2 expressing cells at all depths (example of a L4 cell is shown in Fig. 5b and the population data below, 0.7 ± 0.1 vs. 0.02 ± 0.01 spikes/stim for LED OFF and LED ON; $n=7$ cells, $z = -2.63$, $p=0.015$, Wilcoxon signed rank test).

To estimate the contribution of thalamic input to the total whisker evoked excitatory current in awake mice, we recorded from 12 neurons located at L4 and L5. The average excitatory currents in 4 cells are demonstrated during intact cortical activity (Fig. 5c black traces) and when cortical firing was silenced (Fig. 5c blue traces). Similar to anesthetized mice, a large variability in the contribution of thalamic input was also found in awake mice and as before, the thalamic contribution in L4 cells was larger compared to L5 cells (Fig. 5d, 0.59 ± 0.1 and 0.27 ± 0.04 , respectively, $p=0.05$). Importantly, we found no differences between awake and anesthetized mice when comparing the thalamic contribution in each layer (Fig. 5e $p=0.275$, two way ANOVA).

Whole cell recordings in awake animals were made simultaneously with local field potential (LFP) recordings using an additional glass pipette that was placed in proximity to the recorded cell in L4 (Fig. 6a, $<200 \mu\text{m}$). Inactivation of cortical firing reduced the amplitude of the averaged LFP response to whisker stimulation (Fig. 6b, two examples of simultaneous cell-LFP recordings). Population analysis showed that thalamic contribution varied also for LFP recordings (Fig. 6c). On average, the contribution of thalamic inputs to the two signals was similar (Fig. 6c, 0.57 ± 0.1 vs. 0.46 ± 0.1 , $p=0.57$, $z=-0.56$, Wilcoxon signed rank test), showing that as for the EPSCs, a significant amount of the evoked LFP response arises from thalamic input.

To reveal the contribution of shared thalamic inputs to cortical synchrony during ongoing activity in awake mice, we calculated the correlation between membrane potential and the LFP when cortical firing was intact and when firing was optogenetically silenced. Importantly, we found that the magnitude of the correlation coefficient (CC) between the LFP signal and the electrical activity of the recorded cells was independent of the recording mode method (Fig. 6d, $cc=-0.45$ at current clamp and $cc=0.47$ at voltage clamp). Hence, voltage-clamp recordings capture the

functional correlations that exist between subthreshold activity of individual cells and the LFP signal. We interleaved trials in which cortical firing was intact with trials in which cortical firing was silenced and calculated the correlation between EPSCs of L4 cells and the LFP signals during ongoing activity. The example paired recording in Figure 6e shows that the thalamic contribution for both signals is nearly one, as evident from the negligible change in the average responses of both signals to whisker stimulation when the cortex was illuminated (Fig. 6e, inserts). Yet, optogenetic silencing of cortical firing during ongoing activity drastically reduced the correlation between the excitatory current of the recorded cell and the nearby LFP signal (from 0.68 to 0.13). Silencing cortical firing in 8 similar recordings reduced the correlation between the LFP and the excitatory current during ongoing activity from 0.31 ± 0.08 to 0.03 ± 0.03 (Fig. 6f; $n=8$, $p=0.01$, $z=-2.8$, Wilcoxon signed rank test). We can therefore conclude that cortical synchrony during ongoing activity in L4 of the barrel cortex in awake mice is not driven by thalamic inputs.

Next, we examined the effect of cortical silencing on the trial to trial correlation between intracellular excitatory current and a nearby LFP signal in response to vibrissa stimulation (TTC_{EL}). Similar to anesthetized mice, cortical silencing reduced the response variability of the individual cells and of the LFP (Supplementary Fig. 7), suggesting that noise correlations are affected by recurrent cortical circuits. Indeed, the example in Fig. 6g shows that the response to vibrissa stimulation varied considerably from trial to trial for both signals. Sorting the cellular responses from the smallest to the largest, while plotting the corresponding LFP signal, reveals a clear correlation between the two signals ($r^2=0.85$, $p=0.00001$). Silencing cortical firing by light reduced the TTC_{EL} (Fig. 6h to $r^2=0.6$ $p=0.005$). On average, no significant change in TTC_{EL} was found between the two conditions (Fig. 6i, $TTC_{EL}=0.47 \pm 0.1$ and 0.41 ± 0.1 for LED OFF and LED ON respectively, $p=0.57$, $z=-0.56$, $n=7$ Wilcoxon signed rank test). As in anesthetized animals, the TTC_{EL} in the intact cortex was not correlated to that found during cortical silencing ($r^2=10^{-5}$, $p=0.99$). Taken together, noise correlation between single cell and the population LFP response in the intact cortex cannot be inferred from the measured correlations of the isolated thalamic inputs, implying that cortical recurrent connections determine the degree of synchronization in L4 of awake mice.

Discussion

In this work, we investigated the role of thalamic inputs in shaping the synaptic correlations between neighboring cells in thalamic recipient cortical layers during ongoing and sensory evoked activities. To address this question, we optogenetically silenced cortical firing in anesthetized and awake mice in order to isolate the thalamic excitatory inputs of intracellularly recorded cells in L4 and L5. Specifically, in awake mice we examined the effect of silencing cortical firing on the correlation between excitatory inputs of individually recorded cortical cells and a nearby LFP signal whereas in anesthetized mice we simultaneously recorded the excitatory inputs of nearby pairs of neurons. Our results show that synchronized activity during ongoing activity emerges from intracortical inputs, rather than being driven by direct thalamic inputs. Trial to trial sensory evoked correlation ('noise correlation') in response to vibrissa stimulation during intact cortical firing is poorly related to the noise correlation in the thalamic inputs, indicating that it is also a product of intracortical recurrent activity.

The contribution of thalamic inputs to sensory response of cortical cells

To isolate the thalamic input of cortical cells we illuminated the barrel cortex of transgenic mice expressing ChR2 in GAD+ cells while recording excitatory currents. A similar approach was used in recent studies of the auditory and visual cortices of anesthetized mice³⁸⁻⁴⁰ where ChR2 was expressed in PV+ cells. Due to the high level of expression in these transgenic mice, it is reasonable to assume that neurons that did not exhibit direct activation by light are excitatory cells. In anesthetized mice we found that thalamic inputs contributed on average about 46% of the total excitatory input of layer 4 cells, which is slightly higher than previously reported in the visual cortex (~30%)³⁸ and roughly the same as in the auditory cortex of mice (41%)⁴⁰. Our estimate is slightly lower than in the rat auditory cortex where cortical firing was pharmacologically silenced (61%)⁴⁹. The higher contribution of thalamic inputs to the total response of L4 neurons in the barrel cortex, compared to the visual cortex, may reflect the stronger damping of recurrent cortical activity due to the prominent feedforward inhibition in the somatosensory^{38,50,51} and auditory²⁰ cortices. Thus, across different modalities, recurrent cortical circuits may amplify thalamic inputs in a slightly different manner. Bruno and Sakmann³⁷ suggested,

however, that cortical amplification is not required to explain the sensory response of L4 cells in the barrel cortex. In a few cells we indeed observed almost no amplification (thalamic contribution ~100%, Fig. 1e), but for most cells amplification was prominent. It is possible that this discrepancy reflects differences across species (mice in our study and rats in ref#37).

To the best of our knowledge, our study is the first that compared the amplification of thalamic inputs by recurrent cortical circuits across anesthetized and awake mice. In both conditions, the contribution of thalamic input to the total excitatory input varied with the recording depth (Figs. 1e and 5d). Higher contribution of thalamic input was found in cells that were recorded in L4 compared to L5 cells. The higher contribution of thalamic inputs in L4 is expected from the dense innervation of L4 by thalamic inputs^{41,44,52}. Importantly, the contribution of thalamic input in L4 and L5 of anesthetized mice was very similar to the contribution of these inputs to the same layers in awake mice (Fig 5e).

Similar to previous studies of the visual and auditory cortices^{38–40}, cortical silencing showed that the contribution of thalamic inputs was invariant to the optimality of stimulation. We demonstrated it comparing the contribution of thalamic inputs when independently stimulating the PW and one of the AWs within the same cells (Fig 1f). This suggests that the local circuitry of a cortical cell amplifies its thalamic inputs in a particular manner for each cell, regardless of the feature that activates this cell.

Recurrent cortical activity engaged quite rapidly, roughly at the same time of the onset of thalamic input, as evident when the average response to whisker stimulation in intact cortex was compared to the time course of thalamic input alone under cortical silencing (Fig. 1d, 2b, 5c and 6b). Naively, one would expect that recurrent inputs will be delayed by a few milliseconds with respect to the onset of thalamic input, as it involves at least one additional synapse. However, this does not necessarily need to be the case. Assuming that we sampled the cortical population randomly, the thalamic input would arrive to some cells relatively early while to others it would arrive later, The earliest firing in L4 can be as short as 5 ms following whisker stimulation⁵³, therefore, local cortical cells should provide input to other cells roughly at the same time or even before the onset of thalamic input of cells that are not the 'primer' cells. Indeed, the latency of the response under cortical silencing in some of our recorded cells was clearly delayed by a couple of milliseconds relative to

the onset of the response when the cortex was intact (Fig. 6b, cell #W8). Hence, recurrent cortical activity engages rapidly in the somatosensory cortex. Rapid amplification of thalamic inputs is evident also in the studies of the visual and auditory cortices^{38,40}.

Origins of cortical synchrony during ongoing and sensory evoked activities

The origin of noise correlation of sensory responses in primary sensory cortical areas is under dispute. In one view, the variability in sensory responses mostly depends on subcortical processing of sensory inputs and therefore on the variability of the thalamic inputs. According to this possibility, cortical responses fluctuate from trial to trial due to noisy thalamic inputs, and since these inputs are shared, the responses of different cortical cells are correlated. This view is supported by measurements of trial to trial spiking variability in geniculate cells of the visual system⁵⁴ and the similarity in the variance of membrane potential responses to brief visual stimulation of L4 cells in V1, before and after inactivation of cortical firing using electrical stimulation⁴. However, our results are in line with a different view, suggesting that cortical synchrony emerges due to intracortical inputs^{25–28,9,5}. In contrast to the findings of Sadagopan and Ferster⁴, our experiments show that the cortex adds substantial variance to that which originates from the thalamic inputs, as the standard deviation of the response was significantly larger during intact cortical firing compared to that measured when the cortex was silenced (Fig. 4). Direct measurements of trial to trial correlation indicate that they are not determined by thalamic inputs. In awake mice, the correlation between excitatory inputs of L4 cells and nearby LFP signal, when the cortex was intact, was highly variable across the population. This was observed both for ongoing activity (Fig. 6f) and for the evoked response (Fig. 6i). A large range of correlations was also measured between the excitatory currents in anesthetized mice (Figs. 3c and 4e). In other studies of the barrel cortex in awake mice^{18,19}, nearby cells, recorded in layer 2/3, exhibited a much narrower range of correlation during ongoing activity and on average it was higher than what we report in this study of L4. This discrepancy probably reflects laminar differences in the strength of correlations. Indeed, the correlated variability of extracellularly recorded neurons in upper cortical layers of the visual cortex of awake monkeys was found to be significantly higher than between cells located in the granular layer (i.e., layer 4)⁵⁵.

The wide range of correlation strengths between individually recorded cells and the nearby LFP in awake animals, as well as between the paired intracellular recordings in anesthetized animals, is reminiscent of the large diversity of network coupling that was recently reported in the visual cortex using extracellular recordings⁵⁶. According to the study of Okun and his colleagues, the diversity in network coupling is related to the strength of synaptic connections made between individual cells and their neighboring population. They showed that cells that received more synaptic inputs from their neighbors exhibited higher coupling with network activity⁵⁶. Although we have no direct evidence that supports this conjuncture in our study, we know from our recordings that the strength of ongoing and noise correlations between cortical cells are weakly dependent on their shared thalamic inputs. This happens despite the large contribution of thalamic inputs to the total sensory evoked excitatory currents (~50%).

Several factors contribute to noise correlation of thalamic excitatory inputs of cortical cells upon sensory stimulation. These include noise correlation of thalamic cells, the convergent-divergent organization of thalamo-cortical ascending axons and co-modulation of thalamo-cortical synapses by neuromodulators or GABA(B) presynaptic contacts⁴⁶. In addition, the reliability of axonal transmission of individual thalamic cells, such as result from axonal failure and from the reliability of synaptic release, may reduce the noise correlation between cortical cells. Because of the large number of thalamic fibers that converge on each cortical cell^{37,44}, due to averaging, the reliability in axonal conductance or synaptic release should have a negligible effect on the variability of the total synaptic thalamic input of individual cortical cells, or their impact on correlated variability. Our method, however, bypasses these factors all together, allowing us to measure the impact of these factors when summed together.

In conclusion, we found that synaptic correlations of nearby cortical cells in L4 and L5 during ongoing and sensory evoked activities are poorly related to their thalamic excitatory inputs. Moreover, the contribution of thalamic inputs varies considerably across the population. The functional role of the asynchronous nature of thalamic inputs and diversity in thalamic contribution in L4 is unclear. An intriguing possibility is that such connectivity may smooth the population response curve to a wide range of stimuli, allowing better encoding of sensory inputs.

Material and Methods

Animals:

All procedures involving animals were reviewed and approved by the Weizmann Institutional Animals Care Committee. Animal surgeries and *in vivo* recordings were performed as previously described²¹. Briefly, recordings were made on young adult mice of either sex (9-16 weeks old) housed up to 5 in a cage with a 12/12h dark/light cycle. Two strains were used, GAD-CRE mice (JAX #010802) and PV_CRE mice (JAX #008069) crossed with a ChR2 reporter strain (JAX # 012569). Since cortical firing was silenced similarly in both strains, data were pooled from both types.

Anesthetized animal preparation:

For intracellular recording from the barrel cortex, after initial anesthesia with ketamine (90 mg/kg; i.p.) and xylazine (2 mg/kg; i.p.), a tracheotomy was made and the animals were mounted in a stereotaxic device and artificially respired with a mixture of halothane (0.5–1%) and oxygen-enriched air. The scalp and fascia were removed and a metal headplate was mounted over the left hemisphere using dental cement (Lang dental) and VetBond (3M). A craniotomy (~1 mm in diameter) was made above the barrel cortex (centered 1.3 mm posterior and 3.3 mm lateral to the bregma) and a portion of the dura mater was carefully removed. The craniotomy was constantly washed with artificial cerebrospinal fluid (ACSF) containing (in mM): 124 NaCl, 26 NaHCO₃, 10 Glucose, 3 KCl, 1.24 KH₂PO₄, 1.3 MgSO₄ and 2.4 CaCl₂. The levels of end-tidal CO₂ and heart rate (250–450 beats/min) were monitored throughout the experiments. Body temperature was kept at 37°C using a heating blanket and rectal thermometer.

Awake animal preparation:

Animals underwent the implantation of a head bar to allow awake head-fixed recordings as follows: Following initial anesthesia in an induction chamber containing a mix of isoflurane and oxygen enriched air, animals were mounted in a stereotaxic device, and kept deeply anesthetized, monitored by checking for lack of reflexes and pace of breathing. Area of incision was treated with lidocaine and cleaned with iodine and 70% ethanol. The skullcap was exposed and cleaned. The skull above the barrel cortex (1.3 mm posterior, 3.3 mm lateral to the bregma) was covered with silicon glue (Smooth-On, Inc., USA). A small titanium headbar was firmly affixed to the skull slightly anterior to bregma with dental acrylic (3M, Germany).

Following a recovery period (4-7 days) animals were anesthetized in an induction chamber containing a mix of isoflurane and oxygen enriched air, animals were then mounted in a stereotaxic device, and kept deeply anesthetized. The silicon glue covering the skull over the barrel cortex was removed and a craniotomy was performed exposing the barrel cortex and leaving the dura intact. The brain was then covered in an agar layer (2% w/v) held in place with silicon glue and the animal was returned to the cage for a recovery period (1-2 hours). The animal was then returned to the set and head-fixed for the electrophysiological recordings.

Cortical patch recordings:

Borosilicate micropipettes were pulled to produce electrodes with a resistance of 4–10 MΩ when filled with an intracellular solution containing (in mM) as follows: 135 Cesium-Met., 4 TEA-Cl, 10 HEPES, 1 MgATP, 0.3 NaGTP, 3 QX-314 and 10 phosphocreatine (310 mOsm). Intracellular signals were acquired using an Axoclamp-700B amplifier (Molecular Devices) and low passed at 3 kHz before being digitized at 10 kHz. Recording depth ranged between 300-700μM. Cells up to 500 μM were

classified as layer 4 cells while cells recorded from this depth and up to 700 μM were classified as layer 5 cells. For double intracellular recording two path pipets were inserted to the brain to a depth of 300 μM . After reaching a successful whole cell recording in one pipet the second pipet was advanced until getting the second whole cell recording.

Voltage clamp recordings were started immediately after a successful breach of a giga-seal. To record only excitatory currents under voltage clamp, membrane potential was clamped at the reversal potential of inhibition. This potential was determined under voltage clamp for each cell by adjusting the holding potential until no change in current was measured upon activation of the GAD or PV ChR2 with LED illumination. Current-clamp recordings were also made in a subset of cells.

For simultaneous LFP recordings a patch pipet was inserted to a recording depth of 400 μM . The signal was band passed at 0.1-300Hz before being digitized at 10 kHz.

Thalamic extracellular recordings:

Extracellular recordings were performed using Juxta electrodes filled with patch solution with a resistance of 20-30 M Ω . The craniotomy was centered 1.5mm lateral and 1.5mm posterior of the bregma over the ventral posteromedial nucleus (VPM) at a depth of 3.6mm. Signals were amplified using Axoclamp-700B amplifier, low passed at 3 kHz and digitized at 10 kHz.

Cortical silencing:

In order to activate ChR2, a LED light source at 460nm (Prizmatix Opt-LED-460) was coupled to a bare optical fiber (200 μm dia., 0.22NA; ThorLabs M25L05) placed above the cortex. The LED was driven by an analog output from our acquisition system (National Instruments) for one second. The intensity of the light

was around 7mW at the tip of the fiber. As Li et al.²², we estimated the effect of cortical silencing on the inputs resistance of the cells. A step current of $\pm 100\text{pA}$ was injected under LED OFF and LED ON conditions. Cortical silencing decreased input resistance (from 330 ± 25 to $220 \pm 20 \text{ M}\Omega$, $p = 0.006$, two-tailed paired Wilcoxon signed rank test, $n = 15$). We estimated how much the decrease of input resistance would affect the recorded current amplitude based on:

$$I_{rec} = \frac{R_{in}}{R_{in} + R_s} * I_{syn}$$

Where I_{syn} is the actual amplitude of synaptic current, I_{rec} is the recorded amplitude, R_{in} is the input resistance and R_s is the effective series resistance. R_s was unchanged after cortical silencing (70 ± 25 to $60 \pm 20 \text{ LED OFF vs. LED ON}$; $p = 0.68$, two-tailed paired Wilcoxon signed rank test, $n = 6$). Assuming no change in I_{syn} , the decrease in R_{in} and R_s during illumination would lead on average to a 5% reduction of the recorded synaptic amplitude, which is negligible compared with the measured amplitude reduction after cortical silencing.

Whisker stimulation and protocols:

Whiskers were trimmed to a length of 10–20 mm. When single whisker stimulation was given either the principal whisker (PW) or adjacent whisker (AW) were inserted into 21G needle attached to a galvanometer servo motor with a matching servo driver and controller (6210H, MicroMax 677xx, Cambridge Technology Inc.). The displacement was measured off-line using an optical displacement measuring system (optoNCDT 1605, Micro-Epsilon), indicating that ringing was negligible. A fast-rising voltage command was used to evoke a fast whisker deflection with a constant rise time of $\sim 1 \text{ ms}$ followed by a 20 ms ramp-down signal. The stimulation velocity and the corresponding deflection amplitude ($\sim 50 \text{ mm/s}$, $145\mu\text{m}$ amplitude) were adjusted to evoke clear subthreshold responses in

the cortical cells. When global whisker stimulation was used the tip of the needle was placed on the whisker pad and multiple whiskers were stimulated simultaneously.

Whisker stimulation was delivered without and with LED illumination, which started 300ms before the whisker was stimulated and the light was turned on for 1sec. Trials with LED stimulation alone were also delivered and they were used to correct drifts in voltage recordings, if occurred. These trials were pseudo-randomly delivered and were either 3s or 5s long with 2s inter-trial intervals. Each condition was repeated at list 6 times.

Data analysis:

The recordings were analyzed using custom software written in MATLAB (The MathWorks). We smoothed the raw traces using a symmetric Savitzky–Golay filter with a first-order polynomial and a window size of 21 points. The amplitude of the evoked excitatory postsynaptic current (EPSC) was measured as the difference between the minimum peak membrane current response and the mean baseline value obtained over the 10 ms before stimulation. Excitatory charge (Q) was calculated as the time integral of the EPSCs over a period of 900ms before or during LED illumination. Spike counts were calculated as the sum of spikes observed during the 5–45 ms period after whisker stimulation, without subtracting spontaneous firing as in the absent of stimulation cells fired very sparsely. Crosscorrelation coefficient (CC) between each paired traces (at 0 time-lag) was calculated and the average CC between shuffled traces was subtracted from this value. Data are presented as mean \pm SEM.

Statistical difference between the thalamic contribution in the recorded pairs was calculated using bootstrap analysis where traces from LED ON and OFF were pooled randomly and averaged for each cell in the pair. The thalamic fraction was calculated 300 times, averaged and compared (Wilcoxon rank-sum test) to that

calculated for the second cell in the pair. Similarity index (SI) of cortical amplification was calculated as follow: $= 1 - \frac{|TC1-TC2|}{TC1+TC2}$, *TC1* and *TC2* are the relative thalamic contributions of the cells. SI=1 implies that thalamic contributions are identical. The mean SI of simulated pairs was calculated using bootstrap analysis by artificially constructing 11 random pairs (the same number of pairs in our data base) from the individually recorded neurons and repeating this procedures 500 times to obtain mean and 95% confidence limits.

Acknowledgements: This work was supported by ISF, Minerva and DFG-SFB 1089. We thank all the members of the I.L. laboratory and especially Inabl Meir and Rebekah Tumasus for their helpful contributions.

Author contributions: K.C.K.M. and B.M. contributed equally to this work. K.C.K.M., B.M and I.L. designed the experiments; K.C.K.M. performed the experiments with A.R & B.M.; K.C.K.M., B.M. and I.L. analyzed the data; K.C.K.M., B.M. and I.L. discussed the results and wrote the manuscript.

Figure Legends:

Figure 1: Optogenetic silencing of cortical firing isolates the thalamic excitatory inputs of cortical neurons in the barrel cortex of anesthetized mice.

(a). Schematic illustration of cortical silencing experiments in anesthetized mice. Light activates ChR2 expressing inhibitory cells which in turn silence the firing of cortical cells. (b). Peri-stimulus spike time histogram (PSTH) for an example GAD⁺-ChR2 cell in response to 1s LED illumination (top) and population mean firing rate of GAD/PV⁺-ChR2 cells (bottom). (c). PSTH of a putative excitatory L4 cell in response

to repetitive whisker stimulation (orange bars) in LED OFF and LED ON conditions (top) and population average spike count per stimulus of cells located in layers 2/3, 4 and 5 (bottom left) and deep layers (700-1100 μ M, bottom right). (d). Average whisker evoked excitatory currents in two example L4 (left, top panel) and L5 (left, bottom panel) cells recorded independently during LED OFF and LED ON conditions and the population average currents (right). (e). Population depth profile of the thalamic contribution to evoked excitatory response of all recorded neurons (n=47). (f). The contribution of thalamic input for each cell, when the principle whisker (PW) or adjacent whisker (AW) was stimulated. (g). Average EPSC in response to 10 mV step (left, top panel) and whisker deflection in two recorded cells during LED OFF and LED ON (left, bottom panel) conditions. Right panel shows population thalamic contribution versus change in input resistance. (h). PSTH of a VPM neuron in response to whisker stimulation during LED OFF (left, top panel) and LED ON (left, bottom panel) condition. Right panel shows the population average spike count per stimulus of VPM cells.

Figure 2: Thalamic contribution in nearby cortical cells is unique. (a) Schematic illustration of paired whole cell recordings. (b). Average whisker evoked excitatory currents in two example L4 cells recorded independently during LED ON and LED OFF conditions and below an example of a L4-L5 pair. (c). The similarity index (SI) of thalamic contribution (\pm s.e.m) for the 11 recorded pairs compared to the expected mean SI in simulated pairs from single cell recordings (bootstrap analysis, see Methods).

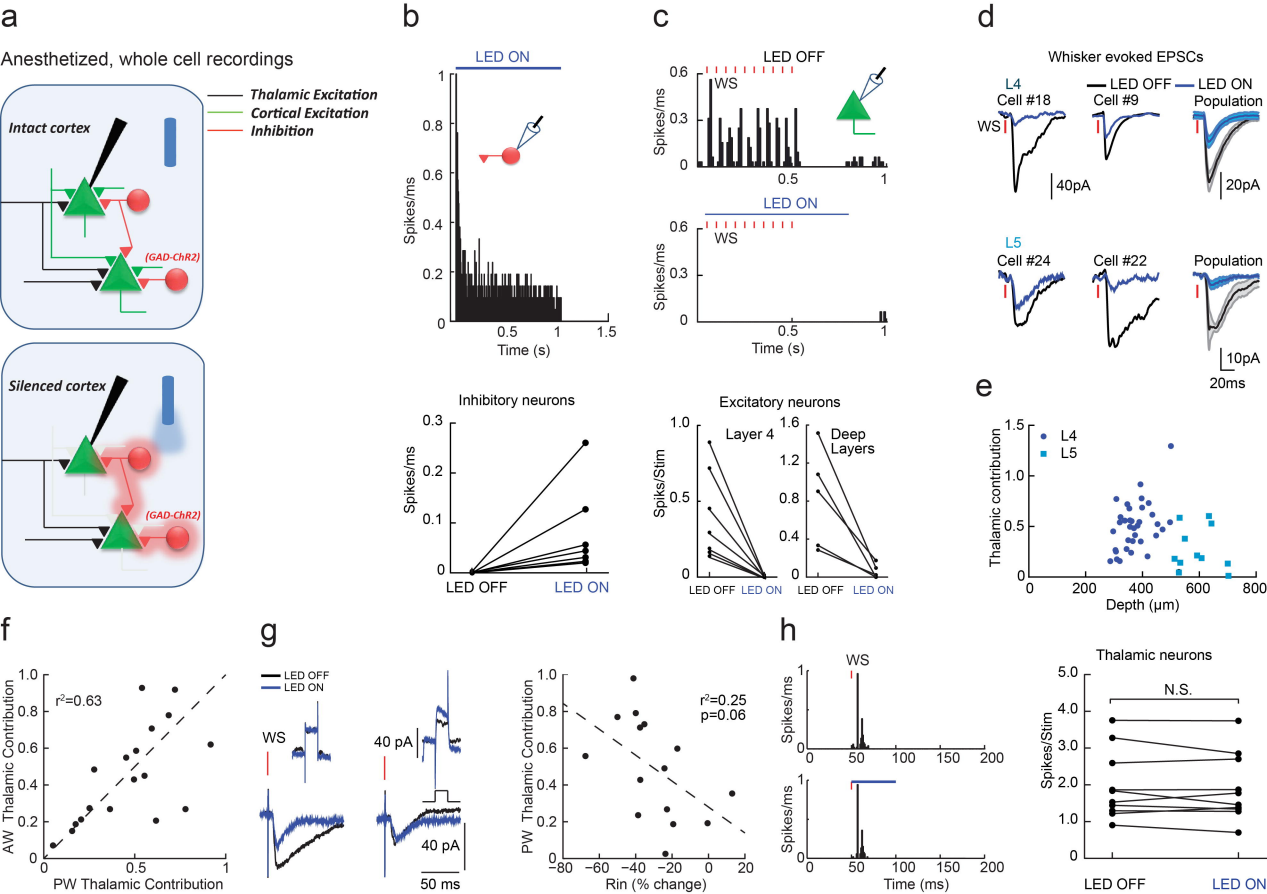

Figure 3: Correlation of spontaneous excitatory inputs between cortical cells in the barrel cortex is not determined by thalamic inputs. (a). Simultaneous whole cell recordings of two putative excitatory L4 cells during ongoing activity in current clamp and voltage clamp (at the reversal potential of inhibition) modes. (b). Example traces of ongoing excitatory currents in two simultaneously recorded L4 cells during LED OFF and LED ON conditions. Upper insets, average excitatory responses to whisker stimulation. Lower insets, cross-correlation between the cells. (c) Population CC values for L4-L4 pairs $n=10$, $p=0.002$, Wilcoxon signed rank test) and L4-L5 pairs $n=6$, $p=0.0313$, Wilcoxon signed rank test). Example pair in b is depicted in red.

Figure 4: Trial to trial correlation of sensory evoked response between nearby cortical cells in anesthetized mice is not determined by thalamic inputs. (a). Example of all the responses of an example L4 cell to whisker stimulation under LED OFF (gray traces with black trace for the mean) and under LED ON (blue traces with mean as dark blue). Data was normalized to the mean of each condition. (b). Population data of the standard deviation of the peak response measured for each trial at the two conditions. (c) Same as b for the coefficient of variation (CV). (d). TTC_{EE} measurements during LED OFF (left) and LED ON trials (right). Responses to 10 sequential whisker stimuli of one cell (orange traces) sorted from the smallest to the largest amplitude with the corresponding responses of the second cell (blue traces). Scatter plots show peak excitatory current responses of one cell plotted against that of the second cell. (e). Population data and averaged TTC_{EE} for LED OFF and LED ON conditions in L4-L4 pairs (mean $TTC_{EE}=0.38\pm0.14$ and 0.16 ± 0.05 , respectively, $p=0.219$ Wilcoxon signed rank test, $n = 7$) and in mixed L4-L5 pairs (mean $TTC_{EE}=0.16\pm0.09$ and 0.29 ± 0.06 , $p=0.375$, Wilcoxon signed rank test $n=4$).

Figure 5: The fraction of thalamic input of cortical cells in awake mice is similar to anesthetized animals. (a). Peri-stimulus spike time histogram (PSTH) for an example GAD⁺-ChR2 cell in response to 1s LED illumination (top) and population mean firing rate of GAD/PV⁺ cells (bottom). (b). PSTH of a putative excitatory L4 cell in response to repetitive whisker stimulation (orange bars) in LED OFF and LED ON conditions (top) and population average spike count per stimulus of cells located in layers 4 and 5. (c). Average whisker evoked EPSCs of two examples L4 (top) and L5 (bottom) cells recorded independently during LED OFF and LED ON conditions. To the right are the average EPSCs of the two populations. The two vertical scale bars represent 20pA. (d). Population depth profile of the thalamic contribution to the EPSCs of all recorded neurons (n=12). (e). Mean population data of the thalamic contributions in L4 and L5 of awake and anesthetized mice.

Figure 6: Simultaneous EPSCs and LFP recording in awake mice indicate that ongoing and whisker evoked correlations do not arise from thalamic inputs. (a). Schematic illustration of whole cell and LFP paired recordings in awake mice. (b). Average of paired recordings showing mean whisker evoked EPSCs and LFP responses recorded from two animals. (c). Population data and mean peak EPSCs and the corresponding LFP response under LED OFF and LED ON conditions. (d). Simultaneous whole cell and LFP recordings in L4 during ongoing activity when the cell was recorded in current clamp and voltage clamp (at the reversal potential of inhibition) modes. (e). Example traces of ongoing excitatory currents in a L4 cell and the corresponding nearby LFP signal that was recorded simultaneously during LED OFF and LED ON conditions. Upper insets, average whisker evoked EPSCs and LFP

under the same conditions. Lower insets, cross-correlation between the cell and the LFP. (f). Population CC values for L4-LFP pairs $n=8$, $p=0.01$, Wilcoxon signed rank test). (g-h). TTC_{EL} of EPSC-LFP paired recordings during LED OFF (g) and LED ON (h) conditions. Responses to 10 sequential whisker stimuli of one cell (light blue traces) sorted from the smallest to the largest amplitude with the corresponding responses of LFP (black traces). Scatter plots show peak LFP responses against the peak EPSC response of the cell. (i). Population data and averaged TTC_{EL} for LED OFF and LED ON conditions in EPSP-LFP paired recordings ($TTC_{EL}=0.47\pm0.1$ and 0.41 ± 0.1 , respectively, $p=0.57$ Wilcoxon signed rank test, $n = 7$).
