## 25

#### 26 Abstract

27

28 Heterozygous mutations within homozygous sequences descended from a recent common ancestor 29 offer a way to ascertain de novo mutations (DNMs) across multiple generations. Using exome sequences 30 from 3,222 British-Pakistani individuals with high parental relatedness, we estimate a mutation rate of 31  $1.45 \pm 0.05 \times 10^{-8}$  per base pair per generation in autosomal coding sequence, with a corresponding non-32 crossover gene conversion rate of  $8.75 \pm 0.05 \times 10^{-6}$  per base pair per generation. This is at the lower end 33 of exome mutation rates previously estimated in parent-offspring trios, suggesting that post-zygotic 34 mutations contribute little to the human germline mutation rate. We found frequent recurrence of 35 mutations at polymorphic CpG sites, and an increase in C to T mutations in a 5' CCG  $3' \rightarrow 5'$  CTG 3' 36 context in the Pakistani population compared to Europeans, suggesting that mutational processes have 37 evolved rapidly between human populations.

- 38
- 39 Main
- 40

41 In recent years, several approaches have been taken to estimating the human mutation rate, yielding 42 results that differ substantially. These approaches can be grouped into three main categories: direct 43 observation of mutations in present day parent-offspring comparisons (the direct rate), calibrating genetic 44 divergence against fossil evidence for a past separation time (the phylogenetic rate)<sup>1</sup>, or, more recently, 45 population-genetic approaches that effectively estimate the ratio of the mutation rate to the recombination 46 rate<sup>2,3</sup>. For a genome-wide average mutation rate, the direct approaches have consistently estimated a rate 47 of 1-1.25  $\times$  10<sup>-8</sup> per base pair (bp) per generation, significantly lower than phylogenetic estimates, which 48 suggest around  $\sim 2 \times 10^{-8}$  per bp per generation<sup>1</sup> or estimates from population-genetic methods which suggest 1.6-1-7  $\times$  10<sup>-8</sup> per bp per generation. Measurements of the mutation rate in coding sequence, 49 50 obtained via the direct method applied to exome sequences of trios, are widely scattered but typically

51 higher than the genome-wide rate at around  $1.25 \cdot 2.1 \times 10^{-8}$  per base pair (bp) per generation<sup>4</sup>; the increase 52 over genome-wide rates is usually attributed to differences in base composition giving higher frequencies 53 of CpG dinucleotides, which are more mutable.

54

Many explanations have been suggested for why these estimates differ from each other<sup>4,5</sup>. Possible 55 56 shortcomings include: (a) small sample sizes, both in terms of the number of individuals the estimate is 57 obtained from as well as the number of true DNMs detected; (b) inaccurate characterization of the false 58 negative or false positive rates, perhaps because of comparisons of sequencing data with different 59 properties from different individuals; (c) consideration only of mutations occurring in a single generation, 60 leading to incomplete ascertainment of post-zygotic mutations in parents or offspring<sup>6</sup>; (d) incomplete 61 allowance for the correlation with paternal age; (e) the inclusion of diseased individuals who might have a 62 higher rate of DNMs; or (f) failure to account for gene conversion events.

63

64 In order to address these shortcomings, and to obtain an estimate which, like population-genetic 65 approaches, averages over multiple generations and many mutational events, we adopted an approach 66 based on observing heterozygous genotypes within sequence intervals inherited identical-by-descent 67 (IBD) from a recent common ancestor (autozygous segments). Here we use exome sequences from 68 healthy individuals with closely related parents, typically with  $\sim 5\%$  percent of their genome autozygous 69 in long (>10Mb) segments. Heterozygote sites within autozygous segments can arise from DNMs in the 70 generations since the common ancestor, or from gene conversions in the same period that led to transfer 71 of existing variants onto one or other IBD lineage, or from sequencing errors. We estimate the 72 contribution of all three of these sources. Essentially the same approach was used previously on a small 73 scale in a study of five individuals from the Hutterite cohort, and gave a genome-wide mutation rate 74 estimate of  $1.1 \times 10^{-8}$  per bp per generation<sup>7</sup>. The Palamara et al. population genetic method<sup>3</sup> takes a 75 similar approach, but makes a statistical estimate of the number of generations back to the most recent 76 common ancestor in haplotype matches across individuals.

77

We analyzed exome sequences obtained from DNA from whole blood and sequenced to mean depth 28x from 3,222 individuals of British Pakistani ethnicity<sup>8</sup>. The mean maternal and paternal age of the sampled individuals was 27.6 and 30.3 years respectively. These individuals are from communities with frequent first, second and third cousin marriages, in a clan or 'Biraderi' structure<sup>9</sup>. This level of relatedness allows us to examine DNMs accumulated across 6-10 meioses (**Figure 1**). We restricted our analysis to autosomal single nucleotide substitutions with the same genotype call from both samtools<sup>10</sup> and GATK<sup>11</sup> when calling across all samples.

85

86 To calculate the mutation rate, we first obtained L, the total length of the genome in which we counted 87 heterozygous mutations. Previous work on this dataset<sup>8</sup> showed that the locations of autozygous segments 88 across individuals are randomly distributed with a mean of 210 individuals autozygous at each site. To 89 enrich for segments that truly result from identity by descent we only consider segments that are at least 90 10Mb long, as these arise in fewer than 8% of chromosome pairs that are separated by more than 10 91 meioses (Supplementary Figure 1). To avoid calling mutations in segments adjacent to an autozygous 92 stretch with a higher time to most recent common ancestor (tMRCA), we ignored the last 2Mb at each 93 end of the segment, having shown that truncating by more than this did not affect our estimate 94 (Supplementary Figure 2). We then took the intersection of the final set of autozygous core segments 95 with the Illumina V5 exome bait regions and the 1000 Genomes Project accessibility mask<sup>12</sup> to yield a 96 total evaluated length of  $9.46 \times 10^9$  bp of DNA within the protein-coding regions of the genome.

97

98 Next, we estimated N, the number of heterozygous genotype calls within the autozygous sections, 99 accounting for the false positive (FP) and false negative (FN) rates of the sequencing data. To estimate the 100 FN rate, we simulated mutations by selecting a set of random sites and switching the base in reads 101 mapping there to an alternate base with probability 0.5. Then we remapped the modified reads, and 102 measured the fraction of such simulated mutations that we could recall using our standard calling 103 pipeline. To estimate the FP rate, we resequenced 176 individuals from whole blood taken at least 9 104 months apart using the same library preparation, sequencing protocol and calling pipeline. We then 105 modeled the replication rate of heterozygous mutations found in one sample and its duplicate, using a 106 probabilistic framework that jointly accounts for both the false positive and negative rates, as well as the 107 allele frequency information of the site (Methods). For singletons (mutations seen just once in our 108 samples) these approaches yielded a set of  $N_0 = 1152$  heterozygous mutations with a FN rate of 17% and 109 a FP rate of 1%. For mutations seen at allele frequencies above 10% (644 or more copies in 3,222 110 samples) the estimated FN rate is lower, at 7.9%, since we used a multi-sample variant calling method 111 (Supplementary Methods, Supplementary Table 3).

112

113 Then, we determined M, the number of meioses leading to the most recent common ancestor, for each 114 autozygous segment. We did this per individual, based on the autozygous segment length distribution in 115 that individual. We used a supervised learning approach that assigns the observed segment length 116 distribution to an expected number of separating meioses, based on simulating recombinations in 117 pedigrees with different degrees of relationship, according to the fine-scale recombination map<sup>13</sup>. This 118 yielded a weighted mean number of meioses across our entire data set of 6.63 (Methods). The inferred 119 number of meioses per individual was in good agreement with the degree of relatedness from self-stated 120 records for the approximately one third of our samples where this information was available 121 (Supplementary Table 1).

122

Finally, we obtained mutation rate estimates in two different ways. First, we used the count of singleton 123 124 heterozygotes N<sub>0</sub> to obtain the value  $1.51 \times 10^{-8} \pm 0.05$  /bp/gen (= N<sub>0</sub>/LM). Then we calculated a second 125 value which was corrected for gene conversion by examining segregating variation in our dataset. Here, 126 we adopted an approach called minor allele frequency (MAF)-threshold regression<sup>3</sup>, wherein we start 127 from counts of  $N_{f}$ , the number of candidate heterozygous mutations in our truncated autozygous regions 128 that have MAF less than f in the whole cohort. For f > 0, N<sub>f</sub> will include alleles introduced by gene 129 conversion, which occur at a rate proportional to the allele frequency. Therefore, we can use linear 130 regression to obtain both the gene conversion rate (as the slope) and the mutation rate (as the intercept 131 with the f = 0 axis). This approach yielded a single-nucleotide mutation rate of  $1.41 \pm 0.04 \times 10^{-8}$  /bp/gen 132 and a non-crossover gene conversion rate of  $8.75 \pm 0.05 \times 10^{-6}$  /bp/gen (Figure 2). This gene conversion rate estimate is a little higher than the previously reported rate of  $6 \times 10^{-6}$ /bp/gen, which was obtained for 133 whole genomes using phased trio data<sup>14</sup>. Our higher estimate for exome data may reflect higher 134 135 recombination rates in coding sequence.

136

The discrepancy between our two estimates for the mutation rate (1.51 and  $1.41 \times 10^{-8}$  /bp/gen) is not 137 138 statistically significant, but it is possible that our singleton estimate may be biased slightly upwards by 139 including some gene conversions from rare alleles, whereas the regression estimate may be biased slightly 140 downwards by removing some recurrent mutations. Thus we suggest a summary estimate of  $1.45 \times 10^{-8}$ 141 /bp/gen. Overall, our estimates lie at the lower end of the published range for mutation rates in exome 142 sequence, and below recent population genetic estimates for the whole genome. A concern for previous 143 direct estimates based on a single generation is that postzygotic mutations prior to separation of the germ 144 line that lead to mosaicism could cause undercounting. However, our method covers the whole germ line 145 life cycle in most of the generations, strongly mitigating such an effect if it exists. The fact that our 146 estimates are not greater than previous exome estimates from trio studies suggests that the contribution of 147 post-zygotic, pre-germline mosaic-inducing mutations to the germline mutation rate is marginal<sup>6,15</sup>.

148

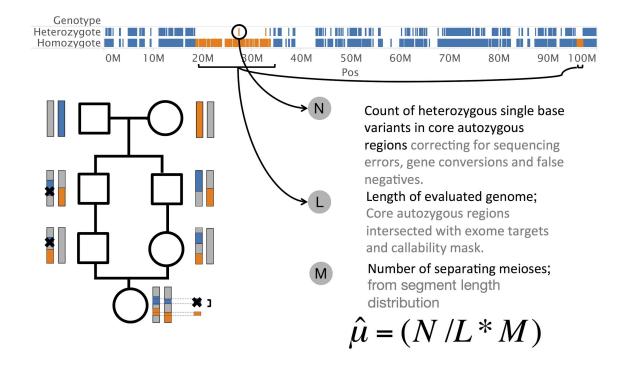

149 Comparing our DNMs to segregating variation seen in over 60,000 individuals from the Exome 150 Aggregation Consortium (ExAC)<sup>16</sup>, we found evidence for large-scale recurrence. Overall, 357/1152

(30.9%) of all our singleton DNMs were seen in ExAC, with a large proportion of these at CpG sites, the
 most mutable dinucleotide sites in the genome, for which ExAC is close to saturated<sup>17</sup> (Figure 3a).

153

154 Our ascertainment of DNMs is amongst the first in non-Europeans. Previous results that examined 155 mutations private to each population from Phase 1 of the 1000 Genomes Project showed elevated rates of 156 mutation in the tri-nucleotide context 5' TCC  $3' \rightarrow 5'$  TTC 3' in Europeans compared to Africans<sup>18</sup>. We 157 therefore examined whether or not we could detect differences in mutational spectra between DNMs of 158 South Asian and European ancestry (see Supplementary Table 5). Here, we compared the mutational 159 spectra observed in our dataset with those from a meta-analysis of 6,902 DNMs from whole-genome 160 sequencing data of pedigrees of European ancestry<sup>6</sup>. After normalizing for the difference in sequence 161 context between the exomes and whole genomes, we found a difference in the proportion of a 5' CCG 162  $3' \rightarrow 5'$  CTG 3' mutational signature that was nominally significant in our South Asian ancestry study 163 compared to those from the European studies (ratio 1.35, p = 0.0044) (Figure 3b). This replicated in a 164 comparison of 849 genome-wide DNMs from a set of 15 trios from the PJL population from the 1000 165 Genomes Project to the meta-analysis DNMs (ratio 1.42, p = 0.019). Both sets of Pakistani ancestry 166 DNMs were similarly significant when compared to a different control set of variants private to 167 Europeans in the 1000 Genomes Project data (Figure 3b), with a combined p-value for independent comparisons of  $7.3 \times 10^{-5}$ , which is experiment-wide significant across the 96 triplet mutation contexts. As 168 169 a second line of validation, we compared mutations private to the PJL population from the 1000 Genomes 170 Project with the set of variants private to Europeans which was again significant with p-value of  $5.4 \times 10^{-37}$ 171 (Figure 3b). No other context showed such a consistent difference in effect or an experiment-wide 172 significant combined p-value, nor were there any experiment-wide significant differences for control 173 comparisons using a set of 747 DNMs from the Scottish Family Health Study (SFHS)<sup>6</sup> (Supplementary 174 Figure 3). The discovery of a second human sequence context with apparent differential mutation rates between continental populations supports and extends the observations by Harris<sup>18</sup> that mutational 175 176 processes in at least some human populations have changed in the last 50,000 years, and is the first such 177 effect to be seen in de novo mutations.

178

181

#### 182 Figure 1: Study Design

Strategy to estimate the mutation rate. Bottom left: regions of the genome in an individual with first cousin parents are autozygous due to being inherited by two routes from a common founding chromosome. The X marks represent a DNMs transmitted along the pedigree to the sequenced individual. Top: most sites in autozygous regions are homozygous, except for recent mutations, gene conversions and sequencing errors. Bottom right: the estimate  $\hat{\mu}$  depends on three factors: N, L and M, as described in the text.

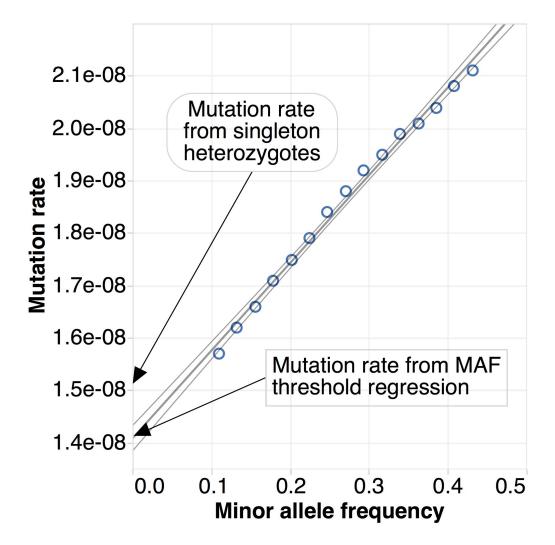

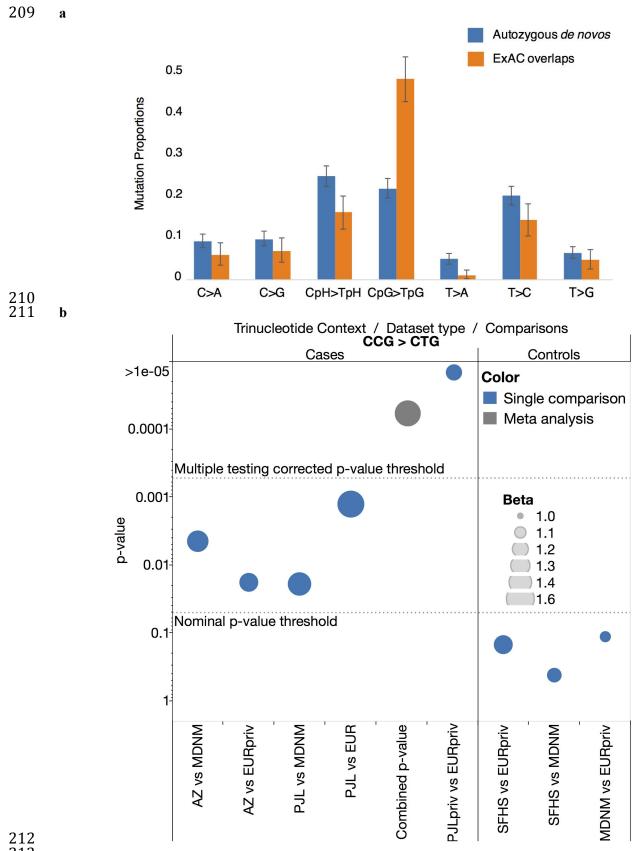

Figure 2: MAF-threshold regression to simultaneously obtain mutation rate and gene conversion
 rate

194 The mutation rate  $\mu$ , is calculated by obtaining values of N<sub>f</sub> at different thresholds of minor allele 195 frequency. The intercept on the y axis of the regression provides an estimate of the mutation rate that is

195 inequency. The intercept on the y axis of the regression provides an estimate of the initiation rate that is 196 corrected for gene conversion and the slope is used to calculate the estimate of the gene conversion rate.

#### Figure 3 Signatures of *DNMs* and overlap of mutations with ExAC

215 **a** The distribution of de novo mutational signatures across all 1152 singleton candidate de novos and 350 216 that overlap with ExAC. b Differences in context-specific mutation rate. y-axis: significance of the 217 difference in proportion of 5' CCG  $\rightarrow$  CTG 3' DNMs in 1152 mutations from the autozygosity dataset 218 (AZ) and 849 DNMs from the 1000 Genomes Complete Genomics trio dataset (PJL) in comparison with 219 6948 mutations from the meta-analysis dataset (MDNM) and variants private to Europeans in the 1000 220 Genomes Project (EURpriv). The combined p-value shows the result of meta-analysis of the AZ/MDNM 221 and PJL/EURpriv comparisons. A comparison between private mutations in PJL in the 1000 Genomes 222 Project population data set (PJLpriv) and EURpriv is also shown. Significance of the difference in 747 223 DNMs from the Scottish Family Health Study (SFHS) is shown as a control; The size of the disk 224 indicates the fold difference of the test as in the legend.

225

#### 226 Contributions

The study was conceived by V.N., and the results were interpreted by V.N., R.R., A.S., Y.X., C.T.-S. and R.D.; A.A. and A.W. performed PJL trios de novo SNV discovery and validation; V.N. and R.R. performed the statistical and bioinformatic analyses. The manuscript was drafted by V.N.. Data analyzed in the study were provided by D.M., J.W., E.M., R.T. and D.v H.. All authors contributed to the final version of the manuscript.

#### 232 Acknowledgements

233 The study was funded by the Wellcome Trust (WT102627 & WT098051). This paper presents 234 independent research funded by the National Institute for Health Research (NIHR) under its Collaboration 235 for Applied Health Research and Care (CLAHRC) for Yorkshire and Humber. Core support for Born in 236 Bradford is also provided by the Wellcome Trust (WT101597). Born in Bradford is only possible because 237 of the enthusiasm and commitment of the Children and Parents in BiB. We are grateful to all the 238 participants, health professionals and researchers who have made Born in Bradford happen. We would 239 like to thank the Exome Aggregation Consortium and the groups that provided exome variant data for 240 comparison. A full list of contributing groups can be found at http://exac.broadinstitute.org/about. We 241 would also like to thank Adam Auton for providing us with a set of DNMs obtained from the PJL 242 Complete Genomics Trios.

Finally, 251 we thank Anna Rutterford for useful discussions relating to the study design.

- 252
- 253

#### 254 255 **Methods**

## 256

#### 257 Cohort selection and variant calling

258 We analyzed exome sequence data from a recent study of 3222 individuals of British Pakistani origin 259 from Birmingham and Bradford. Full details of the sampling, sequencing and variant calling are available 260 from the paper describing the dataset<sup>8</sup>, but we provide a brief overview here. These individuals were participants in either the UK Asian Diabetics Study<sup>19</sup> or the Born in Bradford study<sup>20</sup>. Individuals with 261 262 severe long term disease as reflected by their electronic health records and prescription rates were 263 excluded. Exomes were sequenced in 75bp paired end reads on the Illumina HiSeq platform from DNA 264 from whole blood. Because that study was focused on identifying homozygous rare variants, the 265 sequencing was at lower average coverage than standard for exome sequencing, with a mean coverage of 266 28x. In addition, 176 samples with biological replicates collected at least 9 months apart were 267 resequenced for quality control purposes using the same protocols.

268

Variant calling was performed by taking the intersection of two variant call -sets, one with Genome Analysis Toolkit (GATK) HaplotypeCaller<sup>11</sup> and one with samtools/bcftools<sup>10</sup>. Calling was restricted to the Agilent V5 exome bait regions +/-- a 100bp window on either end. The concordance between the two call -sets for SNPs was 95%. Discordant genotypes were set to missing and variant sites with >1% missing genotypes were excluded. These calls were then run through a GATK VQSR training scheme at 99% True Positive Rate threshold using a set of SNPs from phase 3 release of the 1000 Genomes cohort.

275

#### 276 Paternal age effect on mutation rate

There is a known strong paternal age effect on mutation rate<sup>17</sup>. Our approach averages over several 277 278 generations, and we were not able to obtain parental ages all the way back to the shared ancestor or the 279 ratio of transmissions through the maternal and paternal germlines. We obtained the average parental age 280 at birth in this population by analyzing age information collected from the sampled individuals while they 281 were admitted at a maternity ward during pregnancy. The mean maternal age in the present generation 282 from this cohort was 27.6 years and the mean paternal age was 30.3, which are slightly lower than the 283 average parental age in the UK overall, with mean paternal age of 32, and maternal age of 29. Notably, 284 our mean parental and maternal age estimates were within the range of the first direct estimate of the 285 long-term generational interval estimated to be between 26-30 years<sup>21</sup>.

286

#### 287 Estimating the false positive and false negative rate in our exome sequencing data

288 To obtain estimates of our false positive sequencing error rate, we used 176 pairs of known duplicate

- samples that were sequenced and called with the same procedure and protocols and examined the
- 290 probability of replication of heterozygous calls, P(het in dup 2 | het in dup 1,  $\alpha$ , $\beta$ , f) in these individuals
- 291 on the false positive rate  $\alpha$ , the false negative rate,  $\beta$  and the allele frequency of the variant, f.
- The replication rate, of seeing a heterozygote in duplicate 2, given that it is seen in duplicate 1 is:

$$P(het in dup \ 2 \mid het in dup \ 1, \ \alpha, \beta, f) = \frac{P(het in dup \ 2, het in dup \ 1 \mid \alpha, \beta, f)}{P(het in dup \ 1 \mid \alpha, \beta, f)}$$

By law of total probability, we can write this by conditioning on various scenarios of error and realgenotypes.

=  $\frac{P(het in dup 1, het in dup 2 | reality is hom alt, a, \beta, f)P(reality is hom alt) + P(het in dup 1, het in dup 2 | reality is het, a, \beta, f)P(reality is het) + P(het in dup 1, het in dup 2 | reality is ner, a, \beta, f)P(reality is het) + P(het in dup 1 | reality is ref, a, \beta, f)P(reality is hom ref)}{P(het in dup 1 | reality is hom alt, a, \beta, f)P(reality is hom alt) + P(het in dup 1 | reality is het, a, \beta, f)P(reality is het) + P(het in dup 1 | reality is ref, a, \beta, f)P(reality is hom ref)}$ 

$$= \frac{2f^2(1-\beta)^2 + 2f(1-f)(1-\alpha)^2(1-\beta)^2 + 2f(1-f)\alpha^2\beta^2 + 4f(1-f)(1-\alpha)(1-\beta)(\alpha\beta)}{2f^2(1-\beta) + 2f(1-f)(1-\alpha)(1-\beta) + 2f(1-f)(\alpha\beta) + 2(1-f)^2\alpha}$$

We then observed the replication rate empirically for each allele frequency from 0 to 1 in linear intervals of 0.01 to obtain an overconstrained system of 100 non-linear equations in  $\alpha$  and  $\beta$ . To get an estimate averaged across all allele frequencies, we obtained solutions subject to the constraint that  $0 < \alpha, \beta < 1$  and implemented this using the BBsolve package in R. Using this approach, we estimated a value for  $\alpha$ , 1%; and  $\beta$ , 9%.

302

303 In addition, we used a novel approach of introducing new sequence variation on reads to obtain an 304 independent estimate of the false negative rate in our data. To do this we picked 10,000 sites at random 305 for which the reference allele was well defined (not reference N), and which were inside both the Illumina 306 V5 exome baits and the 1000 Genomes Project callability mask, ensuring that selected sites were at least 307 100 bp away from each other (slightly longer than our read length). Then at each of these positions we 308 decided on an alternate base to be synthetically introduced with  $\frac{2}{3}$  being transitions and  $\frac{1}{3}$  being 309 transversions. Then, using a Bernoulli process (p=0.5) for each read covering that site we switched the 310 base of the selected position to the predetermined alternate base. The qualities, read lengths and insert 311 sizes of these reads were maintained. We next removed the changed reads from the BAM and remapped 312 them to the genome using the same command of BWA used to map the original data. We then proceeded 313 to call variants at the given sites using the same calling procedure used to call the original dataset (see 314 above). Our estimate of false negative rate is simply the number of introduced mutations that we failed 315 recall using the above process.

316

317 As we performed joint calling across all 3,222 exomes, variants seen in a single individual (i.e. 318 singletons) were less likely to be called in comparison to shared variants with higher allele frequency. To 319 adjust for this effect we carried out the procedure of synthetically generating reads in multiple samples at 320 various allele frequencies. In this setting, the false negative rate was investigated two fold. First, we 321 calculated a rate for which we were unable to call the synthetically generated variable site in any sample. 322 Second, we calculated a rate for which we were unable to call genotypes on an additional sample, given 323 that the site was already known to be polymorphic. We report each of these categories of false negative 324 rates, along with their allele frequency (Supplementary Table 3). We find that there are significant 325 differences in the False Negative rate between singleton mutations and those at higher allele frequencies. 326 However, we find that there is little difference in our ability to call SNPs at frequencies above 10%, and 327 use an average value of 7.9% false negative rate in this region.

328

## 329 The length of evaluated genome in autozygous sections

Using allele frequency information obtained from all 3,222 individuals and the fine-scaled recombination map, we used BCFtools RoH<sup>22</sup> to obtain autozygous tract lengths as first reported in reference 8. These segments were found to be randomly distributed across the genome with any site autozygous in an average of 210 individuals.

334

335 To allow us to reliably infer the number of meioses giving rise to tract lengths, we chose to restrict 336 ourselves to analyzing regions that could only arise from a very small number of recent generations, up to 337 and including those from third cousins. To examine this, we used the R-package IBDsim<sup>23</sup> (see section on 338 the predicted number of meioses from observed autozygous tract lengths) to simulate IBD sections in 339 individuals separated by varying numbers of meioses. We then observed the longest autozygous block in 340 each pedigree simulated 10000 times, and found that fewer than 8% of pedigrees that are separated by 341 more than 10 meioses have their longest autozygous segments longer than 10Mb (Supplementary Figure 342 1).

#### 343

We then examined two further sources of bias that might affect the determination of the autozygous

345 stretches. First, we might be overcalling regions because our Hidden Markov Model might be making an 346 error by terminating a certain length after the end of a real stretch. This could introduce false

346 error by terminating a certain length after the end of a real stretch. This could introduce false 347 heterozygous mutations and increase the estimated mutation rate. Secondly, segments that are

heterozygous mutations and increase the estimated mutation rate. Secondly, segments that are identical bydescent but separated by a larger number of meioses might lie directly adjacent to a long segment. These

349 are more likely to have a higher number of heterozygous mutations on them per unit length as mutations

would have accumulated over more generations. To reduce the impact of both of these scenarios, we used

an approach of truncating our regions by varying distances from each end and recalculating the mutation

352 rate using only heterozygotes within the truncated sections. When we do this there is no discernable

353 change to the mutation rate estimate beyond a truncation of 2Mb (**Supplementary Figure 2**). To ensure

that the positions within these regions were themselves callable, we further restricted our evaluation to

those that intersected the 1000 Genomes Callability mask, obtained from

356ftp://ftp.1000genomes.ebi.ac.uk/vol1/ftp/pilot\_data/release/2010\_03/pilot1/supporting/README\_callabil357ity\_masks. This resulted in a total length of callable genome of  $9.46 \times 10^9$  bp of DNA.

358

#### 359 The predicted number of meioses from observed autozygous tract lengths

360 We infer the number of meisoses separating the two chromosome pairs of the sequenced individual 361 from the distribution of autozygous segment lengths. We began by simulating individuals who descend 362 from pedigrees with varying parental relatedness from first cousin (6 meioses of separation between 363 chromosome pairs identical by descent) up to and including fourth cousin relationships (6 meioses of 364 separation between chromosome pairs identical by descent). As we are only interested in examining 365 sections that are larger than 10Mb long, we only examined We simulate these recombinations in pedigrees using the R-package IBDsim<sup>13</sup>, which uses the sex-specific fine-scale recombination maps, with 366 random sex assignment through the pedigree. For each degree of parental relatedness, we simulated 367 368 10000 pedigrees to obtain an empirical distribution of segment lengths and restricted our analysis to 369 segments that are at least 10Mb long. From these segment lengths obtained for each pedigree, we 370 calculated three summary statistics that we used for inference; the length of the longest segment obtained, 371 the average length of the segments and the total number of segments seen. Using these three features from 372 the simulated data, we trained a supervised classification scheme to infer the number of separating 373 meioses from a given segment length distribution. This was implemented using the supclust package in R 374 that performs neighborhood component analysis for cluster assignment. As a validation of this approach, 375 we compared our inferred parental relationships with those from self-stated relatedness and we report the 376 most likely assignment for each individual along with information if available on their known self-stated 377 relationship (Supplementary Table 1). As a second line of evidence we obtained information on the 378 segment length distribution obtained from well characterized pedigrees where kinship was studied genetically from consanguineous families involved in rare disease studies<sup>24</sup>. In this evaluation, our 379 380 approach inferred the pedigree relationships almost perfectly (Supplementary Table 2). Using the 381 probabilistic assignment from our machine learning model of the number of meioses separating the 382 chromosomes in individuals from our dataset, and weighting this by the length of the genome that is 383 autozygous in a particular individual, we calculated a weighted mean number of separating meioses 384 across all the individuals of 6.63, i.e. between first and second cousin parental relatedness.

385

## 386 Estimating the gene conversion rate using MAF-threshold regression

Non-crossover gene conversion events require a copy of the alternate allele to be present on the chromosome from which the variant is copied, so can be modelled as occurring at a rate proportional to the allele frequency of the variant in the population. In order to obtain an estimate of the gene conversion rate, we utilized an approach known as maf-threshold regression<sup>3</sup>. To do this we compute the mutation rate using a range of maximum allele frequency thresholds, and perform a linear regression of the resulting mutation rate on the allele frequency threshold. The intercept of this regression on the y-axis 393 (allele frequency 0) provides an estimate of the mutation rate that is corrected for gene conversion while 394 the slope corresponds to the gene conversion rate. We compute this regression line for allele frequencies 395 between 10 and 50%. To obtain the mutation rate in this allele frequency range, we use the average false 396 negative rate across these frequencies of 7.9% that we obtained above. We also need to consider the 397 population heterozygosity which determines the chance that a particular variant is present on a 398 chromosome. The population heterozygosity in this dataset is  $9.56 \times 10^{-4}$  which is in line with other 399 exome estimates from the 1000 Genomes Project. We computed standard errors for both the intercept and 400 the slope by using a bootstap procedure that we implemented using the boot package in R.

401

#### 402 Partitioning of DNMs into mutational spectra and comparisons across datasets

403 We subclassified the six distinguishable point mutations and their reverse complements (C:G $\rightarrow$ T:A, 404 T:A $\rightarrow$ C:G, C:G $\rightarrow$ A:T, C:G $\rightarrow$ G:C, T:A $\rightarrow$ A:T and T:A $\rightarrow$ G:T) by calculating the relative frequency of mutations at the 96 triplets defined by the mutated base and its flanking base on either side<sup>25</sup>. For each of 405 the trinucleotide classes, we compare the mutational signatures across sets of DNMs using a 2x2 table and 406 407 test whether the proportion of mutations of one class is significantly different in one population versus 408 another. To be as conservative as possible we use Yates continuity correction and correct for multiple 409 hypothesis due to the 96 tests we perform for each signature using the Bonferroni method. We show in 410 Supplementary Table 2 the 2×2 table for one comparison of the 5' CCG 3'  $\rightarrow$  5' CTG 3' class of 411 mutation that is discussed in the main text, and full data for all context classes and comparison datasets 412 are available in **Supplementary Data Set 1** and the significance of the tests in **Supplementary Figure 3**.

413

#### 414 Comparison of DNMs in the 1000 Genomes Project Samples

415 We defined derived SNPs that were private to each continent in the same manner as Harris 2015. 416 Specifically for the African continent, we chose to differ slightly from the definitions used to define the 417 1000 Genomes Project phase 3 AFR category. We excluded populations from the Americas (those which 418 fall under continental ancestry denoted as AMR) which are known to have recent admixture from both 419 Africa and Europe, and so dropped ASW (African Americans from the Southwest US) and ACB (African 420 Caribbeans from Barbados) from our African category. Therefore we consider SNPs private to Africa if 421 they are variable in at least one of the populations LWK (Luhya from Kenya), YRI (Yoruba from 422 Nigeria), ESN (Esan from Nigeria), GWD (Gambian from western divisions of Gambia) and MSL 423 (Mende in Sierra Leone) and and not variable in the South Asian, European and East Asian categories, as 424 defined by the 1000 Genomes Project. Then we obtained SNPs that were private to each continental 425 group with allele frequency at least two, to avoid any increased noise in singletons (as Harris 2015), and examined differences in their trinucleotide contexts as above for our set of DNMs. 426

427

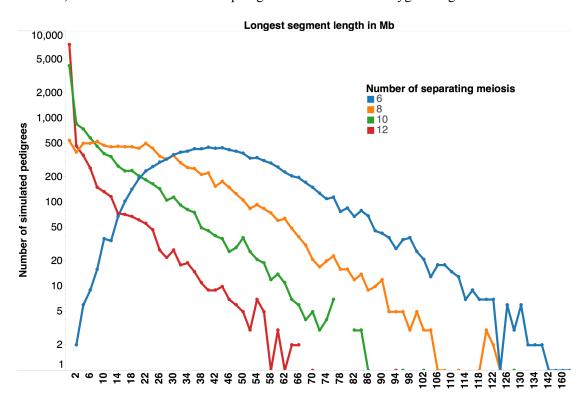

#### 428 1000 Genomes Punjabi trios de novo mutations discovery and validation

429 Blood-derived DNA samples of 15 Punjabi trios from the Lahore, Pakistan (PJL) population of the 1000 430 Genomes project were whole genome sequenced by Complete Genomics (CG), resulting in 12,496 431 candidate DNMs per trio on average. In our initial filtering we removed calls seen in any other individual, 432 or in the CG founder, and sites that were polymorphic in 1000 Genome Project Phase 1. This resulted in 433 3,609 candidate DNMs per trio. There were two criteria by which a putative DNMs were selected for 434 validation: either they were genotyped as a de novo call using Samtools, or the de novo call had a quality 435 score > 50 (i.e. ALT EAF, as defined by Complete Genomics). This resulted in 759 candidate DNMs per 436 trio for validation. Candidate sites were validated by designing Agilent SureSelect probes for the 437 candidate sites, followed by enrichment and sequencing on Illumina Hi-Seq. Overall, 849 sites were 438 validated as DNMs (56.6 per trio on average).

## 439 Supplementary Information

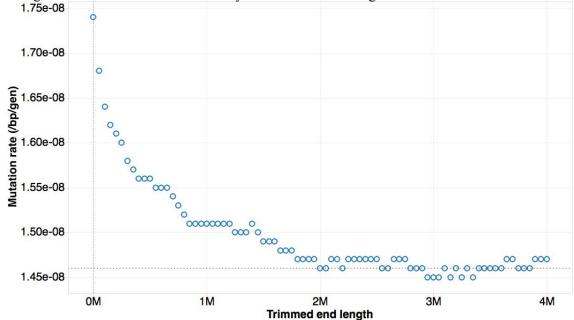

440

441 Supplementary Figure 1. Simulated data of showing histograms of the number of pedigrees for which 442 the longest autozygous segment found is of a certain length. Beyond a separation of 10 meioses to the 443 tMRCA, there are fewer than 8% of pedigrees that have an autozygous segment of at least 10Mb.

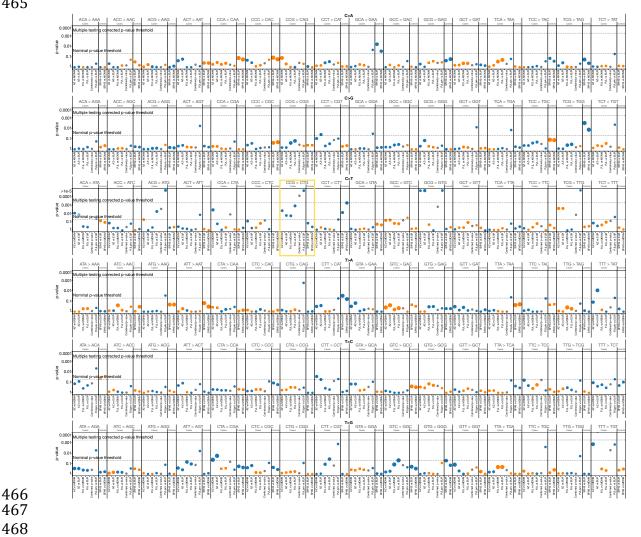

- 451
- 452

453 Supplementary Figure 3. Comparisons of the proportion of each of the 96 tri-nucleotide signatures 454 across datasets. Differences in context-specific mutation rate. y-axis: significance of the difference in 455 proportion of DNMs for each signature between 1152 mutations from the autozygosity dataset (AZ) and 456 849 DNMs from the Complete Genomics trio dataset (PJL) in comparison with 6948 mutations from the 457 meta-analysis dataset (MDNM) and mutations private to Europeans in the 1000 Genomes Project 458 (EURpriv). Additional comparisons for mutations private to the PJL population from the 1000 Genomes 459 Project (PJLpriv) and private to Europeans (EURpriv) shown in rightmost panel. As controls significance 460 of the difference in 747 DNMs from the Scottish Family Health Study (SFHS); Colors (Orange, first 461 population has a lower proportion, Blue, otherwise) and size reflect the sign and fold difference of the 462 test. Comparisons for which de novo mutations have 0 counts shown in squares. The only tri-nucleotide 463 context, 5' CCG  $\rightarrow$  CTG 3' that shows experiment wide significance, and consistent direction of effect 464 shown in yellow box.

465

## 

470 Supplementary Table 1. Most probable number of separating meioses giving rise to autozygous segment

- 471 lengths as compared with those from self-stated parental relatedness.

		Self stated parental relatedness					
		First cousin	First cousin once removed	Second cousin	Other blood	Other marriage	Do not know
Inferred Meiosis	6 (First cousin)	835	7	33	29	2	528
	8 (Second cousin)	423	1	47	63	15	621
	10 (Third cousin)	78	1	13	17	11	356
	→10 (Not considered	19	0	6	14	0	103

#### 

474 Supplementary Table 2. Most probable number of separating meioses giving rise to autozygous segment
 475 lengths as compared with those from well studied pedigrees.

		Pedigree ascertained relatedness				
		Double First cousin	First cousin	First cousin once removed	Second cousin	Third cousin
Inferred Meiosis	6 (First cousin)	2	46	2	0	0
	8 (Second cousin)	0	2	0	5	0
	10 (Third cousin)	0	0	0	0	1

Supplementary Table 3. Estimates of the false negative rates on the allele frequency based on our approach of altering reads to contain a new mutation then remapping them and recalling. Two components to the false negative rate are measured: first the percentage of introduced sites that failed to be called, and second the fraction of introduced heterozygous genotypes that failed to be called at a site that was already known to be polymorphic based on other individuals. The total false negative rate is reflected by aggregating both of these types of error.

Allele Frequency	Percentage of sites identified correctly	Percentage of genotypes identified correctly	False negative rate
Singleton	83.77	NA	16.23
10%	94.55	97.22	8.23
20%	94.27	98.10	7.63
30%	93.91	98.17	7.92

**Supplementary Table 4.** 2x2 table showing the number of mutations of the particular class, 5' CCG 3' 495  $\rightarrow$  5' CTG 3' in the PJL complete genomics trios and those from a set of meta denovo mutations

496 ascertained in Europeans

Class of mutation	PJL	MDNM
5' CCG 3' → 5'CTG 3'	54	310
not 5' CCG 3' $\rightarrow$ 5' CTG 3'	795	6592

500 Supplementary Table 5. Table showing a listing of various datasets their acronyms, the total number of

501 DNMs seen and the sequencing technology used along with their ancestry

Dataset	Total Number of DNMs	Type of sequencing	Ancestry
Autozygosity, this dataset (AZ)	1152	28x WES illumina HiSeq 2500	South Asian
Scottish Family Health Study (SFHS) <sup>6</sup>	747	30x WGS illumina HiSeq 2500	European
Meta de novo mutations <sup>6</sup>	6902	Variable coverage WGS	European
PJL Complete Genomics Trios <sup>26</sup>	849	80x Complete genomics	South Asian
Mutations private to Europeans in the 1000 Genomes Project excluding singletons <sup>12</sup>	7272743	7.4x WGS illumina HiSeq 2500	European
Mutations private to PJL in the 1000 Genomes Project excluding singletons <sup>12</sup>	163855	7.4x WGS illumina HiSeq 2500	European

Supplementary Data Set 1. Positions of discovered DNMs seen in autozygous sequences, as well as
 Scottish Family Health Study, along with their partitions into the various mutational spectra and
 comparisons with continental private mutations in 1000 Genomes.
