ABSTRACT

T7 transcriptional promoters can control well the amount of RNA produced during transcription-translation with the PURE system and do so consistently across different gene sequences. However, T7 transcriptional promoters are poor in regulating the production of protein. Conversely, ribosome binding sites greatly impact the synthesis of protein, but the effect is inconsistent between different sequences, likely reflecting complications arising from the structure of the mRNA. Further, the variability in expressed protein is significantly greater than that of expressed mRNA. Nevertheless, a computational model that takes into account the variability of transcription-translation and data on the exploited biological parts can be used to select for a subset of sequences with desired activity.

Cell-free expression systems have a wide-range of applications, from experiments designed to gain insight into the workings of biology^{1,2} to the development of new technologies.³⁻⁵ Although there are several cell-free systems to choose from, none have been well characterized with respect to the influence of different biological parts on system performance. This is a problem, because complex genetic circuitry requires varying degrees of expression of each component. Perhaps the lack of cell-free standardization data reflects an initial bias towards producing maximum amounts of protein from a single gene, just as commercial vectors typically contain sequences, such as the T7 gene 10 leader sequence, to enhance the recombinant expression of protein.⁶ Additionally, when cell-free systems are used to screen genetic constructs for later insertion into bacteria, protein output is often controlled by adjusting the DNA template concentration rather than by controlling gene expression through sequence changes, e.g. by changing the transcriptional promoter or ribosome binding site.⁷ In this case, each gene product is typically encoded on a separate piece of DNA. However, the use of separate pieces of DNA is not suitable for encapsulation in vesicles for the assembly of artificial cells nor ideal for insertion in a genome of a living cell.

Currently, there are several methods that can be used to try to build genetic circuits with desired performance. One method is to create a computational model that can accurately predict gene expression. Such a model may incorporate the kinetic parameters of association, dissociation, and enzymatic activity as well as the influence of RNA folding. Although much progress has been made,⁸⁻¹¹ several of the parameters governing transcription-translation are still too poorly characterized to build a model that can predict the behavior of a genetic circuit accurately with a high success rate, although the inclusion of transcriptional insulators greatly improves predictability¹². Other kinds of computational models do not directly consider the biophysical process of gene expression, but instead rely on previously characterized genetic parts to infer the behavior of such parts in novel circuits. Instead of relying on a computational model, a library of DNA molecules each containing a different mixture of biological parts can be assembled and then screened for activity.^{13,14} One down side of this approach is that only a small subset of all the potential sequences can be practically tested in the laboratory, decreasing the likelihood of identifying a construct with the sought after behavior. Additionally, the assembly and testing of the library of sequences incurs significant cost and time. Both computational and wet lab screening methods frequently depend on the use of biological parts that were previously characterized by assessing the expression of a fluorescent protein. The assumption is that the substitution of the fluorescent protein by the gene of interest will be largely innocuous to system performance. For the time being, a more reasonable approach may be to exploit computational methods to identify a small subset of potential sequences with the desired behavior followed by screening in the laboratory.

Previously we explored the influence of genetic organization¹⁵ and T7 transcriptional promoter strength¹⁶ on cell-free expression with the PURE¹⁷ system. The data revealed that RNA but not protein concentrations were easily tuned with transcriptional promoter strength with a transcription-translation system that depended on T7 RNA polymerase. It thus seemed that the use of different ribosome binding sites would be more amenable to controlling protein synthesis, since the RBS-mRNA complex is initially mediated by known base pairing interactions that directly correlate with the strength of interaction.^{18,19} Although a few reports have exploited the RBS to modulate gene expression *in vitro*,^{20,21} a systematic

investigation with the PURE system¹⁷ is lacking. Here, we investigated the influence of different ribosome binding sites on gene expression with the PURE system. Unlike the strength of the T7 RNA polymerase, the RBS greatly impacted protein synthesis but not in a predictable manner. The activity of the RBS was strongly influenced by the sequence and thus the structure of the mRNA. To ensure that data from different sets of experiments were comparable, the variability in transcription and translation was assessed. Although the noise associated with cell-free expression in compartmentalized, low copy number systems have been well characterized^{2,22,23} the variability from reactions under bulk conditions have not been reported. We found that the variability in protein synthesis was greater than for RNA synthesis for single gene constructs. The variability increased for cascading reactions, and that a computational model that included parameters for variability helped to screen genetic constructs for a subset with desired activity.

RESULTS AND DISCUSSION

Ribosome binding sites strongly but unreliably control gene expression. 18 different ribosome binding sites were designed and tested (Table S1). The sequence of the ribosome binding site (RBS) was varied according to three variables, including the number of base pair interactions between the ribosome and the RBS, the position of the base pair interactions within the RBS, and the nucleotide composition of the non-base pairing positions within the RBS. 13 of these sequences were generated using a D-criterion optimal statistical design of experiments methodology,²⁴ so that few sequences could be used to efficiently explore the sequence space of the RBS. The remaining five sequences were taken from previously tested constructs.^{15,16}

The set of different ribosome binding sites was tested within a genetic construct encoding a red fluorescent protein (RFP) and with a purified, *E. coli*-based transcription-translation system containing T7 RNA polymerase (i.e. the PURE system).¹⁷ Contrary to what was previously observed with a series of T7 transcriptional promoters,¹⁶ the set of ribosome binding sites gave a well dispersed distribution of expressed protein concentration (Figure S1). However, a statistical model built with data from the expression of the 13 D-criterion optimal statistically designed sequences explained less than 50% of the variability of the data (adjusted R-squared=0.49, p-value=0.03). Most of the explained variability came from the correlation (equal to 0.5) between RFP expression and the number of potential base pairing interactions between the RBS and the ribosome (Figure S2a). This suggested that something other than ribosome binding was also significantly impacting expression. To determine whether the sequence of the encoded gene influenced the activity of the ribosome binding site, the same set of ribosome binding sites was tested within a construct encoding green fluorescent protein (GFP) (Figure S1). The correlation between the GFP and RFP data was 0.61 for the same set of 13 sequences (Figure 1), indicating that while a significant correlation existed, data from the expression of one protein could not be used to reliably predict the expression of the other protein. The correlation between the expression of GFP to the number of base pairing interactions with the RBS was 0.87 (with respect to the 13 D-optimal sequences) (Figure S2b), significantly higher than for the expression of RFP. Since the sequences of these two genes greatly differed (48% identity), it seemed likely that the folding of the mRNA strongly influenced protein expression, as previously noted.^{25,26} No correlation was found

between gene expression and the position of the base pairing interactions within the RBS nor the composition of the non-base pairing positions within the RBS. Taken together, RBS sequences significantly impacted protein expression, as expected, but the effects were not consistent between different genetic sequences, likely reflecting the influences of competing intramolecular base pairing interactions.

The 5'-UTR and 3'-UTR influence protein expression. To more rapidly screen genetic constructs, linear, PCR product DNA templates were used. Since the incorporation of a transcriptional terminator at the 3'-end of mRNA has been found to increase the expression of protein,^{27,28} we investigated the effect of the 3'-untranslated region (UTR) on the expression of GFP and RFP. The tested DNA templates either ended directly with a stop codon (TAA) or a sequence that encoded a 56 bp sequence of low folding stability, a 91 bp sequence of low folding stability, the bacteriophage T7 T ϕ terminator (153 bp), a Spinach aptamer sequence (171 bp), the T ϕ terminator embedded in a longer sequence (175 bp), and a sequence containing both the Spinach aptamer and the T ϕ terminator (367 bp) (Table S2). Protein expression was the lowest from constructs that lacked a 3'-UTR (Figure S3), as expected.^{27,28} Longer 3'-UTR sequences increased protein yield up to approximately 90 bp in length at which point expression was 26-fold and 12-fold greater for RFP and GFP, respectively, than constructs without a 3'-UTR. There was not a strong dependence on whether the 3'-UTR contained a transcriptional terminator, a random sequence, or an aptamer domain (10% and 17% variance for RFP and GFP, respectively). To confirm that the 3'-UTR was only important for the terminal gene of an operon, two gene operons were constructed encoding both GFP and RFP. The inclusion of the T ϕ terminator within the 3'-UTR increased protein synthesis from the second but not the first gene of the operon (Figure S4).

Next, the influence of the 5'-UTR (excluding the ribosome binding site) on gene expression was investigated. Five different 5'-UTR sequences, including four randomly generated sequences lacking strong structural elements (LS1-LS4) and one sequence (LS5) generated by the RBS calculator²⁹ were tested (Table S3). Of these five sequences, the different 5'-UTR sequences resulted in different amounts of RNA (based on the fluorescence of the Spinach aptamer) and protein (based on the fluorescence of RFP) synthesis, with three 5'-UTR sequences (LS1, LS2, and LS3) giving more similar protein output (Figure S5). The influence of each of these three 5'-UTR was also similar across different coding sequences, including those of GFP, RFP, and a blue fluorescent protein (BFP). However, the expression of RFP was lower with LS2 than the other fluorescent proteins (e.g. the final RFP concentration was 44% lower than that of GFP with LS2).

Variability in protein synthesis outweighs variability in RNA synthesis. Four T7 transcriptional promoters and four ribosome binding sites were then selected to make sixteen different combinations of genetic constructs (Table S4, Table S5). Each DNA template contained a LS1 leader sequence and a T ϕ terminator sequence. For both RFP and BFP, the relative transcriptional promoter strength gave predictable distributions of mRNA concentrations regardless of the strength of the RBS (Figure 2, Figure S6). This is consistent with our previous data on a much larger set of T7 transcriptional promoters with a consistent RBS.¹⁶ Constructs encoding GFP were not assessed because of spectral overlap between GFP and the encoded Spinach aptamer used to quantify the mRNA. The influence of the RBS on the expressed protein

concentration again showed poor correlation between constructs encoding RFP, BFP, and GFP for all four transcriptional promoters (Figure S7).

To better assess the variability of transcription-translation, the coefficient of variation was measured for both triplicates run on the same day with transcription-translation machinery from the same batch (total experiments = 3) and on three different days with three different batches of transcriptional-translation machinery (total experiments = 9). The weakest transcriptional promoters were not used for these experiments. The one batch experiments showed greater variability in expressed protein than expressed RNA for both RFP (48% greater variability) and BFP (116% greater variability) encoding constructs. The multiple batch experiments did not greatly increase the coefficient of variation of transcription, whereas the coefficient of variation of translation increased by 89% for RFP and by 101% for BFP when comparing multiple batch to single batch reactions. (Figure 2). The coefficient of variation of experiments run on the same day from a single batch of transcription-translation machinery reflected, in part, error arising from the assembly of the reaction. The data collected over multiple days were additionally influenced by batch-to-batch variability of transcription-translation solutions. The low coefficient of variation of transcription for both genetic constructs was consistent with the fact that in the PURE system only a single protein is required to synthesize mRNA and that DNA templates possess a consistent structure regardless of sequence, i.e. double stranded DNA typically assumes a b-form α -helix under physiological conditions. Conversely, the increased coefficient of variation observed for translation was consistent with the large number of RNA and protein molecules required to synthesize protein. Further, the folding of the RNA template is sequence dependent and would be expected to affect the efficiency of translation, as observed when comparing RFP and BFP synthesis. In fact, while the coefficient of variation was within 15% for the transcription of RFP and BFP, the coefficient of variation was 65% and 75% greater for the translation of BFP than RFP for one batch and multiple batch experiments, respectively. This is consistent with the lower correlations observed above for the synthesis of different proteins when compared to the synthesis of different mRNA.

The variability of transcription-translation was confirmed by assembling transcription-translation reactions in a 1536-well plate to construct a pixelated image. In this way, the clarity of the image would visually reveal the variability of RNA (based on the fluorescence of the Spinach aptamer) and protein (based on the fluorescence of RFP) synthesis. A 196 pixel version of the yin-yang symbol was designed by exploiting genetic constructs that would give rise to four different color intensities based on RNA and protein synthesis levels. Some of the wells that contained the same genetic construct also contained different batches of transcription-translation machinery. Since each color intensity was represented by at least 57 contiguous pixels, variability was easily observed visually. Consistent with the data presented above, the RNA-based image was much clearer than the protein-based image (Figure 3), confirming that RNA synthesis was less variable than protein synthesis.

A simple computational model that includes parameters for variability can reasonably predict cell-free expression. A generalization of the computational model described by Stogbauer et al.⁸ was built to serve as a predictive tool for the design of more complex genetic circuits in cell-free systems (Figure S8).

In this model, the resources needed for transcription and translation were grouped separately. However, parameters for the strength of the T7 transcriptional promoter and the RBS were also included.¹⁶ Additionally, two noise parameters were incorporated. The first noise parameter was meant to address the error that was observed from the single batch experiments by allowing the DNA template concentration to fluctuate by $\pm 5\%$. The second noise parameter approximated the error observed from the multiple batch experiments by allowing the concentrations of components of the PURE system to vary by $\pm 10\%$. Kinetic parameters were inferred from a subset of experiments with different combinations of T7 transcriptional promoters and RBS sequences (Figure S7). To address the absolute difference in RFP, GFP, and BFP expression, the parameters for the kinetics of transcription and translation ($r_{\text{rna_prod}}$ and $r_{\text{prot_prod}}$, respectively), as well as the parameter describing protein maturation ($r_{\text{prot_mat}}$) were inferred for each protein. The final inferred parameters, along with the starting concentrations of the molecular components and the parameters accounting for noise were also included (Table S6, Table S7, Table S8). The resulting model fit well the experimental data (Figure S9).

Since a wide-range of colors can be made by mixing different intensities of red, blue, and green colors together, we wondered if genetically encoded colored pictures could be produced by expressing different amounts of RFP, BFP, and GFP or if the variability in protein expression would interfere with the predictable formation of new colors. The kinetic model was used to identify genetic constructs that could be assembled into a 25 pixel RGB color triangle. Each well contained three different DNA templates at the same concentration, each encoding a different fluorescent protein. The model was used to indicate which T7 transcriptional promoter and which *E. coli* ribosome binding site could be used to produce 25 different colors. As seen in Figure 4, the assembled reactions produced a color triangle that closely matched the prediction, and the variability associated with the expression of three different proteins was low enough to allow for the development of the image. The average absolute difference between the predictions and the experimental proportions for the three fluorescent proteins was 32%, 11%, and 17% for RFP, GFP, and BFP, respectively. The greatest difference between the prediction and the measured protein expression was associated with RFP, which was overestimated by the model.

We then explored the effect of a simple genetic cascade on the variability of protein expression. This cascade consisted of the expression of T3 RNA polymerase from a T7 transcriptional promoter followed by the expression of RFP from a T3 transcriptional promoter (Figure 2e). The computational model was updated to include the new parameters (e.g. the kinetics of T3 RNA polymerase) (Table S9, Table S10, Table S11). Thirteen different constructs containing three different T7 transcriptional promoters and three different ribosome binding sites were selected. The model predicted that increased expression of RFP was mainly due to two elements, a medium to weak strength T7 transcriptional promoter and a strong RBS for RFP (Figure S10). By modifying the noise parameters according to their estimated probability distribution, the model did not predict a significant increase in the coefficient of variation for the synthesis of protein in the cascade reaction with respect to the expression of the single gene. The thirteen constructs were then tested in the laboratory in two different ways. The two genes of the cascade were either placed on separate pieces of DNA or together on the same DNA template. Most cell-free genetic circuitry reported in the literature exploit separate pieces of DNA to speed up the screening of biological parts; however, the effect of such

architecture on expression and variability are unexplored. Contrary to what the model predicted, the coefficient of variation increased by 120% and 70% for RNA and protein synthesis, respectively, for reactions run with a single batch of transcription-translation machinery and using a single DNA template when comparing the cascade reaction to the expression of a single gene (Figure 2). The analogous increase in the coefficient of variation for experiments run with multiple batches was 130% and 43% for RNA and protein synthesis, respectively. The fact that the coefficient of variation significantly increased when going from a single gene construct to a simple, two-step cascade suggests that genetic circuitry of increased complexity will concomitantly increase the variability of expression. Also, unlike the single gene data, this specific cascade showed variability in the expression of the final RNA of the cascade that was similar to that of the final protein. This is likely because the first gene of the cascade expressed the RNA polymerase needed to transcribe the second gene. In other words, the variability associated with producing the T3 RNA polymerase directly impacted the extent of transcription of the second gene. The coefficient of variation of the cascade consisting of two pieces of DNA run with multiple batches of transcription-translation machinery was large, so care should be taken in screening genetic circuits with multiple pieces of DNA *in vitro*. The increase in variability of expressed RNA and protein from the cascade was visually confirmed by the construction of a yin-yang image (Figure S12). Finally, the genetic cascade also revealed the existence of the influence of depleting resources. Transcription and translation share common reactants⁹, and so some degree of competition for resources was expected although not previously observed for non-cascading reactions.¹⁶ For example, the use of strong transcriptional promoters and ribosome binding sites resulted in relatively low amounts of RFP (Figure S13). The configuration that produced the most RFP contained a weak T7 Transcriptional promoter, a medium strength RBS for T3 RNA polymerase, and a strong RBS for RFP, which was consistent with the kinetic model for the cascade.

Since the inclusion of a transcriptional repressor can be exploited to confer sensing capability on artificial cells^{5,30} and potentially on cascading cell-free networks, we next sought to investigate the behavior of genetic constructs encoding a transcriptional repressor. This construct contained two T7 transcriptional promoters and two ribosome binding sites (Figure 2e). Each transcriptional promoter and RBS pair controlled the expression of a single gene, either RFP or the transcriptional repressor. The region upstream of the RFP encoding sequence also contained an operator sequence to bind the transcriptional repressor. A LuxR homologue, D91G EsaR³¹ (hereafter referred to as EsaR), from the organism *Pantoea stewartii* was used as the transcriptional repressor. In the absence of EsaR's cognate ligand, EsaR blocks transcription, and in the presence of the quorum signal 3-oxohexanoyl-homoserine lactone (3OC6HSL), expression is derepressed.

After screening a small set of different spacer sequences between the transcriptional promoter and the operator sequence (Table S13, Figure S14), a kinetic model for protein expression under the control of EsaR was built and estimated (Table S14, Table S15, Table S16). Eight different genetic constructs that the model predicted to show a gradient of expression between repressed and derepressed states were assembled onto a single DNA (Table S17). Of these genetic constructs, four showed at least 5-fold derepression of transcription in the presence of 3OC6HSL, and four gave at least 2-fold more cell-free expressed protein when 3OC6HSL was added to the reaction (Figure S15). The transcription and translation

data correlated well with the predictions from the computational model (0.74 and 0.87 for RNA and RFP expression, respectively) even if the model predicted higher absolute concentrations. When rescaled to the actual observed concentrations, the expression ratios matched well the experimental data (Figure S16). However, since little RNA is needed to make much protein,¹⁶ none of the constructs yielded low RFP concentration in the absence of 3OC6HSL and high RFP concentration in the presence of 3OC6HSL. Altering the DNA template concentration from 1.6 nM to 0.42 nM did not significantly impact the difference between repressed and derepressed states (Figure S17). Nevertheless, clear on-off switching activity was observed. The coefficient of variation of expressed protein was similar to the transcription-translation of single gene constructs (Figure 2). The difference was again with the RNA, which was similar to that of the protein. This similarity in variability in expressed RNA and protein was observed with both genetic cascades, the cascade in which the first gene encoded a RNA polymerase and the cascade in which the first gene encoded a transcriptional repressor. In both cases, the variability in the synthesis of the product of the first gene directly impacted the extent of transcription of the second gene.

A better understanding of the influence of RNA folding on transcription-translation may improve predictability. It has often been argued that biological parts need to be thoroughly characterized so that a set of rules and equations can be formulated that would allow for the construction of more complex systems with predictable behavior.^{32,33} However, to date this approach has not been successful *in vivo* or *in vitro*. Even in the simplified case of the cell-free transcription-translation of a single gene, the influence of the RBS is not consistent. The inconsistency in the activity of the RBS likely reflects a dependence on the entire sequence of the mRNA, that is, different sequences fold differently which affects the accessibility of the RBS and the codons of the gene. Conversely, the activity of T7 transcriptional promoters is consistent across different gene sequences. The problem is that while T7 transcriptional promoters in PURE system reactions are effective in controlling the synthesis of mRNA, protein synthesis remains largely unaffected.¹⁶ A likely explanation for this discrepancy is the decoupling of RNA and protein synthesis when using T7 RNA polymerase and *E. coli* ribosomes.^{1,16,25} Perhaps substituting T7 RNA polymerase with *E. coli* RNA polymerase, as in ePURE,³⁴ would allow for proper coupling and thus the ability to predictably control protein output through the activity of the transcriptional promoter.

The RBS is not the only complicating factor in predicting the expression of protein. Variability is always present due to the intrinsic stochastic nature of basic molecular events, such as transcription and translation. The stochasticity of compartmentalized systems has been evaluated,^{22,23,35} but the variability of bulk transcription-translation reactions have not been thoroughly investigated. Some of the noise observed in encapsulated, cell-free gene expression was thought to either arise from differences in DNA template copy number across different droplets or from the intrinsic stochasticity of transcription itself.^{22,23} In bulk, where complications arising from encapsulation do not exist, transcription was not found to exhibit much variability. However, variability in transcription significantly increased when different genes of a network were encoded within different strands of DNA. Having genes on separate DNA strands likely introduced variability in the ratio of templates in a somewhat similar way to the influence of DNA template copy number on transcription encapsulated within droplets. In bulk reactions, protein synthesis provided the largest source of variability, which likely reflected, in part, the the complexity of translation and the consequences of using a template

that can assume a variety of structures with different degrees of stability. Further, the variability associated with translation is confounded by the batch-to-batch variability of the transcription-translation machinery used to mediate gene expression.

Current computational models do not adequately take into consideration RNA folding. Thus far, models are built by incorporating a data set containing the activity of biological parts, and these resulting models can usually describe accurately the behavior of those same biological parts under previously tested conditions. But much more is needed if these models are to be of real engineering value. It is not sufficient to describe and understand a system. Instead, within a certain margin of error, the behavior of a new device, potentially under new conditions needs to be reliably predicted. Otherwise, the construction of new genetic devices remains a process of trial and error. Unfortunately, the development of a model that fits the experimentally available data does not necessarily mean that the model is capable of predicting experiments that have yet to be run, i.e. there is a difference between model estimation and prediction. For example, the model used herein can predict the expression of each protein individually but the data set for the expression of RFP cannot be used to reliably predict the expression of GFP. It seems that what is missing is a deeper understanding of the role of RNA. A step forward in this direction was the development of an equilibrium statistical thermodynamic model to predict the activity of a RBS sequence within the context of the surrounding RNA.³⁶ However, the dynamics governing the folding of mRNA and the relationship between the kinetics of mRNA folding and gene expression are still not sufficiently understood.³⁷ Therefore, as noted before,^{38,39} there is approximately a 50% chance that the predictions will fall within two-fold of experimentally determined protein levels. For now, it may be wise to simply exploit tools that incorporate the folding of the RNA, as in the RBS calculator, and the variability in gene expression to identify a restricted set of candidate sequences for screening in the laboratory.

METHODS

Genetic Constructs. Genes encoding the fluorescent proteins GFPmut3b and mRFP1 and the spinach aptamer were from previously described constructs.¹⁶ Genetic sequence of the T3 RNA polymerase (BBa_K346000) was from the registry of standard biological parts (<http://partsregistry.org>). Genes encoding the proteins Azurite (referred to as BFP) and D91G EsaR were from Addgene (plasmid #14034 and plasmid #47646, respectively). All genes were subcloned into pET21b by isothermal Gibson assembly.⁴⁰ All constructs were confirmed by sequencing by GATC Biotech.

Cell-Free Transcription–Translation: Unless otherwise indicated, 9 μ L transcription–translation reactions with the PURExpress in vitro protein synthesis kit (New England Biolabs) contained 12.6 nM of linear DNA template and 4 units of human placenta RNase inhibitor (New England BioLabs). When needed, DFHBI (Lucerna) was added to a final concentration of 60 μ M. The reaction components were assembled in an ice-cold metal plate, and the reaction initiated by incubation at 37 °C. Reactions were monitored for 6 h with a Rotor-Gene Q 6plex system (Qiagen). The blue channel was used to detect Azurite (excitation, 365 \pm 20 nm; emission, 460 \pm 20 nm), the green channel was used to detect GFPmut3b and Spinach (excitation, 470 \pm 10 nm; emission, 510 \pm 5 nm), and the orange channel was used to detect mRFP1 (excitation, 585 \pm 5 nm;

emission, 610 ± 5 nm). Each reaction was repeated at least three times. The template DNA concentration was 0.5 nM for single gene expression experiments. The cascade genetic circuit with the two genes on two separate pieces of DNA employed the following template concentrations: 12.6 nM (reporter gene encoding mRFP1 and Spinach) and 4.2 nM (gene coding for T3 RNA polymerase). The cascade genetic circuit with two genes on the same piece of DNA employed a template DNA concentration of 5 nM. Finally, the experiments performed with the repressible genetic circuit employed a template DNA concentration of 5 nM. When used, the concentration of 3-oxohexanoyl-homoserine lactone was 5 μ M.

Genetically encoded pictures: 14x14 pixel pictures were generated with four different DNA templates. Following the target picture, the number of different 9 μ L PURE system reactions required to fill the pixels was calculated. Reactions were setup with components from different batches of the PURE system. After 6 h of incubation at 37 °C, each reaction was pipetted into the wells (of a ViewPlate-1536 F from Perkin Elmer) of the plate to produce the pixelated image. After filling all of the required wells, the plate was centrifuged at 4000 rpm for 1 min at 4 °C with a Thermo Scientific Legend X1R centrifuge with a T20 microplate rotor. A Typhoon Trio from GE Healthcare was used to visualize the picture. For the RNA picture, a blue laser was used (488 nm) for excitation in combination with a 526 SP filter (short-pass filter transmitting light below 526 nm) for emission. For the protein picture, a green laser was used (532 nm) for excitation in combination with the 610 BP 30 filter (transmitting light between 595 nm and 625 nm) for emission. For both of the pictures, the gain was set to 1000 V.

For the multicolored triangle picture, a 384-well plate (Greiner Bio-one 384 Flat Bottom Black) was employed. Each well, representing a single pixel of the picture, was filled with a 9 μ L PURE system reaction. Each reaction included three different DNA templates encoding the fluorescent proteins mRFP1, GFPmut3b, and Azurite, each controlled by the appropriate combination of promoter and ribosome binding site. The reaction was incubated in a PCR tube at 37 °C for 6 h, after which each reaction was placed into the corresponding well of the 384-well plate. Next, a plate reader Tecan Infinite 200 was used to record the fluorescence of Azurite (λ_{ex} = 377 nm, λ_{em} = 472 nm), GFPmut3b (λ_{ex} = 474 nm, λ_{em} = 511 nm), and mRFP (λ_{ex} = 579 nm, λ_{em} = 613 nm). The excitation bandwidth was 9 nm. The emission bandwidth was 20 nm. The gain was set to 115. The image generated with the repressor encoding genetic cascade was additionally collected with the Spinach aptamer (λ_{ex} = 469 nm, λ_{em} = 501 nm).

Protein and RNA Standard Curves: Standard curves to translate fluorescence intensity into molar concentrations were generated by using recombinantly expressed and purified fluorescent proteins. His-tagged versions of GFPmut3b, Azurite, and mRFP1 were generated by mutating the stop codon within pET21b. The resulting constructs contained an additional 24 residues including a carboxy-terminal hexahistidine-tag. Each His-tagged construct was purified as described previously.¹⁶ Similarly, purified RNA harboring the Spinach aptamer and transcribed from the different constructs was used to equate the fluorescence intensity of the Spinach aptamer with molar concentrations. Transcription reactions were assembled and then purified as previously described.¹⁶

Computational kinetic model: COPASI⁴¹ was used to implement a computational model that consisted of

10 reactions and 12 parameters describing cell-free RNA and protein expression (Figure S8, Table S6, Table S7, Table S8). The resources necessary for transcription and translation were modeled as a single species (R1 and R2, respectively) and were subject to degradation. Here, resources refer not only to the molecular machinery required to sustain transcription and translation, such as the T7 RNA polymerase, the ribosomes and all the accessory protein factors, but also to the small molecules required to sustain each reaction. Following the PURE system composition,¹⁷ only the initial concentration of T7 RNA polymerase and ribosomes were defined. For the rest of the species and for the reaction rates, parameter estimations based on experimental data were performed. Parameter estimations were also included for two noise parameters, including a $\pm 5\%$ range for the template DNA concentration and a $\pm 10\%$ range for the composition of the PURE system.

Statistical analysis: The coefficient of variation was calculated as the ratio between the standard deviation and the mean value of each experiment ($C_v = \sigma/\mu$). The coefficient of variation for single batch experiments was calculated by averaging the coefficients of variation of three replicates, each collected with the same batch of the PURE system. The coefficient of variation for multiple batch experiments was calculated by averaging the coefficients of variation of nine replicates, using three different PURE system batches (three replicates per batch).

Figure 1. The expression of single gene constructs encoding RFP and GFP do not correlate well. Each point represents a template DNA containing a different ribosome binding site. Reactions were at 37 °C for 6 h. The correlation was 0.61. The different ribosome binding sites employed are listed in Table S1.

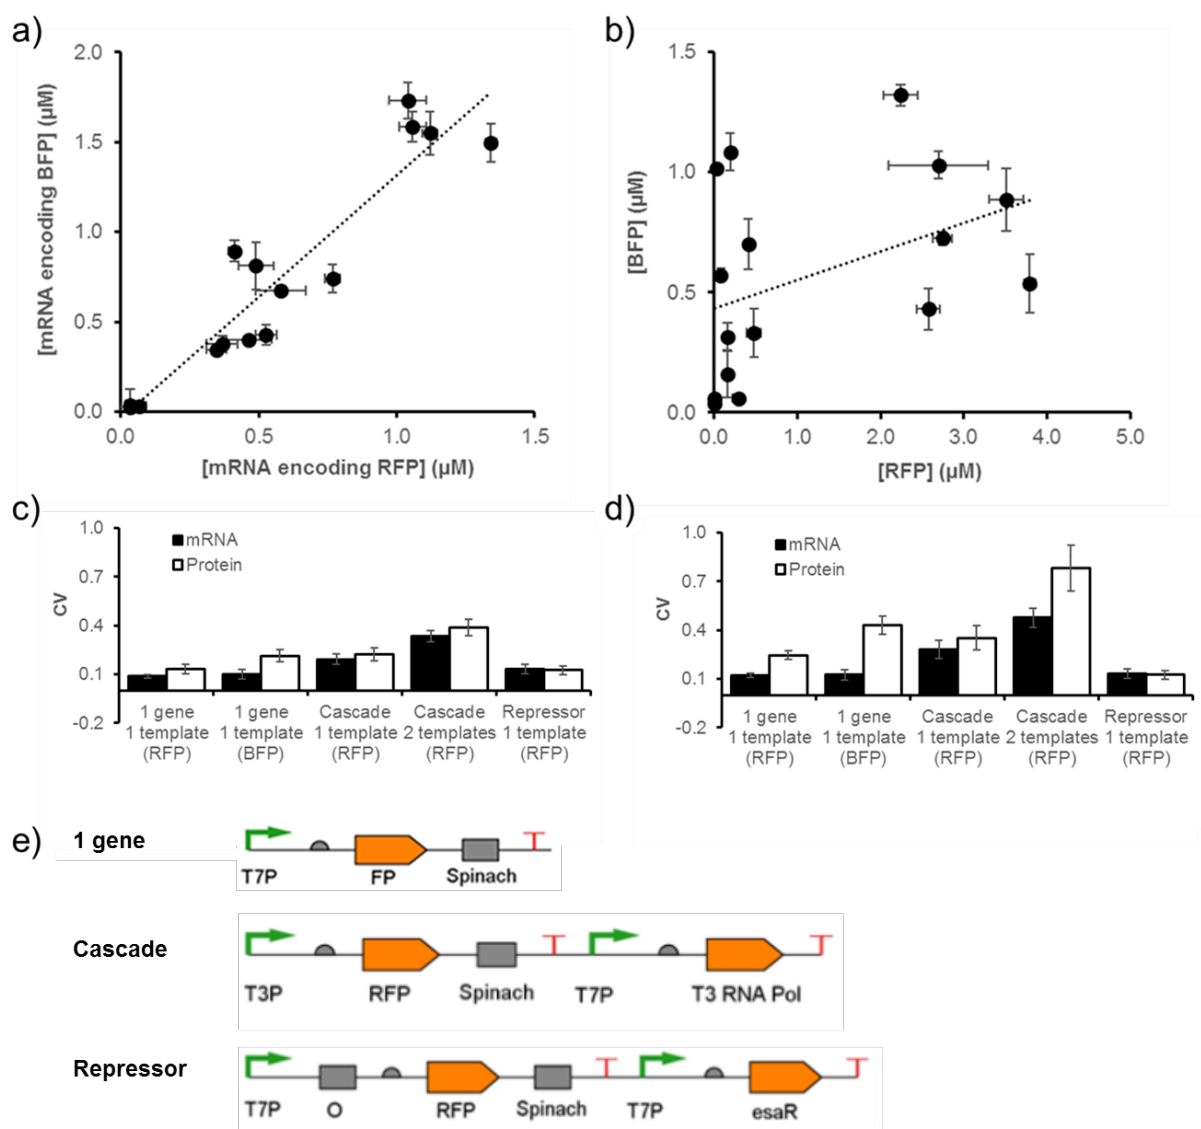

Figure 2. The consistency of transcription and translation in PURE system reactions. (a) Transcriptional promoters predictably control transcription with consistency across different template sequences without influence of the ribosome binding site, whereas (b) the same constructs show significant differences in protein synthesis. Each data point in panels a and b represent the transcription-translation of a different genetic construct with a different combination of transcriptional promoter and RBS. Sequence information and RNA and protein yields can be found in Table S5 and Figure S6. Single (c) and multiple (d) batch transcription-translation reactions show more variability for translation than transcription. The coefficient of variation (CV) was calculated for constructs encoding either one gene or two genes (labeled Cascade and Repressor) for reactions containing only one template or two. All of the templates encoded RFP except for one which coded for BFP. (e) Single template versions of each genetic construct used in panel c are shown. All of the genetic constructs contained the LS1 5'-UTR for the expression of the reporter gene, i.e. a fluorescent protein followed by Spinach. In the Cascade and Repressor genetic circuits the LS3 5'-UTR was employed for the expression of T3 RNA polymerase and EsaR, respectively. The T7 transcriptional promoter (T7P), T3 transcriptional promoter (T3P), fluorescent protein (FP, representing either RFP or BFP), Spinach aptamer (Spinach), and the binding site for EsaR (O) are all labeled.

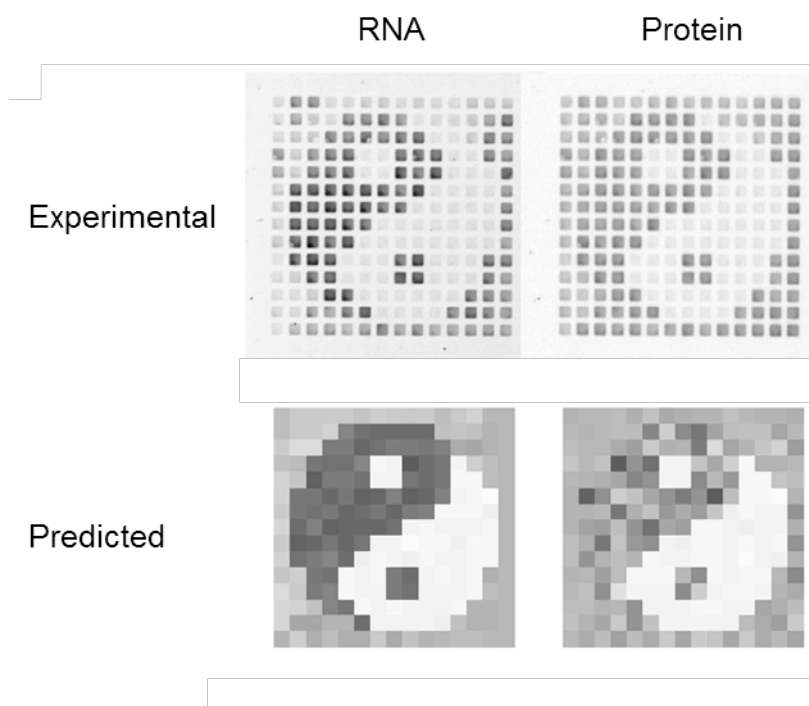

Figure 3. Yin-Yang pictures were built with PURE system reactions placed in a 1538-well plate to confirm the variability of transcription and translation. The pictures were visualized by the fluorescence of expressed RNA (via the Spinach aptamer) and protein (via RFP). The DNA templates of black (strong transcriptional promoter, strong RBS), white (very weak transcriptional promoter, mid RBS), light grey (weak transcriptional promoter, strong RBS), and dark grey (mid transcriptional promoter, mid RBS) pixels were derivatives of pFC013A. Sequences are listed in Table S4.

Figure 4. Transcription-translation reactions can be used to construct a RGB color triangle. (a) The target picture is composed of 25 pixels, each displaying a different color resulting from the three different gradients that stem from the vertexes of the triangle. (b) The computational model was employed to decide which combination of promoters and ribosome binding sites should be used to achieve the desired color for each pixel (Figure S11, Table S12). Based on the computational prediction for the expression of each gene in each pixel, a predicted image was generated. Each sequence was then assembled and run.
