Music is increasingly used as an adjuvant for chronic pain management as it is not invasive, inexpensive, and patients usually report positive experiences with it. However, little is known about its clinical efficacy in chronic pain patients. In this systematic review and meta-analysis, we investigated randomized controlled trials (RCTs) of adult patients that reported any type of music intervention for chronic pain, chosen by the researcher or patient, lasting for any duration. Searches were performed using PsycINFO, Scopus and PubMed for RTCs published until the end of May 2016. The primary outcome was reduction in self-reported pain using a standardized pain measurement instrument reported post-intervention. The secondary outcomes were: quality of life measures, depression and anxiety measures, among others. The study was pre-registered with PROSPERO (CRD42016039837) and the meta-analysis was done using RevMan. We identified 768 titles and abstracts, and we included 14 RTCs that fulfilled our criteria. The sample size of the studies varied between 25 and 200 participants. We found that music reduced chronic pain, and depression, with higher effect size on pain and depression. We also found music had a higher effect when the participant chose the music in contrast with researcher-chosen music. The sample size of RCTs was small and sometimes with different outcome measures. Our analysis suggests that music may be beneficial as an adjuvant for chronic pain patients, as it reduces self-reported pain and its common co-morbidities. Importantly, the analgesic effect of music appears higher with self-chosen over researcher-chosen music.

Introduction

Chronic pain (CP) is highly prevalent worldwide, although estimates vary considerably across countries [12,14,27]. It is an important socio-economical and health problem due to the secondary disability, co-morbidities such as anxiety, depression and suicide, as well as the high rate of dependency on opioid painkillers. It is estimated that between 10 - 50% of patients with CP suffer mild to severe secondary disability, and CP is one of the leading causes of years lived with disability according to the Global Burden Disease study [39]. Furthermore, there is evidence that addiction to painkillers can be a route to heroin dependency [23]. For these reasons, there is a need for adjuvant therapies that help reducing pain, its comorbidities, and particularly to reduce or avoid painkiller dependency.

The most accepted hypothesis states that pain perception can be centrally modulated via the descending pain modulatory system (DPMS) by either inhibiting or facilitating nociceptive input at the brainstem and spinal cord level [36]. The DPMS can be affected by many intrinsic factors including: expectation, attention, context, sensitization, emotion, mood, chemical pathways (neurotransmitter dysfunction), and even genetics [4]. A number of studies have shown the analgesic effects of music in acute experimental pain [17,25,30,31]. The underlying mechanisms for the so-called “music-induced analgesia” (MIA) may not be specific to music, but surely related to the DPMS [35]. Music characteristics such as: high familiarity [25], few beats-per-minute [11], and self-chosen music [26], have been reported to elicit cognitive and emotional mechanisms, such as: distraction [22], pleasure [32], sense of control [4], and placebo-like effects [21], that may contribute to the analgesic effect, all of which can affect the DPMS. It is therefore possible that music provides an easily accessible and strong medium for top-down influence of the DPMS, thus reducing pain. If this hypothesis is correct, then characteristics of the “music treatment” such as music genre or delivery (listening or performing) may be less relevant for the analgesic effect, and personal preference may be more important instead.

The interest in music for the management of chronic pain during or after hospitalization is growing [1,15,18], but its use is far from routine. A growing number of studies have supported the use of music as an adjuvant [20,37,38]. A recent meta-analysis by Hole et al 2015 published in *Lancet* highlighted the importance of listening to music as an aid for postoperative recovery, as it reduces pain and anxiety. Nevertheless, an assessment of study quality and synthesis of findings is clearly warranted, especially in the subject of chronic pain. Providing evidence of its potential effect could encourage physicians and healthcare professionals to use it more widely with this population. In this systematic review and meta-analysis, we aim to assess the effect of music as an adjuvant for chronic pain, as well as the characteristics of the music, if any, with the

1
2
3
4 better clinical response. For this we assessed evidence for the efficacy of music in
5 reducing pain and comorbidities such as anxiety and depression in randomized
6 controlled trials (RCTs) treating chronic pain patients. We also investigated a priori
7 identified subgroups such as patient familiarity with the music, experimenter-chosen vs
8 self-chosen music, and type of pain condition.
9
10

11 12 13 14 **Methods**

15
16 This meta-analysis and systematic review followed procedures from the Cochrane
17 Handbook for Systematic Reviews [19] and from the Center for Reviews and
18 Dissemination (Centre for & Dissemination, 2014). The review protocol was registered
19 with PROSPERO No. [CRD42016039837].
20
21

22 23 24 **Search Strategy**

25
26 Searches were performed using PsycINFO, Scopus and PubMed for randomized
27 controlled trials (RCTs) published until the end of May of 2016, which reported on a
28 music intervention for chronic pain. The search terms were prevalent chronic pain
29 conditions obtained from the IASP ([http://www.iasp-
30 pain.org/PublicationsNews/Content.aspx?ItemNumber=1673&navItemNumber=677](http://www.iasp-pain.org/PublicationsNews/Content.aspx?ItemNumber=1673&navItemNumber=677))
31 and MeSH terms for these (for details and search strings see Supplementary Materials).
32 Only RCTs with adults aged between 18-70 years old were included. Exclusion criteria
33 were: not using an RCT design, acute rather than chronic pain conditions and testing a
34 pediatric population. At full text review, studies were checked to ensure reporting of
35 results from unique, non-overlapping participants. We included studies that reported any
36 type of music intervention for chronic pain: active music playing, listening to music
37 (passive), or 'music medicine', chosen by the researcher or patient, lasting for any
38 duration. Chronic pain was defined as pain persisting or recurring for more than 12
39 weeks [24]. Pain conditions were broadly defined to encompass all types of pain
40 according to the terms by the International Association for the Study of Pain. The
41 primary outcome was reduction in self-reported pain using standardized pain
42 measurement instruments such as: Visual Analogue Scale, Numerical Rating Scale,
43 The McGill Pain Questionnaire, West Haven-Yale Multidisciplinary Pain Inventory,
44 reported post-intervention [6]. The secondary outcomes were: quality of life measures,
45 psychological health (depression, anxiety measures), physical health (such as pain-
46 related disability) reported post-intervention and longer-term intervention outcomes, if
47 available. The comparison/control were: wait list control, no music control and active
48 control, hence, there were no restrictions placed on the control.

1
2
3
4
5
6 Information was extracted from each study as follows: (1) The characteristics of the
7 study where relevant, including: the year of publication, design, randomization, blinding,
8 number of participants, attrition, type of outcome measures, overall treatment effects,
9
10 (2) The characteristics of the intervention: the type of music, list of songs or any other
11 detail on music included, the duration of the music intervention, measures of patient
12 engagement and enjoyment and the qualifications/background of the individual(s)
13 delivering the intervention, if relevant, (3) The characteristics of the participants: sex,
14 age, dropouts, length of pain condition, co-morbid conditions. To avoid risk of bias, two
15 reviewers (VP, EGV) independently assessed the methodological quality of the included
16 RCTs using the Cochrane Risk of Bias (RoB) tool. We also assessed for risk of
17 publication bias. We performed a sensitivity analysis, removing studies at high risk of
18 bias. Any disagreements that arose between the reviewers was resolved through
19 discussion, or with a third reviewer (CEP).
20
21
22
23
24

25 To analyze the association between intervention and outcome, and to avoid variability
26 from the different pain measurement instruments and missing data, we used the primary
27 outcome post-intervention as reported by the study investigators and calculated the
28 effect size. Only in one study [34], the post-intervention improvement was shown as an
29 increase in the pain variable, hence the effect size was calculated backwards. If studies
30 showed pain reduction as a secondary outcome of interest, we considered it the primary
31 outcome for our analyses. Statistical analyses, including pooled mean home practice
32 data and meta regression and risk of bias, was conducted using the software RevMan
33 5.3 [10]. An estimation of heterogeneity was calculated.
34
35
36
37
38

39 **Subgroup Analyses**

40

41 We investigated several *a priori* identified subgroups of interest: “primary vs secondary
42 pain”, “central vs peripheral pain”, “long-term chronic pain conditions (> 5 years) vs
43 short-term pain conditions”, and “participant-selected vs researcher-selected music”.
44 We conducted the subgroup analyses using difference of means. As *post-hoc*, we
45 removed the “primary vs secondary pain” contrast because the terms are not commonly
46 used, and we also removed “long-term vs short-term pain” contrast due to the low
47 sample size for the later (n = 1). Instead, we included the contrast “etiology of pain” that
48 includes IASP categories: neoplasm, degenerative/mechanical, inflammatory, unknown
49 etiology and combined etiology (studies that included two or more pathologies). We also
50 studied the contrast intervention “familiar vs unfamiliar music”. Finally, we added “music
51 delivery” (recorded music, live music, or active music) as a subgroup contrast of
52 interest.

Study characteristics

Figure 1 shows the PRISMA flow chart for the included studies. A total of 65 studies were identified that reported a music intervention for chronic pain (N=768). Of those, 14 studies fulfilled our criteria and/or provided data when contacted. 11 studies investigated pain reduction as a primary outcome, while 3 investigated pain as a secondary outcome. The characteristics of the included studies are shown in Table 1. The sample size of the studies varied between 25 and 200 participants (M = 84 ; SD = 47). The total sample of participants included for this review and meta-analysis was n = 1,178. The majority of included studies examined patients experiencing either cancer pain (4/14) or fibromyalgia (3/14), but a variety of other patient groups were also examined (palliative care, osteoarthritis, multiple sclerosis, chronic non-malignant pain, and inflammatory bowel disease). The mean age of included participants was 55 years (± 10.8), and the mean length of pain condition was 7.3 years (± 4.1). The mean music duration in the included studies was 30 minutes (± 10.05), 80% of them between 20 - 30 minutes. The majority of studies with recorded music intervention used headphones for delivery (7/11), while the others used CD players.

Insert Figure 1 here

The music delivery was performed by the participant in most studies (7/14), while in others the intervention was delivered by a trained researcher, a trained nurse, or a music therapist. Music was delivered via recorded tapes in the majority of cases (11/14), or live music (2/14). One study was considered “active music”, as choir singing was the intervention (1/14). Only 2 studies (14%) reported “music enjoyment” as a variable, both reporting patients’ liking of music as > 90% (cite). Neither study stated the method used to assess music enjoyment. Timing of delivery was anytime of the day, including moments with increased perceived pain. We identified some genres of music delivered: Chinese classical music, Swedish songs, Taiwanese folk songs, buddhist music, classical western music, jazz, pop, as well as instrumental and ambient music such as: ocean drum, harp, piano, orchestra, water and wave sounds. Therefore, music genre varied greatly between studies.

Comparator/control descriptions varied and include different ones: no music (11/14), tactile touch (1/14), conversation (1/14), and routine patient care (1/14). Pain was usually measured with VAS (10/11), but other scales were used such as numerical rating scales (NRS) (1/14), functional pain scale (FPS) (1/14), and pain rating index (PRI) (1/14). Secondary outcomes were measured with a variety of scales, such as: the Hospital Anxiety and Depression Scale (HADS) [40], the Edmonton Symptom Assessment System (ESAS) [28], the Beck Depression Inventory (BDI) [2], the

1
2
3
4 Fibromyalgia Impact Questionnaire (FIQ) [3], and the Health Assessment Questionnaire
5 (HAQ) [5].
6

7 8 **Results** 9

10 We identified a total of 768 titles and abstracts, of which we reviewed 65 studies at full
11 text that reported music intervention for chronic pain (see PRISMA Figure 1). We
12 included 14 RCTs in the final qualitative and quantitative synthesis. Of the 14 studies
13 included in the review, 11 investigated pain reduction as a primary outcome, while 3
14 investigated pain reduction as a secondary outcome. Other secondary outcomes
15 included: anxiety, depression, fatigue, quality of life, disability and biological parameters.
16 We found that music reduced chronic pain in general (14 RCTs, SMD -0.60 [-0.72, -
17 0.48], $Z = 9.81$, $p < 0.001$) (Figure 2), anxiety (4 RCTs, SMD -0.55 [-0.80, -0.30], $Z =$
18 4.31 , $p < 0.001$) (Figure 3), and depression (4 RCTs, SMD -0.82 [-1.08, -0.56], $Z = 6.12$,
19 $p < 0.001$) (Figure 4). Effect size was moderate for chronic pain and anxiety, while
20 depression had a high size effect. Heterogeneity was high for pain, anxiety, and
21 depression, with an $I^2 = 60\%$, 85% , and 88% respectively. A domain-based evaluation
22 was used as the tool for assessing risk of bias. The quality of studies was adequate for
23 most of the included authors, with a low risk of bias overall (Figure 5). Selection bias,
24 attrition bias, and reporting bias had a low risk given that randomization was well
25 performed, outcome data was complete, attrition was low, and all measured outcomes
26 were reported. We found that performance risk of bias was moderate, due to lack of
27 blinding for 8 of the 14 studies. Assessing for selection bias, we found moderate risk
28 because the allocation concealment was not stated (3/14), or was not done (2/14)
29 (Figure 6).

41
42

43 **Subgroup analysis** 44

45 The subgroup analysis by “etiology of pain” (Figure 7) showed a non-significant ($p =$
46 0.17) higher effect size of music intervention when the pain etiology was neoplasm (4
47 RCTs, SMD -0.78 [-1.00, -0.56]) rather than degenerative/mechanical (2 RCTs, SMD -
48 0.33 [-0.64, -0.03], inflammatory (1 RCT, SMD -0.60 [-1.14, -0.06], unknown etiology (3
49 RCT, SMD -0.68 [-0.99, -0.38]), and combined etiology (4 RCT, SMD -0.52 [-0.73, -
50 0.32]). The subgroup analysis “central vs peripheral pain” showed no differences of
51 music intervention ($p = 0.81$) between central pain (4 RCTs, SMD -0.66 [-0.93, -0.40]),
52 peripheral pain (5 RCTs, SMD -0.61 [-0.80, -0.43]), and studies with both central and
53 peripheral pain (5 RCTs, SMD -0.56 [-0.75, -0.36]) (Figure 8). In the “familiar vs
54 unfamiliar music” contrast, music had a non-significant ($p = 0.11$) higher effect size
55 when musical pieces were familiar (6 RCTs, SMD -0.72 [-0.91, -0.53]), when compared
56
57
58
59
60
61
62
63
64
65

1
2
3
4 to unfamiliar music (8 RCTs, SMD -0.52 [-0.68, -0.36]) (Figure 9). In the contrast
5 “participant-selected vs researcher-selected music”, we found a significant greater effect
6 size ($p = 0.02$) when the participants chose the music (5 RCTs, SMD -0.81 [-1.02, -
7 0.59]) than when the researchers chose the music (9 RCTs, SMD -0.51 [-0.65, -0.36])
8 (Figure 10). Examining the funnel plot (Figure 11) suggests that publication bias was not
9 substantial as studies are evenly distributed either side of the SMD for chronic pain. Our
10 risk of bias analysis shows low risk overall (Fig 5 & 6).
11
12
13

14
15 *Insert Figure 7, 8, 9, 10 & 11 here*
16
17

18 **Heterogeneity**

19
20 Heterogeneity of effects was high across studies, probably due to several reasons: the
21 use of different scales to measure pain, anxiety and depression; the variability in the
22 sample sizes; the variability of the pain etiology; the variability in the duration of the
23 study; the type of music intervention of each study; the type of music delivery (passive
24 vs active, participant- vs researcher-chosen). In the subgroup analysis “etiology of pain”
25 (Fig 5), the heterogeneity of studies that included combined etiology was null
26 ($\text{Chi}^2=1.20$, $\text{df}=3$, $I^2=0\%$), and in studies with degenerative/mechanical processes it was
27 low ($\text{Chi}^2=1.47$, $\text{df}=1$, $I^2=32\%$), when compared with neoplasm ($\text{Chi}^2=10.47$, $\text{df}=3$,
28 $I^2=71\%$) and unknown ($\text{Chi}^2=12.99$, $\text{df}=2$, $I^2=85\%$). Studies in the combined etiology
29 subgroup assessed pain with 0-10 VAS only, studied either CNMP (2/4) or palliative
30 care (2/4), and evaluated both central and peripheral pain. A similar pattern occurs
31 while analyzing heterogeneity in the subgroup “central vs peripheral pain”. Studies that
32 included both central and peripheral pain, showed no heterogeneity ($\text{Chi}^2=2.04$, $\text{df}=4$,
33 $I^2=0\%$). These studies used only 0-10 VAS. Heterogeneity was high for studies that
34 included central pain ($\text{Chi}^2=13.07$, $\text{df}=3$, $I^2=77\%$) and peripheral pain ($\text{Chi}^2=16.99$, $\text{df}=4$,
35 $I^2=76\%$), independently.
36
37
38
39
40
41
42
43

44 The subgroup analysis of “familiar vs unfamiliar music” showed substantial
45 heterogeneity in both familiar ($\text{Chi}^2=11.78$, $\text{df}=5$, $I^2=58\%$), and unfamiliar ($\text{Chi}^2=18.19$,
46 $\text{df}=7$, $I^2=62\%$) music. A different pattern was shown in the subgroup “participant-chosen
47 vs researcher-chosen music”, where heterogeneity was low for participant-chosen
48 music ($\text{Chi}^2=5.00$, $\text{df}=4$, $I^2=20\%$), compared with researcher-chosen music ($\text{Chi}^2=22.37$,
49 $\text{df}=8$, $I^2=64\%$).
50
51
52
53
54

55 **Discussion**

56
57
58 This systematic review suggests that listening to music reduces self-reported pain,
59 anxiety and depression symptoms in a diverse range of chronic pain patients. We also
60
61
62
63
64
65

1
2
3
4 found that music helped to reduce symptoms of anxiety and depression, common
5 disabling comorbidities in chronic pain. In a subgroup analysis, we found that the
6 analgesic effects of music were greater for patient-chosen than researcher-chosen
7 music.
8
9

10
11 All of the included studies reported analgesic effects of music, and in general, these
12 effects were significant, supporting the hypothesis that music is beneficial in chronic
13 pain conditions. This suggests that the analgesic effect of music may initiate in the brain
14 and elicits a top-down regulation mechanism via the DPMS, as it has been suggested in
15 fibromyalgia [17]. Only 4 studies did not report the duration of their whole intervention.
16 The mean duration of the studies was 5 weeks (± 3), and only 1 study lasted for a whole
17 year [9]. The duration of the analgesic effect was not directly discussed in any study, but
18 according to their results we suggest that a daily session of 20 - 30 minutes, while
19 experiencing pain exacerbation or not, is effective and recommended.
20
21
22
23
24

25 Reductions in anxiety and depression symptoms, aside from the pain, is an important
26 effect, given that suicide is not uncommon. Music might improve patient coping with
27 their condition, which at the same time may reduce the feeling of helplessness and
28 suicidal thoughts [8]. It is not clear whether the reduction of anxiety and depression
29 symptoms themselves could be secondary to the analgesic mechanism, but it is
30 important to note that music seems to be positively contributing to more than one
31 dimension and symptom of chronic pain.
32
33
34

35 36 **Subgroup analysis**

37
38 We found no significant differences in response to music based on the etiology of pain
39 or location of pain. Nevertheless, the studies we found did not include all types of pain
40 (i.e. migraine) and more research is necessary to confirm our findings. One question of
41 clear interest is how best to deliver a music intervention. In most of our included studies,
42 the patients listened to music, and only one study used active singing [9] and two others
43 used live music [7,18]. We therefore cannot make clear recommendations about the
44 ideal mode of delivery of a music intervention. More studies are needed to assess if
45 listening to recorded music (passive) provides similar benefits performing music (active)
46 (Doelling & Poeppel 2015). We found no significant difference in pain response to
47 familiar (6/14) and unfamiliar music studies (8/14). This result contrasts with several
48 experimental studies showing a higher analgesic effect of familiarity [25,29]. Listening to
49 familiar music may induce a feeling of “control” of the situation and the expectation of
50 musical “peaks” could induce pleasure and secondary analgesia and relaxation, as well
51 as release dopamine and endogenous opioids [33]. In an experimental study by our
52 group we found that unfamiliar music provided less of an analgesic effect than an active
53 math distraction [16]. However, in this synthesis, we found that the effects of music
54
55
56
57
58
59
60
61
62
63
64
65

1
2
3
4 familiarity were non-significant suggesting no effect or very low effect. This may be due
5 to the small number of studies in our sample and should be studied further.
6
7

8 Evidence from other studies suggests that musical genre is not important for the
9 analgesic effect. It was not possible to study genre, however, the included studies used
10 a somewhat wide range of music genres. In our study, self-chosen music (5/14) had a
11 significantly higher analgesic effect than researcher-chosen music (9/14) in our study,
12 and was in fact the only statistically significant subgroup analysis. This has been
13 reported by several experimental studies [11] and was also shown in another meta-
14 analysis of music in cancer patients [37]. This effect may be related to familiarity, feeling
15 of control and pleasure, thus contributing to the analgesic effect. The use of self-chosen
16 music may present a challenge for standardizing music treatment, and having a pool of
17 musical choices could reduce this problem.
18
19
20
21
22
23
24

25 **Limitations**

26
27 Due to the small number of studies, subgroup comparisons should be interpreted
28 cautiously. In terms of study size, there was only one study with an $n < 35$, which
29 suggests that studies overall were reasonably powered to find a moderate effect size.
30 However, most outcome variables, primary and secondary, were measured using
31 different instruments, which may partly explain the heterogeneity between studies.
32 Several studies lacked complete information (i.e. pain measures and the type of music
33 used). Also, there were many variable factors such as: the person who chose the music
34 (participant- vs. researcher-chosen), the length of the music intervention (1 week - 12
35 months), the type of delivery of the music (active, passive listening, live music) and the
36 type control condition, among others.
37
38
39
40
41
42

43 In our sample, no study reported adverse or negative effects with music, and this could
44 be either because there were none, or because of inadequate reporting, which is typical
45 for many psychological interventions [13]. Nevertheless, we found an sample of RCTs
46 with adequate sample sizes, and overall effect sizes that provide consistent evidence in
47 support of the reduction of pain, depression and anxiety in chronic pain conditions,
48 hence, supporting the use of music as an adjuvant in pain medicine.
49
50
51
52

53 Future RCTs should aim to use active control conditions, and use more than one
54 standard instrument (VAS, numeric, etc), and to use self-chosen music to try and avoid
55 heterogeneity. We still do not know the precise duration of the analgesic effect of music
56 and the dosage of music intervention to produce a positive outcome, and these may
57 explain part of the heterogeneity. Future studies should also record medication intake to
58 assess for any reduction in the amount of painkillers, anxiety and depression medication
59
60
61
62
63
64

2
3
4 after music intervention. While medication information was lacking in our study, it would
5 be of clinical interest to examine the potential reduction in pain medication intake after
6 music intervention. Reducing the intake amount of pain medication, would improve the
7 patients' quality of life by avoiding secondary effects such as gastrointestinal problems
8 and prescribed drug dependency.
9

10 11 12 **Conclusions** 13

14
15 In this systematic review and meta-analysis, we show that music reduces pain in
16 chronic pain conditions, and anxiety and depression symptoms, and that self-chosen
17 music have higher analgesic effect. We suggest that music can be used as an easily
18 administered, effective adjuvant for chronic pain and its common comorbidities. Our
19 systematic review and meta-analysis is the most complete to date on music and chronic
20 pain patients, given the comprehensive search terms and study choice (RCTs). More
21 studies are necessary to untangle specific questions about the mechanisms underlying
22 the effect of music and further studies should focus more on indirect measures such as
23 the amount of medication taken after the music intervention.
