24 **Abstract**

25 Both gene expression levels and eQTLs (expression quantitative trait loci) are partially tissue-specific,
26 complicating the detection of eQTLs in tissues with limited sample availability, such as the brain.
27 However, eQTL overlap between tissues might be non-trivial, allowing for inference of eQTL
28 functioning in the brain via eQTLs measured in readily accessible tissues, e.g. whole blood. Using
29 Stratified Linkage Disequilibrium Score Regression (SLDSR), we quantify the enrichment in GWAS
30 signal of blood and brain eQTLs in genome-wide association study (GWAS) for three brain-related
31 (schizophrenia, BMI, and educational attainment), three immune-related traits (Crohn's disease,
32 rheumatoid arthritis, and ulcerative colitis), and five traits not strongly associated with either tissue
33 (age at menarche, coronary artery disease, height, LDL levels, and smoking behavior). Our analyses
34 established significant enrichment of blood and brain eQTLs in their effects across all traits. As we do
35 not know the true number of causal eQTLs, it is difficult to determine the precise magnitude of
36 enrichment. We found no evidence for tissue-specific enrichment in GWAS signal for either eQTLs
37 uniquely seen in the brain or whole blood. To follow up on our findings, we tested tissue-specific
38 enrichment of eQTLs discovered in 44 tissues by the Genotype-Tissue Expression (GTEx) consortium,
39 and, again, found no tissue-specific eQTL effects. Finally, we integrated the GTEx eQTLs with SNPs
40 associated with tissue-specific histone modifiers, and interrogated its effect on rheumatoid arthritis
41 and schizophrenia. We observed substantially enriched effects on schizophrenia, though again not
42 tissue-specific. We conclude that, while eQTLs are strongly enriched in GWAS signal, the enrichment
43 is not specific to the tissue used in eQTL discovery. Therefore, working with relatively accessible
44 tissues, such as whole blood, as proxy for eQTL discovery is sensible and restricting lookups for
45 GWAS hits to a specific tissue might not be advisable.

51 **Introduction**

52 The aim of genome-wide association studies (GWAS) is to detect statistically significant associations
53 between genetic variants, such as single nucleotide polymorphisms (SNPs), and a trait of interest
54 (Hirschhorn and Daly 2005). GWAS have identified many genetic variants and thereby provided
55 insights into the genetic architecture of complex traits (Hirschhorn and Daly 2005; Visscher et al.
56 2012). However, a large number of variants identified through GWAS are located outside of coding
57 regions and specific knowledge of regulatory elements is limited (Lowe and Reddy 2015). Therefore,
58 uncovering a relationship between GWAS hits and biological function has proven to be complicated
59 (Lowe and Reddy 2015). Expression quantitative trait loci (eQTLs) contain SNPs that influence gene
60 expression, and are not necessarily located in coding regions. eQTLs may aid functional annotation
61 of SNPs that have been identified in a GWAS and are located outside of coding regions (Morley et al.
62 2004; Lowe and Reddy 2015). Previous work has found substantial enrichment of eQTLs among
63 GWAS hits (Manolio et al. 2009; Nicolae et al. 2010; Torres et al. 2014) and an enrichment in their
64 genome-wide effect on complex traits (Davis et al. 2013). Therefore, eQTLs are viewed as an
65 important tool in moving from genome-wide association to biological interpretation.

66 As a result of differences in gene expression between cells originating from different tissues,
67 eQTLs are potentially tissue-specific (Hernandez et al. 2012; GTEx Consortium 2015). Tissue-
68 specificity poses no problem if the tissue of interest is readily available for research, such as whole
69 blood. However, discovery of eQTLs gets complicated when measurement of expression levels in a
70 tissue is limited by ethical and practical considerations, for example in brain tissue. Several studies
71 have shown that the overlap between eQTLs from different tissues might actually be larger than
72 initially assumed (Ding et al. 2010; Nica et al. 2011). The Genotype-Tissue Expression (GTEx)
73 consortium identified eQTLs in a wide range of human tissues and showed that 54-90% of the eQTLs

74 identified in one tissue are also designated as an eQTL in at least one other tissue (GTEx Consortium
75 2015; Aguet et al. 2016). In another study, Liu *et al* (2016) found a high average pairwise genetic
76 correlation ($r_g=0.738$) of local gene expression between tissues. Nevertheless, small differences in
77 terms of eQTL effect may be of considerable importance in terms of the effect an eQTL might have
78 on complex traits related to specific tissues. It is, therefore, worthwhile to investigate the specific
79 utility of tissue-specific eQTLs in their effect on complex traits, as studied in GWAS, as the discovery
80 of eQTLs for tissues such as the brain might be advanced by eQTLs discovered in more accessible
81 tissues, such as whole blood. The use of accessible tissues, though, depends on a substantial degree
82 of similarity of eQTL effect across tissue, and to what extent eQTL differences between tissues are
83 important in complex trait etiology.

84 Stratified Linkage Disequilibrium Score Regression (SLDSR) is a technique that estimates the
85 SNP-heritability (h^2_{SNP}) of a trait based on GWAS summary statistics (Bulik-Sullivan et al. 2015;
86 Finucane et al. 2015). By simultaneously analyzing multiple categories of SNPs (annotations), SLDSR
87 can partition h^2_{SNP} by annotation (h^2_{annot}) and thereby provides a way to jointly quantify the
88 enrichment in GWAS signal of several annotations. Here, we extend SLDSR by including annotations
89 containing *cis*-eQTLs, i.e. eQTLs located closely to the gene with which they associate (Brem et al.
90 2002; Ramasamy et al. 2014), discovered in multiple tissues. To this end, we perform analyses based
91 on representative eQTL resources, and consider a variety of traits as outcomes.

92 Firstly, we selected all eQTLs per gene discovered in large samples of RNA expression levels
93 assessed in whole blood (N=4896)(Wright et al. 2014; Jansen et al. 2017) and in brain tissues (N=134)
94 (Ramasamy et al. 2014), and quantified the contribution of these blood and brain eQTLs to the
95 genetic variance in complex traits captured in GWAS. We then estimated tissue-specific eQTL effects
96 on complex traits by quantifying the enrichments of eQTLs uniquely found in whole blood or
97 uniquely found in brain, conditional on the enrichment of the complete blood eQTL annotation or
98 complete brain eQTL annotation, respectively. We considered the effect of eQTLs on three brain-
99 related phenotypes: schizophrenia, BMI, and educational attainment; three immune disorders:

100 Crohn's disease, rheumatoid arthritis, and ulcerative colitis; and five other complex traits and
101 disorders: age at menarche, coronary artery disease, height, LDL levels, and smoking behavior.

102 Secondly, we retrieved all eQTLs identified in any of the 44 tissues from the GTEx consortium
103 (N=70-361, median=126.5)(GTEx Consortium 2015; Aguet et al. 2016). We considered the
104 enrichment in GWAS signal of the union of all GTEx eQTLs, and, additionally, the enrichment of
105 tissue-specific eQTL effects on top of the union of all GTEx eQTLs. We expected to observe tissue-
106 specific enrichment of eQTLs in their effects on complex traits related to the tissue in question, e.g.
107 eQTLs discovered in immune-related tissues are expected to show higher enrichments in their effect
108 on immune-related traits compared to eQTLs found in skin tissue. We considered tissue-specific
109 enrichment of *cis*-eQTLs in their effect on schizophrenia (a disorder where there is strong prior
110 evidence for the involvement of processes in the brain) and rheumatoid arthritis (a disease with
111 strong prior evidence for the involvement of processes in the immune system) as GWAS for these
112 traits are well powered for extended LD-score-based analyses. We further considered the
113 enrichment of the intersection of *cis*-eQTLs discovered in any tissue, and histone modification in a
114 specific tissue (i.e. tissue-specific epigenetically changed chromatin states in regulatory regions).

115 Our analyses were designed to elucidate the relation between eQTLs and complex traits, and
116 to quantify the extent to which this relation is dependent on the tissue used in eQTL discovery. Our
117 analysis further considered the enrichment of genomic regions related to gene expression and
118 epigenetically modified in specific tissues.

119

120 **Material and Methods**

121 **SLDSR method**

122 A measure of linkage disequilibrium (LD) for each SNP, called an "LD score", can be computed by
123 taking the sum of correlations between that SNP and all neighboring SNPs (Bulik-Sullivan et al. 2015;
124 Finucane et al. 2015). Under a polygenic model, LD scores are expected to show a linear relationship
125 with GWAS test statistics of corresponding SNPs, where the slope is proportional to h^2_{SNP} . For SLDSR,

126 LD scores are based on only (functional) parts of the genome and used as predictors in a multiple
127 linear regression (Finucane et al. 2015). In this manner, SLDSR is able to partition h^2_{SNP} into parts that
128 are explained by these parts of the genome (i.e. h^2_{annot}), while accounting for influences of the
129 remaining annotations in the model. The enrichment of an annotation is then obtained by taking the
130 ratio of h^2_{annot} over the proportion of SNPs that fall within that annotation. For eQTLs, the
131 denominator, i.e. the number of SNPs in the annotation, is a complicated quantity: not all significant
132 eQTLs are likely causal; whereas including only lead, or putative causal, eQTLs may result in very
133 small annotations located near genes and other regulatory elements, which presents a risk of
134 inflated estimates of the enrichment in GWAS signal. Because of these issues, we consider all
135 significant *cis*-eQTLs as an annotation, and retain additional gene-centric and regulatory annotations
136 in the model.

137

138 **Target traits**

139 As outcome for SLDSR, we used summary statistics of GWAS on Crohn's disease (Jostins et al. 2012),
140 rheumatoid arthritis (Okada et al. 2014), ulcerative colitis (Jostins et al. 2012), BMI (Speliotes et al.
141 2010), educational attainment (Rietveld et al. 2013), schizophrenia (Ripke et al. 2014), age at
142 menarche (Perry et al. 2014), coronary artery disease (Schunkert et al. 2011), height (Allen et al.
143 2010), LDL levels (Teslovich et al. 2010), and smoking behavior (Furberg et al. 2010). The first three
144 traits were chosen because these are related to the immune system and are therefore expected to
145 reveal considerable enrichment of blood eQTL signal (Jostins et al. 2012; Okada et al. 2014). Similarly,
146 brain eQTLs are expected to show substantial enriched effects due to previous reports on the
147 involvement of the central nervous system (CNS) in schizophrenia (Ripke et al. 2014), educational
148 attainment (Rietveld et al. 2013), and BMI (Vimalaswaran et al. 2012). Of course, these traits do not
149 perfectly align with either tissue, e.g. the immune system has been implicated in the etiology of
150 schizophrenia (Andreassen et al. 2015) and BMI (Karalis et al. 2009), and might therefore also be
151 enriched in their effects for the other eQTL set. However, this is expected to occur at lower rates.

152 Enrichment of blood and brain eQTL effects on the remaining traits was calculated to contrast the
153 results with traits for which we do not have a strong *a priori* expectation of the relationship between
154 trait and tissue.

155 The discovery sample for detection of blood eQTLs (Wright et al. 2014; Jansen et al. 2017)
156 included participants from the Netherlands Twin Register (NTR)(Boomsma et al. 2008; Ripke et al.
157 2013) and Netherlands Study of Depression and Anxiety (NESDA)(Penninx et al. 2008). Subjects from
158 these studies, not necessarily the same ones, also participated in the GWAS for some of the traits
159 examined (Allen et al. 2010; Speliotes et al. 2010; Teslovich et al. 2010; Furberg et al. 2010; Rietveld
160 et al. 2013; Perry et al. 2014). To ensure that the discovery sample did not affect estimates of
161 enrichments of eQTL effects in the various GWAS signals, we looked at trait-specific enrichment of
162 blood and brain eQTL signal in GWAS signal for educational attainment and smoking behavior. We
163 compared the results from using publicly available datasets with using summary statistics based on
164 the same sample without subjects from the NTR or NESDA. The results did not reveal appreciable
165 differences between the respective datasets for educational attainment, but did show substantial
166 differences for smoking behavior (S1 Figure). This latter finding could conceivably be a function of
167 relatively strong effects of smoking behavior on gene expression levels (Vink et al. 2015). Therefore,
168 the remaining analyses for smoking behavior were performed using the summary statistics without
169 participants from NTR or NESDA, whereas analyses for the other traits (age at menarche, BMI,
170 educational attainment, height, and LDL level) were run using publicly available summary statistics.

171

172 **Blood and brain eQTL enrichment**

173 A catalog of whole blood *cis*-eQTLs was obtained from Jansen *et al* (2017; Wright et al. 2014), where
174 all eQTLs significantly associated with gene expression in whole blood for each probe set were
175 selected for inclusion in our whole blood eQTL annotation. A list of brain eQTLs was obtained from
176 the UK brain expression consortium (UKBEC), for which the analyses are described in Ramasamy *et al*
177 (2014). We based the brain eQTL annotation on SNPs that were significantly associated with the

178 average gene expression across 12 brain regions. SLDSR annotations were constructed as per the
179 instructions in Bulik-Sullivan et al. and Finucane et al. (2015). To guard against upward bias in the
180 eQTL enrichment signal, two extra annotations containing SNPs within a 500 base pair (bp) and
181 100bp window around any eQTL were constructed for each eQTL set (Finucane et al. 2015). Finally,
182 to ensure that the enrichment of eQTL effects in GWAS signal was not in fact caused by their
183 proximity to the genes they influence, an additional gene centric annotation was computed, which
184 contained all genes for which eQTLs were included.

185

186 **Tissue-specific eQTL enrichment**

187 To distinguish between the effects of blood- and brain-specific eQTLs, we split each annotation into
188 two sets based on the overlap in genes that were tagged by eQTLs from both tissue. That is, the
189 brain eQTL annotation was split into an annotation of brain eQTLs which regulate genes for which
190 also at least one blood eQTL was found, and a second annotation of eQTLs that tagged genes for
191 which only brain eQTLs were found. Likewise, the blood eQTL annotation was split into an
192 annotation containing only eQTLs that tagged genes for which eQTLs from both tissue was found,
193 and an annotation consisting of blood eQTLs that tagged genes for which only eQTLs have been
194 found in blood.

195

196 **Enrichment of eQTLs from 44 tissues**

197 There are limitations to above mentioned analyses of tissue-specific enrichments of eQTL effects in
198 GWAS signal. The eQTLs are obtained from two different projects, which vary in terms of sample size
199 and their definition of an eQTL. To mitigate the heterogeneity between studies, and to extend to
200 additional tissues. We performed additional analyses using eQTLs obtained by a common pipeline
201 from 44 tissues (see S2 Table) and based on a broader eQTL locus definition (GTEx Consortium 2015;
202 Aguet et al. 2016). For each of the 44 tissues, we created annotations for analysis in SLDSR following
203 the previously described procedure. Analogous to the procedure of Finucane *et al* (2015) for cell-

204 type-specific analysis using SLDSR, we additionally created an annotation that contained all GTEx
205 eQTLs, i.e. a SNP would be included in this annotation if it was designated as part of at least one of
206 the 44 tissue-specific GTEx annotations, and added a 100bp and 500bp window. No windows were
207 specified for the tissue-specific GTEx annotations. Using GWAS summary statistics for schizophrenia,
208 we then ran one SLDSR model containing only the baseline categories and the union of GTEx eQTLs,
209 and 44 additional models with the two previous annotations and one of the tissue-specific GTEx
210 annotations at a time. We repeated the procedure using summary statistics for rheumatoid arthritis.

211 GTEx has relative small sample sizes for the brain eQTL discovery (mean=89 sample size,
212 range=72-103) compared to other tissues (mean=160 sample size, range=70-361) (GTEx Consortium
213 2015; Aguet et al. 2016). To investigate the effect of differences in sample size on estimates of
214 enrichments in GWAS signal, we collapsed the union of individual brain eQTL annotations into a
215 shared brain eQTL annotation (i.e. an eQTL found in at least one of the GTEx brain annotations was
216 included in the shared brain eQTL annotation). This annotation was then analyzed as an additional
217 GTEx eQTL annotation. We further tested the relationship between tissue sample size and tissue
218 eQTL enrichment.

219

220 **Enrichment of the intersection between eQTLs and histone marks**

221 The availability of annotations based on tissue-specific histone marks made it possible to create an
222 annotation that represents the intersection between eQTLs and this type of epigenetic modification
223 related to enhancers and promoters of actively transcribed genes. We obtained LD score
224 annotations of SNPs in regions that bare histone marks in cells from the CNS or immune system from
225 Finucane *et al* (2015). Out of the 220 cell-type-specific histone mark that were available, 101 were
226 found in the CNS or immune tissues. For each of the 101 annotations of SNPs in cell-type-specific
227 histone marks, we extracted its intersection with the union of GTEx eQTLs and made a new
228 annotation of eQTLs which intersected with histone marks (i.e. SNPs found in both annotations). We
229 then analyzed each of the intersection annotations individually in a model together with the baseline

230 categories, the union of GTEx eQTLs, and the corresponding cell-type-specific histone marks.
231 Enrichments in GWAS signal of the intersection should be interpreted as enrichment of genome-
232 wide SNP effects on a complex trait beyond the additive effects which work on all SNPs that are a
233 *cis*-eQTL and histone mark in question. In fact, we test whether the interaction between tissue-
234 specific chromatin state and eQTLs are enriched in their genome-wide effect on complex traits.

235

236 **Results**

237 **Blood and brain eQTL enrichment**

238 We fitted an SLDSR model containing the baseline categories; the complete annotation for both
239 brain and blood eQTL tissues, their 100 and 500bp windows, and gene-centric annotations to all
240 traits (Crohn's disease, rheumatoid arthritis, ulcerative colitis, BMI, educational attainment,
241 schizophrenia, age at menarche, coronary artery disease, height, LDL levels, and smoking behavior).
242 We found significant effects of brain eQTLs on educational attainment, rheumatoid arthritis,
243 smoking behavior, and schizophrenia, and significant effect of blood eQTLs on height and smoking
244 behavior (see S3 Table). We then meta-analyzed the results for all annotations, both in the baseline
245 model, and those associated with eQTLs across the 11 traits. Our analyses revealed significant effect
246 of both blood ($p < 0.001$) and brain ($p < 0.001$) eQTL effects on all traits (Figure 1, S4 Table),
247 exceeding, in terms of significance, all the baseline categories considered by Finucane *et al* (2015)
248 but conserved genomic regions. The gene-centric annotation for both blood and brain eQTLs showed
249 no effect on any trait. We further observed no evidence for depletion of blood-specific eQTLs
250 (relative to all blood eQTLs) on brain-related traits, nor do we find significant depletion of effect on
251 immune-related traits of eQTLs associated with genes for which eQTLs were solely identified in brain
252 tissue (Table I).

253

254 **Enrichment of eQTLs from 44 tissues in GTEx**

255 We interrogated the enrichment of the union of GTEx eQTLs and 44 tissue-specific GTEx annotations
256 in their effect on schizophrenia and rheumatoid arthritis. Figure 2 shows the coefficient Z-scores of
257 the 45 GTEx annotations, sorted from largest to smallest. In both cases, the union of GTEx eQTLs had
258 a substantial Z-score ($Z=5.501$ and $Z=3.802$ for schizophrenia and rheumatoid arthritis, respectively,
259 both $p<0.001$, S5 Table), indicating that eQTLs were significantly enriched in their effects on complex
260 traits. The tissue-specific annotations, however, performed notably worse and in some cases even
261 suggested depletion of genome-wide effects of tissue-specific eQTLs on schizophrenia and
262 rheumatoid arthritis. For rheumatoid arthritis, the coefficient Z-scores of the whole blood
263 annotation reached nominal significance ($Z=2.036$, $p=0.021$), but failed correction for multiple
264 testing. None of the other annotations reached nominal significance. The union of all GTEx brain
265 annotations did not contribute significantly to explaining h^2_{SNP} ($Z=0.147$, $p=0.441$). Sample size in the
266 eQTL discovery phase appears to be a strong determinant of tissue-specific enrichment in GWAS
267 signal. The correlation coefficients between the coefficient Z-scores and sample sizes were 0.6453
268 ($p=2.253 \times 10^{-6}$) and 0.4247 ($p=0.004$) for schizophrenia and rheumatoid arthritis, respectively.

269

270 **Enrichment of the intersection between eQTLs and histone marks**

271 We interrogated the intersection of eQTLs and histone marks found in specific CNS and immune cells,
272 and estimated the enrichment of the intersection in its effect on rheumatoid arthritis and
273 schizophrenia. We found significant enrichment in GWAS signal for eQTLs that intersect with
274 histones that bare modification H3K4me1, a modification thought to be present in the enhancer of
275 actively transcribed genes (Zhou et al. 2011; Allis and Jenuwein 2016), in CNS cells for schizophrenia
276 (see Figure 3). There was some evidence for significant enrichment of eQTLs that intersected with
277 genomic regions in immune cells baring the H3K4me1 mark in their effect on schizophrenia, but not
278 on rheumatoid arthritis. Specifically, none of the intersecting annotations showed evidence of
279 enrichment for rheumatoid arthritis. For the separate annotations, we found significant enrichment
280 in GWAS signal across all histone marks found in CNS cells and three significant immune cell-types

281 that bare the H3K4me3 modification, a modification associated with transcriptional start sites and
282 promoters of actively transcribed genes (Zhou et al. 2011; Allis and Jenuwein 2016), for
283 schizophrenia (S6 Figure). The opposite picture was seen for rheumatoid arthritis: a wide variety of
284 immune-cell specific histone marks showed significant enrichments in GWAS signal, while all marks
285 found in CNS cells were below zero. The union of GTEx eQTLs reached statistical significance for all
286 models (S6 Figure).

287

288 Discussion

289 Stratified Linkage Disequilibrium Score Regression provides a way to partition h^2_{SNP} into parts
290 explained by (functional) parts of the genome (Finucane et al. 2015). A “full baseline model”
291 containing 24 non-cell-type-specific annotations of SNPs, such as SNPs located in promoters or
292 coding regions, was developed previously for analysis using SLDSR. Here, we added annotations
293 containing eQTLs derived from whole blood and brain tissue into the model, and showed that eQTLs
294 were substantially stronger enriched in their effect on complex traits compared to all categories
295 considered by Finucane *et al* (2015). The complete brain eQTL annotation was significantly enriched
296 in GWAS signal for educational attainment, rheumatoid arthritis, smoking behavior, and
297 schizophrenia. This finding is consistent with previous estimates of eQTL effect enrichment (Davis et
298 al. 2013). Considerable enrichment for eQTLs, even for traits not apparently linked to the brain or
299 immune system (e.g. smoking behavior), suggested that non-trivial eQTL overlap across tissues
300 might be present.

301 Inclusion of both brain and blood eQTLs into the SLDSR model did not separate the signal
302 into tissue-specific effects. In general, we are not able to clearly identify tissue-specific eQTL signals
303 using these datasets and SLDSR. Our second analysis of eQTL enrichment based on 44 tissue-specific
304 *cis*-eQTL sets, obtained from the GTEx consortium (2015; Aguet et al. 2016), confirms the lack of
305 tissue-specific eQTL enrichment. While an annotation containing all eQTLs identified in GTEx is
306 significantly enriched in its effect on schizophrenia and rheumatoid arthritis ($Z=5.501$ and $Z=3.802$,

307 respectively, both $p < 0.001$), none of the analyzed brain tissues are enriched beyond all eQTLs in
308 their effect on schizophrenia. Similarly, whole blood eQTLs are not significantly enriched beyond all
309 GTEx eQTLs taken together in their effect on rheumatoid arthritis. Again, these findings are not
310 consistent with the hypothesis of abundant tissue-specific *cis*-eQTLs with effects on complex traits
311 related to the specific tissue in question. Especially, when contrasted with tissue-specific gene
312 expression levels and tissue-specific histone modifications (Liu et al. 2016; Finucane et al. 2017),
313 tissue-specific eQTLs are of limited value in relating complex traits to a tissue. Our conclusions are
314 limited to *cis*-eQTLs and it is not unlikely that *trans*-eQTLs behave differently in terms of tissue-
315 specificity. We do, find evidence for possible enrichment for eQTLs that intersect with tissue-specific
316 H3K4me1 histone marks in the brain, but also immune cells, in their effect on schizophrenia but not
317 rheumatoid arthritis. This means that eQTLs in H3k4me1 marks are enriched in their effect on
318 schizophrenia above the expected enrichment based on the fact that these SNPs are both eQTLs and
319 located in H3K4me1 histone marks. What is of substantial interest is that the enrichment in GWAS
320 signal appears specific to H3K4me1 marks, and no other histone marks, suggesting that these marks
321 specifically can aid in prioritizing genomic regions in which tissue-specific eQTLs may reside. Though,
322 again, the totality of evidence is inconclusive on the relevance of tissue-specific eQTLs to variation in
323 complex traits.

324 Our results are consistent with, and complimentary to, a study investigating the genetic
325 correlation between gene expression levels across 15 tissues (Liu et al. 2016). This study revealed
326 substantial correlations between *cis*-genetic effects on gene expression across 15 tissues (Liu et al.
327 2016). Our analyses confirmed the value of using whole blood as discovery tissue for detection of
328 *cis*-eQTLs and further demonstrated the usefulness of techniques that use *cis*-eQTLs discovered in
329 whole blood to study the etiology of complex traits related to different tissues (Gamazon et al. 2015;
330 Gusev et al. 2016). The results presented here highlight the overlap of *cis*-eQTL effects across tissues
331 on a genome-wide level. However, the effect of a *cis*-eQTL might vary substantially across tissues for
332 individual genes (Grundberg et al. 2012). Our conclusions are based on genome-wide enrichments

333 and therefore should not be interpreted as limited evidence for tissue-specific eQTL effects for
334 individual genes. Therefore, eQTL discovery in the tissue most relevant to a specific trait or disorder
335 remains important to further our understanding of the genetic regulation of tissue-specific gene
336 expression. What is also clear is that, to discover those tissue-specific eQTLs that are of relevance to
337 the interpretation of GWAS of complex traits, tissue-specific eQTL discovery needs to be refined. The
338 practice of, as a post-hoc analysis to GWAS, performing eQTL lookup in a specific tissue linked to a
339 trait, when larger dataset for other accessible tissues are available, may be suboptimal. In fact, one
340 may prefer to perform a lookup in the overlap between histone modifications in a relevant tissue
341 and eQTLs regardless of tissue. One can further consider utilizing eQTLs to link GWAS findings to a
342 gene, and subsequently consider the differential expression of a gene to identify the tissue in which
343 the gene is most likely to act in effecting the trait. Tissue-specific differential gene expression vastly
344 outperforms eQTLs in tagging regions of the genome enriched in their effect on complex traits
345 (Finucane et al. 2017).

346 It is also evident that a limited dichotomous definition of eQTL/no-eQTL may be insufficient
347 to identify tissue-specific eQTL effects. An evident improvement would be to compute the *difference*
348 in eQTL effect on expression of the gene between tissues, and perform inference based on this
349 difference in effect. eQTLs are strongly enriched SNPs, with clear biological function and utility for
350 the translation of GWAS findings, though tissue-specific eQTL mechanisms remain elusive. The
351 discovery of tissue-specific eQTL effects, which can aid in linking complex trait to tissue, may require
352 novel research strategies.

493 **Figure Titles and Legends**

494 **Figure 1. Average enrichment in GWAS signal of the 24 baseline annotations, 4 brain eQTL**
495 **annotations and 4 blood eQTL annotations.**

496 Bar plot of the average enrichment in GWAS signal across all traits for the 24 main baseline
497 annotations and 8 main eQTL annotations. Grey beans represent the baseline categories. Blue beans
498 represent eQTLs. Black bars indicate average enrichment. Boxes show upper- and lower-bounds of
499 the 95% confidence interval of the mean. Red dots show enrichments for immune-related traits.
500 Horizontal red line indicates enrichment of 1, i.e. no enrichment.

501

502 **Figure 2. Coefficient Z-scores of the 45 GTEx annotations**

503 Barplot of coefficient z-scores for all GTEx annotations for schizophrenia (grey) and rheumatoid
504 arthritis (red). Bars are sorted from highest to lowest based on the results from schizophrenia.
505 Horizontal dotted line indicates Bonferroni threshold for 45 tests. Two asterisks indicate bars passing
506 Bonferroni correction for multiple testing.

507

508 **Figure 3. Coefficient Z-score of intersection between union of GTEx eQTLs and cell-type-specific** 509 **histone marks**

510 Top two graphs show coefficient Z-scores for schizophrenia. Bottom two graphs show the same for
511 rheumatoid arthritis. Grey bars indicate histone marks found in cells from the central nervous
512 system. Red bars represent histone marks found in cells from the immune system. From dark to light,
513 shades of the bars indicate histone marks H3K27ac, H3K4me1, H3K4me3, and H3K9ac. Vertical
514 dotted lines indicate separation between histone marks. One asterisk above the bars indicate
515 annotations passing FDR correction for multiple testing. Two asterisks indicate bars passing
516 Bonferroni correction for multiple testing. Horizontal dotted line indicates Bonferroni threshold for
517 101 tests.
