25   Abstract

26   Non-membrane bound organelles that behave like liquid droplets are widespread among

27   eukaryotic cells. Their dysregulation appears to be a critical step in several neurodegenerative

28   conditions. Here we report that Tau protein, the primary constituent of Alzheimer neurofibrillary

29   tangles, can form liquid droplets and therefore has the necessary biophysical properties to

30   undergo a liquid-liquid phase separation (LLPS) in cells. Consonant with the factors that induce

31   LLPS, Tau is an intrinsically disordered protein that electrostatically complexes with RNA to

32   form droplets that can be tuned by salt concentration and temperature and exhibit low interfacial

33   tension. Uniquely, the pool of RNAs to which Tau binds in living cells are tRNAs. This phase

34   state of Tau is held in 1:1 charge balance across large blocks of the protein and the nucleic acid

35   and forms optimal complexes at multiple RNA:Tau mass ratios. These features define a complex

36   co-acervate in which undergo free diffusion in their interior, despite the high concentration of

37   protein, and rapid exchange with their exterior environment. Counter to most closely packed

38   protein assemblies, the condensed phase state of Tau is not associated with changes in local Tau

39   conformations as verified by distance measurements across a pair of spin labels by pulsed dipolar

40   spectroscopy. In contrast, fibrillar states of Tau are accompanied by large changes in local Tau

41   conformations. Importantly, prolonged residency within a droplet results in the emergence of

42   detectable beta-structure by thioflavin labeling, suggesting that the droplet state can incubate Tau

43   and pre-dispose it toward beta sheet structures typical of insoluble Tau fibrils.

44

Introduction

46   Inclusions consisting of the Tau protein occur in many neurological conditions with

47   Alzheimer's disease the most prominent among them. Normally, Tau is in a kinetic equilibrium

48   between a microtubule bound and free state. Under disease conditions Tau self-assembles into

49   fibrils that eventually lead to highly insoluble polymeric inclusions known as neurofibrillary

50   tangles. The underlying biophysical basis for the transition of Tau from a microtubule-associated

51   protein to an insoluble fibril is unknown. However, a clue comes from the observation that

52   polyanions, such as heparin, promote Tau fibrillization [1]. Although less effectively, RNA can

53   also induce Tau fibrillization [2, 3], and unlike heparin, RNA is present intracellularly, making it

54   accessible to interact with Tau.

55   Our experiments began with the finding that Tau can bind RNA in living cells and

56   interestingly Tau-RNA binding shows selectivity for tRNAs. This observation along with the

57   known categorization of Tau as intrinsically disordered and its ability to spread from cell to cell

58   in a manner that resembles prions [4, 5], suggested that Tau might share additional properties

59   with other RNA binding proteins involved in neurodegeneration. These proteins include FUS [6],

60   TDP-43 [7], C9ORF72 [8, 9], hnRNPA2B1 and hnRNPA1 [10, 11] all of which can undergo

61   liquid-liquid phase-separation from the surrounding aqueous medium into droplets *in vitro*.

62   These highly protein dense structures, known in the chemical literature as complex coacervates

63   [12, 13], establish a liquid liquid phase state (LLPS) associated with (1) increasing protein

64   concentration, (2) tuning the salt concentration and temperature, (3) the presence of RNA

65   complexed to an intrinsically disordered protein and (4) low interfacial tension to promote fusion.

66   A consensus property of a complex coacervate is high internal fluid dynamics rooted in low

67   cohesive energy between the polyelectrolyte complexes and weakly bound water constituting the

68   fluid [13, 14]. Complex coacervate chemistry has facilitated bio-inspired coating, wet adhesion

69   and engulfment [15-17].

70   Here we show that Tau-RNA complexes have all the properties of a complex coacervate.

71   When multiple Tau molecules weakly bind RNA and overall charge matching is achieved

72   between the polycation, Tau, and polyanion, RNA, Tau undergoes condensation and phase

73   separation into micrometer sized droplets. Remarkably, within this liquid phase-separated state

74   Tau maintains internal segment mobility and a compact conformation between two spin labels

75   around the core region of Tau known as PHF6(*) despite the molecular crowding associated with

76   coacervation. In contrast, this region undergoes irreversible fibrillization in the presence of a

77   different polyanion, heparin, which induces full extension of Tau monomers and packs

78   monomers into β-sheet assemblies. The spontaneous and reversible droplet formation suggests

79   that Tau is held in a low energy-barrier fluid state between dilute solution and complex

80   coacervate condensate with the free energy difference toggled by interactions mediated by ions.

81   However, prolonged residence in this phase state begins to induce β-sheet formation suggesting

82   that the highly condensed phase state of Tau is a precursor to fibril formation.

83

84   Results

85   **Tau binds RNA in living cells**

86   RNA binding to Tau in living cells was examined by PAR-iCLIP using the human Tau-

87   specific antibody, HJ 8.5, in HEK 293T cells, human iPSC-derived neurons and retinoic acid-

88   differentiated neuroblastoma SH-SY5Y cells. The HEK 293T cells expressed wild type full-

89   length human Tau (4R2N), mutant Tau (P301L-4R2N) or mutant Tau fused to CFP (P301L,

90   4R1N) (Fig. 1a-b, Fig. S1, Fig. S2a-c). iPSC-derived neurons were derived from carriers of

91   4R2N Tau (Fig. 1c), P301L Tau or a risk variant for progressive supranuclear palsy, A152T. The

92   SH-SY5Y cells expressed both Tau and the short isoform of MAP2 called MAP2c [18] (Fig.

93   S2d). Strong binding of Tau to RNA was observed in all cells, as indicated by ^{32}P-labeled RNA

94   bands corresponding to immunoprecipitated and cross-linked Tau-RNA complexes (Fig. 1a-c,

95   lanes 2; Fig. S2a, lane 2). The radioactive Tau-bound RNA band was found to run as 30-100 nt

96   (data not shown). PAR-iCLIP experiments with varying RNase concentrations did not shift the

97   ^{32}P-labeled band, nor change its intensity (lanes 2-3 in Fig. S2b). These experiments indicate that

98   in contrast to most known RNA-binding proteins that bind to RNA as a smear over a range of

99   sizes, Tau binds specifically and dominantly to small RNAs or RNA fragments.

100   Because small RNAs are abundant and may engage in non-specific interactions, we

101   performed multiple confirmatory controls (Fig. S2b lanes 1, 4 and S2c lanes 3, 4), including

102   immunoprecipitation in HEK cells without Tau expression, without Tau antibody to rule out non-

103   specific binding and without UV exposure to eliminate the possibility that Tau-RNA complexes

104   formed *in vitro* after cell lysis. Various disease mutations of Tau had no effect on the binding to

105   RNA in either the HEK cells or the human iPSC-derived neurons. Although Tau and MAP2 are

106   highly homologous in their proline rich and microtubule binding domains, MAP2 did not bind

107   RNA (Fig. S2d, lane 3).

108   To identify the RNA types crosslinked to Tau, DNA libraries were prepared from the

109   immunoprecipitated radiolabeled bands and sequenced. In all experiments, the controls

110   consistently showed relatively few total reads and very few uniquely aligned reads (Fig. S2e-f).

111   We analyzed the distribution of Tau-bound RNA from the human genome by defining eight

112   regions: exons, introns, lincRNAs, snRNAs, rRNAs, miRNAs, tRNAs and intergenics. In Tau-

113   expressing HEK cells, tRNAs were overwhelmingly the highest category of RNA crosslinked to

114   Tau (Fig. 1d). Endogenous Tau in hiPSC-derived neurons also bound tRNAs; however,

115   background RNA from introns and intergenics were relatively abundant as well (Fig. 1e).

116   Background RNA sequences are common in all CLIP studies, particularly for atypical RNA

117   binding proteins [19]. Despite the abundance of tRNAs in cells however, background reads from

118   CLIP experiments consistently show a paucity of tRNAs. Correcting for background reads by

119   dividing the percentage of Tau-bound RNA by the percentage of nucleotides of each category in

120   the genome demonstrated a selective enrichment of tRNAs (Fig. 1f-g). The specific tRNA

121   species crosslinked to Tau overlapped extensively between HEK and hiPSC-derived neuron

122   samples. Of 625 annotated tRNA loci in the human genome, 462 tRNA genes crosslinked to Tau

123   in HEK cells with 79% of them observed in all four Tau CLIP samples and 94% in at least two

124   samples. In the hiPSC-derived neurons, all 231 tRNA genes identified were also observed in the

125   HEK cells and 119 of these were verified in at least two Tau CLIP samples. The distribution of

126   the cross-linked tRNAs in HEK and hiPSC-derived neurons differed from the distribution of the

127   total tRNAs. This difference indicated that the tRNAs selected by the CLIP experiment were not

128   randomly drawn from the total tRNA pool (Fig. S3a-b). Among the most differentially selected

129   tRNAs by CLIP was tRNA^{Arg} (Fig. S3c).

130   PAR-iCLIP can identify the cross-linked sites in the tRNAs. tRNA sequences extend

131   from the most 3' nucleotide of the tRNA to the covalently cross-linked site where the sequencing

132   terminates. In both HEK cells and hiPSC-derived neurons, the crosslink site was predominantly

133   located within the anti-codon loop (Fig. 2a-b, Fig. S4), followed by the T loop and in the D-loop,

134   both with far smaller frequencies. Overall there was a preference for single-strand segments of

135   tRNA as crosslink sites.

6

136

Tau-RNA Binding Affinity and Stoichiometry

138   A gel shift assay using recombinant wild type full-length human Tau (4R2N) induced a

139   shift in unacetylated tRNA^{Lys} (Fig. 3a), yielding a dissociation constant (K_d) for 4R2N Tau

140   binding to tRNA of 460 ± 47 nM (Fig. 3b). The derived Hill coefficient was 2.8, implying

141   cooperative binding of multiple Tau proteins to tRNA [20]. Isothermal titration calorimetry (ITC)

142   experiments independently confirmed the affinity of Tau binding to tRNA to yield $K_d = 735 \pm$

143   217 nM and 372 ± 9 nM for 4R2N and K18 Tau, respectively (Fig. 3c). The dissociation constant

144   for 4R2N Tau binding to a 43 nucleotide random RNA sequence still yielded a $K_d = 832 \pm 94$ nM

145   with a Hill coefficient of 2.6 according to a gel shift assay, suggesting that Tau effectively binds

146   RNA non-specifically *in vitro*, although there may be differences in binding affinity.

147   Our *in vitro* observation further suggested that Tau binds RNA in two stages, first

148   forming a protein dimer-RNA (P_2R) complex followed by a protein multimer-RNA ($P_{2n}R$)

149   complex, consistent with a two-stage RNA binding model reported for the protein AUF1 [21]

150   and hnRNP A1 [22]. The ITC titration experiments showed that both 4R2N and K18 Tau interact

151   with tRNA with the stoichiometry of a protein dimer (Fig. 3c, $n = 0.52 \pm 0.04$), while the gel

152   shift assay showed multiple bands corresponding to high molecular weight protein-RNA

153   complexes. These include a faster migrating band representing P_2R complexes populated at

154   lower Tau:tRNA molar ratio and a slower migrating band representing $P_{2n}R$ complexes

155   populated at higher Tau:tRNA molar ratios (Fig. 3d-e). The fraction of bound Tau (from the low

156   or high bands) was plotted as a function of Tau:tRNA molar ratios (Fig. 3f), and compared to the

157   theoretical binding saturation curves for 1:1 to 6:1 binding stoichiometries (Fig. 3f). At lower

158   Tau:tRNA molar ratios, Tau and RNA form complexes at a ~2:1 ratio, while at higher Tau:tRNA

7

159   molar ratios, Tau and tRNA form complexes at ratios up to 6:1. We conclude that tRNA is

160   capable of binding multiple Tau proteins in a multi-step process. Judging by the absence of

161   higher stoichiometric signatures in the ITC measurement that is less sensitive to binding events

162   associated with small changes in heat, Tau:tRNA complexes that exceed a ratio of 2:1 must rely

163   on weak interactions.

164

165   **Tau phase-separates in the presence of RNA**

166   Mixing of 4R2N or Δtau187 (similar to K18, see Methods section) constructs with tRNA

167   (25 kDa), poly(A) RNA (66~660 kDa) or poly(U) RNA (800~1000 kDa) reliably produced a

168   turbid solution under a wide range of Tau:RNA mass ratios and salt concentrations (Fig. 4a-e and

169   Fig. S5a-e). According to bright-field microscopy (Fig. 4a), droplets formed and phase separated

170   from the bulk aqueous phase with a clearly visible and highly spherical boundary. Tau droplets

171   were capable of merging into a single droplet with the complete and nearly instantaneous loss of

172   any boundary at the fusion interface, indicating that the droplets are fluidic with a relatively low

173   interfacial tension (a series of snapshots capturing the fusion of two droplets are shown in Fig.

174   4a). Confocal microscopy images of fluorescence-labeled Tau verify that Tau is exclusively and

175   homogenously contained within the droplet (Fig. 4b).

176

177   **Tau-RNA droplets form a complex coacervate phase**

178   Droplet formation follows from the mixing of two oppositely charged biopolymers at a given

179   pH—Tau and RNA. Systematic increase in the salt concentration decreased the number of Tau-

180   RNA droplets that eventually disappeared when the salt concentration was increased to 100 mM

181   or higher (Fig. 4c-d, Fig. S5a left panel). Droplet formation was maximal at Δtau187:tRNA

182   molar ratios of 8:1, Δtau187:poly(A) RNA molar ratios from 33:1 to 330:1 and Δtau187:poly(U)

183   RNA ratios from 267:1 to 333:1 (estimated from the molecular weight of RNAs, see Fig. S5c).

184   Remarkably, each of these stoichiometries converge to a Δtau187:tRNA charge ratio of ~1:1,

185   irrespective of the RNA type (Fig. 4e, Fig. S5a right panel). Droplet formation was also

186   observed with full length Tau 4R2N and RNA, but was less robust than with Δtau187, possibly

187   due to the additional negative charges at the N-terminal segment of Tau 4R2N that would

188   diminish the electrostatic association between Tau and RNA. However, at pH 6 where the net

189   charge of Tau 4R2N is similar to Δtau187, droplets reliably formed, though yielding lower

190   number densities, and were exquisitely sensitive to salt concentration (Fig. S5e). Even at NaCl

191   concentrations as low as 10 mM, the droplets dissolved. In cellular environments however,

192   additional factors—charged co-constituents or posttranslational modifications of Tau—may

193   strengthen Tau-RNA associations, rendering droplet formation more favorable at higher ionic

194   strengths. Together, these observations show that droplet formation is dominated by electrostatic

195   complexation between oppositely charged polyelectrolytes, while the shielding of their excess

196   charge (by the tuning of Tau:RNA ratio) is critical to form an extended assembly constituting the

197   droplets. From this we conclude that Tau-RNA droplet formation follows a complex

198   coacervation mechanism, initiated through non-specific complexation of oppositely charged

199   polyelectrolytes and driven by the further association of these polyelectrolyte complexes to form

200   a macroscopic fluid phase by relying on weak electrostatic attractions tuned by salt concentration

201   [23]. A crucial observation is that complex coacervate droplet formation is spontaneous and fully

202   reversible through the tuning of salt concentration and Tau:RNA ratios. The convergence of

203   different Tau constructs toward the shared property of complex coacervation with different RNA

9

204   species present at a common charge ratio of ~1:1 leads us conclude that complex coacervate-

205   driven droplet formation is an intrinsic property of Tau in the presence of RNA.

206

207   **Tau in condensed droplets is in a solution state**

208   Within a condensed complex coacervate, held together by non-specific and weak electrostatic

209   interactions, we expect the polyelectrolyte constituents to maintain their hydration layer and

210   remain dynamic [14, 24]. To spectroscopically track Tau exclusively from within the condensed

211   phase we first positively verified by confocal fluorescence imaging that Δtau187 was exclusively

212   localized within the droplet (Fig. 4b). This allowed us to characterize the droplet-internal protein

213   properties. First, continuous wave electron paramagnetic resonance (cw EPR) spectral line shape

214   analysis of singly spin labeled Δtau187 at cysteine site 322, Δtau187/322C-SL, diluted with

215   diamagnetically labeled Δtau187/322C-DL (see Methods), was used to compare the protein side

216   chain dynamics and degrees of freedom of the tethered spin label of Δtau187 in dilute solution

217   state (Fig. 4 red, f-h), in the droplet state associated with poly(A) RNA (blue, f) and tRNA (green,

218   g) and upon addition of the Tau aggregation inducer, heparin (black, h). Remarkably, the EPR

219   lineshape of Δtau187/322C-SL within the droplet phase was indistinguishable from the dilute

220   solution state (Fig. 4f vs. 4g). In contrast, the EPR line shape dramatically broadened within

221   minutes of adding heparin—a highly effective aggregation inducer of Tau [1, 25] (Fig. 4f vs. 4h).

222   This finding demonstrates that the condensation of Δtau187 to high protein concentration alone

223   does not effectively induce dehydration and aggregation of Tau, and that Tau remains dynamic

224   and hydrated and retains protein dynamical properties as found in solution state, despite forming

225   long-range associations with RNA in a highly condensed fluid phase.

10

226   To determine whether Tau assumes altered protein conformations in the complex

227 coacervate phase compared to the dilute solution phase, we compared the PHF6 and PHF6[*]

228 hexapeptide regions of Tau under these conditions. These regions of the Tau sequence pack into

229 the β-sheet core once fibrils are formed of Tau [26]. Previously, we identified that both the PHF6

230 and PHF6[*] hexapeptide regions of Tau undergo a dramatic opening from a compact to a fully

231 extended local conformation within minutes of adding heparin, well before fibril formation is

232 seen and remain extended as insoluble fibrils are formed (unpublished data). These local distance

233 measurements of the regions flanking the PHF6[(*)] regions offer a powerful tool to compare the

234 conformational state of Tau in dilute solution, droplet and aggregation-induced states. We

235 prepared a Δtau187 G272C/S285C-SL$_2$ construct that was doubly MTSL-labeled at sites 272 and

236 285 (see Methods) to access the distances across the PHF6[*] hexapeptide region by double

237 electron-electron resonance (DEER) spectroscopy. Surprisingly, the distances flanking the

238 PHF6* region remained unchanged from dilute solution state to when Tau was condensed into a

239 concentrated complex coacervate phase in association with poly(A) RNA and tRNA (Fig. 4i and

240 j). This contrasts with the effect of heparin on Tau that markedly extended the segment distances

241 (from ~3 to ~4 nm) between the labels, within minutes of heparin addition, corresponding to the

242 extended conformation that the PHF6[(*)] segment adopts in insoluble fibrils when neatly stacked

243 in β-sheets (Fig. 4k).

244   Interestingly, we observed a low-level Thioflavin T (ThT) signal under Tau-poly(U)

245 RNA droplet forming conditions (see Fig. S5f) that gradually increased with time over 12 hours.

246 This ThT signal was nearly entirely diminished at increased salt concentration at which Tau-

247 RNA associations are weakened and droplets are resolved. Still, the ThT intensity from the Tau-

248 RNA droplet samples, even after three days of incubation, was significantly smaller (less than

249   5%) compared to what was observed in the presence of the aggregation-inducing heparin under

250   similar charge ratio and mass concentration at any incubation time (Fig. S5f). Since ThT

251   intensity is commonly used as an assay to map β-sheet content, we suggest that droplet formation

252   through association with RNA increases the aggregation propensity of Tau *in vitro*, even while

253   the Tau-RNA complexes are held together by fully reversible weak interactions.

254

255   **Exogenous tRNA can induce sarkosyl insolubility of Tau**

256   To determine whether Tau-RNA complexes have the potential for pathological

257   interactions *in vivo*, hiPSC-derived neurons with a P301L mutation or wild type were transfected

258   with 20U tRNA per 1.2 million cells. Cell lysates (input) were prepared in a high salt/high

259   sucrose buffer, followed by fractionation in a 1% sarkosyl buffer. Transfection in the absence of

260   nucleic acids (mock) or addition of tRNA to the mock lysate (mock + tRNA) were used as

261   controls. Cells transfected with tRNA accumulated sarkosyl insoluble Tau, whereas cells without

262   added tRNA or when tRNA was added to the lysis buffer did not increase Tau in the insoluble

263   fractions (Fig. 5). The increase in sarkosyl-insoluble Tau populations occurred in both wild-type

264   and P301L Tau-containing cells when infected with tRNA.

265

266   Discussion

267   Tau can bind RNA in two stages, mediated by (i) strong binding at a Tau:RNA molar

268   ratio of 2:1 with nanomolar dissociation constants and (ii) weak association between Tau

269   multimers and RNA to form higher order complexes. Although Tau lacks a recognizable RNA-

270   binding motif, it bound tRNA as its dominant partner *in vivo*. Furthermore, Tau was found to

271   spontaneously phase separate upon non-specific complexation with RNA into dense protein

272   droplets, whose formation was reversibly and sensitively tunable by salt concentrations, as well

273   as the Tau:RNA ratios. Crucially, the optimal Tau:RNA molar ratios range from 8:1 to 330:1,

274   which varies among different RNA species. Remarkably, all higher order complexes converge to

275   a common Tau:RNA charge ratio of ~1:1, leading us to conclude that Tau-RNA droplet

276   formation is driven by electrostatic interactions underlying complex coacervation, in which

277   oppositely charged polyelectrolytes associate into extended assemblies held together by weak

278   electrostatic interactions and condense to a macroscopic fluid phase [14, 17, 27].

279   Crucially, Tau complexed with RNA in the highly condensed droplet state maintains the

280   dynamical and conformational signature of free Tau in solution state according to cw EPR and

281   DEER analysis around the β-sheet forming PHF6(*) segment of Tau, implying that small

282   changes in the free energy of Tau accompany its condensation to the droplet phase. At the same

283   time, a low-level ThT signal was observed from the Tau-RNA droplet samples after extensive

284   incubation time, though significantly weaker compared to from Tau solutions *en route* to fibrils

285   as initiated by the addition of heparin. Nevertheless, the implication that Tau droplets have some

286   propensity toward soluble β-sheet complexes suggests that complexation with RNA under

287   droplet forming conditions may be on pathway to fibrils. Consistent with this finding, tRNA

288   increased sarkosyl insolubility of Tau *in vivo*. We conclude that dynamic and free Tau species

289   are stored in the concentrated droplet state that, on the one hand is predisposed to convert to

290   fibrils, and on the other hand can spontaneously and reversibly dissolve into solution at increased

291   salt concentration. This previously unrecognized droplet phase state contrasts with that of Tau

292   following incubation with the polyanion, heparin, in which an irreversible transformation to

293   fibrils occurs and a large intra-Tau conformational change is observed in solution state preceding

294   fibril formation.

295   RNA generally promotes complex coacervation whereas heparin effectively promotes

296   fibrillization of Tau. The distinguishing effects between RNA (a polyphosphate) and heparin (a

297   polysulfate) on Tau—coacervation versus fibrillization—may be an operational principle of Tau-

298   polyanion association. Weak associations between multiples of Tau and RNA is consistent with

299   the consensus property of a coacervate phase in which the hydration layer of the polyelectrolyte

300   constituents remains intact, ensuring fluidity of the condensed phase, as well as reversibility

301   between the dilute and condensed phase [14]. The Tau droplet state fits this biochemical portrait,

302   so that Tau can reversibly and rapidly switch between the dilute solution and the dense droplet

303   state, while involving minimal rearrangement of hydration water and protein conformations. The

304   spontaneous complex coacervation from synthetic polyelectrolyte constituents can be entropy-

305   driven according to several studies [6, 23, 28-30]. We found that Tau-RNA complex

306   coacervation was enhanced at elevated temperatures, consistent with an entropy-driven reaction

307   (data not shown). In fact, the observation of solution state-like protein conformational dynamics

308   of Tau in the coacervate phase implies that the free energy penalty due to lowering of protein

309   configurational entropy from protein ordering is minimal in the droplet state, and thus the cost

310   for an entropy-driven complex coacervation reaction, paid by salt and/or water release, is small.

311   Given this insight, we conclude that the transformation to insoluble aggregates from Tau droplets

312   should be energetically more favorable than from dilute solution state, given the elevated protein

313   concentration in the complex coacervate phase. Along these lines ten Wolde and Frenkel [31]

314   have proposed that condensed liquid droplets serve as a "metastable crucible" to lower free

315   energy barriers for crystal nucleation, while the discovery of the involvement of nucleic acids in

316   coacervation-driven phase separation dates back to 1949 by Bungenberg de Jong [15]. Here, we

317   identify a new state of Tau in which soluble Tau is reversibly stored in concentrated complex

318   coacervate droplets, readily bioavailable for cellular functions or vulnerable to pathological

319   aggregation depending on the environmental cues at hand.

320

321   Materials and Methods

322   **Cell culture**

323   A total of eight samples were used for PAR-iCLIP studies. Four samples were human embryonic

324   kidney (HEK 293T) cells that expressed either 4R2N (residues 1-441) wild type *tau* (one

325   sample), 4R2N *tau* harboring the P301L mutation (one sample), and 4R1N *tau* harboring the

326   P301L mutation fused to CFP (2 samples). Four samples were neurons derived from human

327   induced pluripotent stem cells (hiPSCs) obtained by reprogramming dermal fibroblasts with

328   virally transduced Yamanaka factors [32] that expressed wild type *tau*, two harboring a P301L

329   *tau* mutation (with and without fused CFP) and one harboring the A152T variant [33, 34]. The

330   hiPSC lines were karyotyped by Cell Line Genetics. Both wild type and P301L were normal

331   males (46XY). A152T displayed a balanced three-way translocation of chromosomes 1, 13 and 7,

332   which most likely occurred during the reprogramming process (46XY, t(1;13;7)

333   (q31.2;q21;q36.3). Pluripotent cells were maintained in feeder-free conditions and cultured in

334   BD Matrigel (BD Biosciences) coated six-well plates and fed with mTSER daily (Stemcell

335   Technologies). Neuroectoderm differentiation utilized dorsomorphin and SB431542 (Sigma-

336   Aldrich) for a week [35]. When neural-rosettes were clearly observable, the media was gradually

337   replaced with neuronal induction media containing Knockout DMEM F12 with N2, and

338   Glutamax 1X supplemented with laminin (Sigma-Aldrich) and maintained for an additional six

339   days with every other day feeding. Neuro-rosettes were microdissected, and grown as

340   neurospheres in the neuronal induction media supplemented with B27. Neurons were

15

341   differentiated from neurospheres by dissociating them into individual cells enzymatically with a

342   1/1 mixture of 0.25% trypsin / StemPro accutase (Thermo Fisher), and plated on Poly-L-

343   Ornithin/Laminin coated six well plates at a density of 200,000 cells per well. Neuron

344   differentiation and maturation were stimulated by the addition of 10 mM each of NT3, BDNF,

345   and GDNF (Preprotech) to the neuronal growth media containing Neurobasal, N2 supplement,

346   B27 Supplement and Glutamax. Neurons were fed twice per week by replacing half of the

347   conditioned media with pre-warmed supplemented fresh media, and underwent maturation for at

348   least five weeks. SH-SY5Y Neuroblastoma cells were plated as monolayers in DMEM/F12

349   medium with 10% FBS at 1x 10^6 per 10 cm dish, and the cells switched to neurobasal medium

350   the next day and differentiated for seven days using 10 µM retinoic acid.

351

352   **Antibodies**

353   The Tau antibodies used were Tau-5 (1 mg/ml, Abcam); HJ 8.5 and HJ 9.2 (4.5 mg/ml and 2.8

354   mg/ml, both HJ antibodies are gifts from Dave Holtzman, Washington University); PHF-1 (gift

355   from Peter Davis, Albert Einstein College of Medicine), MAP2 antibody (0.3 mg/ml,

356   Proteintech^{TM}); CDK5 rabbit antibody (0.2 mg/ml, Santa Cruz); GFP rabbit antibody (5 mg/ml,

357   Abcam); β-Actin (Sigma-Aldrich); mouse IgG_1 Alexa 680, (2 mg/ml, Invitrogen); mouse IgG

358   Alexa 680 (2 mg/ml, Invitrogen); rabbit IgG 800 (1 mg/ml, Odyssey).

359

360   **PAR-iCLIP**

361   Cells were treated with 4-thiouridine (4SU) (Sigma-Aldrich) for 1h at a final concentration of

362   500 µM at 37°C, rinsed with ice-cold 1x PBS and irradiated one time with 400 mJ/cm^2 of

363   365 nm UV light on ice. 4-SU can enhance the cross-linking efficiency especially for proteins in

364   the cytoplasm [36-38]. The cells were centrifuged and the pellet stored at -80°C. The major steps

365   of PAR-iCLIP are listed in Fig. S6 and detailed in the supporting information. CLIP experiments

366   require an antibody, which can effectively immunoprecipitate Tau under stringent high salt wash

367   conditions. HJ 8.5 [39] raised against human Tau efficiently depleted Tau. With a dissociation

368   constant of 0.3 pM, HJ 8.5 pulled down Tau under the high-stringency purification conditions of

369   CLIP and remained bound to Tau throughout the procedure. Control experiments with GFP or

370   CDK5 antibody for the lysate expressing those proteins, or with HJ 8.5 antibody for lysates

371   without expressing Tau were always done in parallel to rule out false positive binding caused by

372   the beads. After immunoprecipitation, the cross-linked RNA was radiolabeled, the protein

373   separated on an SDS-PAGE gel, and transferred to nitrocellulose membrane and blotted. The

374   RNA-protein complexes from CLIP experiments (Fig. 1a-c) were cut from the blot, and the RNA

375   extracted followed by reverse transcription for library preparation [36]. The ^{32}P-labeled RNA

376   band was run on a polyacrylamide Tris-Borate Urea (TBU) denaturing gel to demonstrate the

377   confirm the size of the complex.

378

379   **Library preparation, deep sequencing and bioinformatics analysis of iCLIP**

380   The iCLIP libraries contained an experimental and a random barcode, which allowed

381   multiplexing and the removal of PCR duplicates. After the barcodes were introduced, sample and

382   control from one set of experiments were mixed to remove batch-to-batch variation. Libraries

383   were sequenced on an Ion Torrent Proton. Fastx collapser from FASTX-Toolkit was used to

384   collapse reads and filter replicates resulting from the PCR based on the random barcode. Reads

385   were separated into samples by the barcodes at the 5` ends of reads. The reverse transcription

386   primers sequences at both ends of the reads were trimmed with Cutadapt [40]. After trimming

387   the barcodes, reads with 18 bps or more were kept and counted as total unique reads, and aligned

388   to the human genome (hg19) by Bowtie2 [41]. RseQC [42] was used to evaluate the quality of

389   sequencing and mapping reads. Alignments with scores equal or greater than ten were kept for

390   downstream analysis. Reads from these RNA pools were clustered by their alignments, and

391   Pyicos tools [43] were used to identify the significant clusters. Clusters with at least five reads

392   were retained and considered to contain target sites for RNA-Tau crosslinking. Gene models for

393   RefSeq mRNAs, tRNAs, rRNAs were downloaded from the UCSC genome browser. miRNAs

394   were downloaded from miRBase (release 20) and other categories of RNAs were download from

395   Ensemble (release 73). Cross-link sites were identified as the termination site of the sequencing

396   based on the iCLIP protocol [44]. Individual tRNA genes from the UCSC genome browser were

397   predicted by using tRNAscan-SE v.1.23. The secondary structure for each tRNA was obtained

398   from GtRNAdb (http://gtrnadb.ucsc.edu/).

399

400   **Deep sequencing and analyses of small RNA expression in HEK cells and hiPSC-derived**

401   **neurons**

402   Small RNAs were extracted from HEK cells and hiPSC-derived neurons using miRNA isolation

403   kit (mirVana^{TM}. Library preparation was adapted from the Ion RNA-seq v2 (Thermo Fisher)

404   protocol. cDNAs with size range from 30-100 bp were selected and sequenced. Reads were

405   aligned to both human genomes and tRNA sequences. When mapping reads to tRNA sequences,

406   the Bowtie read aligner [45] protocol was used, in which a maximum of two mismatches were

407   allowed. Reads aligned to tRNAs were counted and analyzed with a custom Perl scripts.

408

409   **Recombinant Tau and Tau fragments**

18

410   Full length recombinant human 4R2N Tau, N-terminal truncated, microtubule binding domain

411   containing, K18 Tau (residues 244-372) and Δtau187 (residues 255-441 with a His-tag at the N-

412   terminus) were used for *in vitro* studies. Methods for expression and purification of all

413   recombinant Tau variants are detailed in the supplementary text. Two variants of Δtau187 were

414   prepared via site-direct mutagenesis: Δtau187/322C contains a C291S mutation, leaving only one

415   cysteine at site 322, and Δtau187G272C/S285C contains C291S, C322S, G272C and S285C

416   mutations, leaving two cysteines at sites 272 and 285).

417

418   **RNA gel mobility shift assay**

419   The gel shift assay was performed with recombinant full length 4R2N Tau and

420   chromatographically purified unacetylated yeast $tRNA^{Lys}$ (tRNA Probes) in 100 mM sodium

421   acetate buffer at pH 7.0. The molar concentration of $tRNA^{Lys}$ was accurately re-measured with

422   UV spectrophotometry after base-hydrolization to account for the hyperchromic effect from the

423   secondary and tertiary structure of tRNA [20]. RNA43 was purchased in a kit (Pierce) with the

424   sequence 5'-CCUGGUUUUUAAGGAGUGUCGCCAGAGUGCCGCGAAUGAAAAA-3' to

425   represent a random sequence. The hydrolyzed tRNA and RNA43 samples were then quantified

426   with UV spectrophotometry at 260 nm using an extinction coefficient of 0.025 $(\mu g/ml)^{-1}cm^{-1}$. For

427   the gel shift assay, protein was incubated with tRNA at 37℃ for 10 minutes in the presence of

428   0.5 mM EDTA, 0.5 mM $MgCl_2$, 2 U SUPERase• In™ RNase Inhibitor (Thermo Fisher), 0.01%

429   IGEPAL CA-630 (Sigma-Aldrich), and then applied to a TBE 8% Polyacrylamide Gel (Thermo

430   Fisher). After gel separation, tRNA was stained with SYBR Gold II (Thermo Fisher). For

431   quantitative analysis, the fraction of free and bound tRNA was quantified in ImageJ2 (National

432   Institute of Health).

433

Isothermal Titration Calorimetry (ITC) experiments

434

435 Full length Tau or the K18 Tau were dialyzed overnight into a specified buffer for ITC (20 mM

436 ammonium acetate, pH 7). tRNA (from Baker's yeast, Sigma-Aldrich) was re-suspended in the

437 ITC buffer and concentration determined using a Nanodrop 1000 (Thermo Scientific).

438 Experiments were run on a Nano ITC (TA Instruments), in which 300 μM tRNA was titrated (5

439 μl injections) into a 1 ml protein solution of 30 μM Tau. Data was analyzed using the

440 NanoAnalyze v3.6 software (TA Instruments). After substracting the heat generated by tRNA

441 titration into empty buffer, the experimental data was fitted with an Independent binding model.

442 Experiments were repeated in triplicates and standard error of the mean reported.

443

444 **Spin labeling of Δtau187**

445 To achieve labeling with paramagnetic or diamagnetic probes, the protein was dissolved in 6 M

446 guanidinium hydrochloride and labeled overnight at 4°C using a 20-fold molar excess of the spin

447 label (1-oxyl-2,2,5,5-tetramethylpyrroline-3-methyl) methanethiosulfonate (MTSL, Toronto

448 Research Chemicals) or the diamagnetic analog of MTSL (1-Acetoxy-2,2,5,5-tetramethyl-δ-3-

449 pyrroline-3-methyl) methanethiosulfonate (Toronto Research Chemicals). Excess label was

450 removed using a PD-10 desalting column (GE Healthcare) equilibrated in a 20 mM ammonium

451 acetate buffer at pH 7.0. The protein was concentrated using a 3 kDa centrifugal filter (Amicon

452 UFC800396). The final protein concentration was determined by UV-Vis absorption at 274 nm

453 using an extinction coefficient of 2.8 $cm^{-1}mM^{-1}$, calculated from extinction coefficient of

454 Tyrosine [46]. The two variants Δtau187/322C and Δtau187G272C/S285C were spin labeled

455 with paramagnetic MTSL probes at the one or two cysteine sites, and are respectively referred to

456 as Δtau187/322C-SL and Δtau187G272C/S285C-SL$_2$. In order to achieve spin dilution,

457 Δtau187/322C and Δtau187G272C/S285C were also labeled with the diamagnetic analogue of

458 MTSL probes, and are referred to as Δtau187/322C/322C-DL and Δtau187G272C/S285C-DL$_2$.

459 Images in Fig. 4a-b were taken using 400 μM Tau, 800 μg/ml poly(A) RNA and 30% glycerol in

460 20 mM ammonium acetate at pH 7.

461

462 **Preparation of Tau-RNA complex coacervate**

463 Droplets were formed in the 20 mM ammonium acetate buffer with NaCl concentration varying

464 between 0 and 100 mM and glycerol concentration from 0 to 50% v/v. Solutions of Δtau187 or

465 full length 4R2N Tau was mixed with tRNA (Baker's yeast, Sigma-Aldrich), poly(A) RNA or

466 poly(U) RNA (Sigma-Aldrich) at varying protein, RNA, NaCl and glycerol concentrations in a

467 0.6 ml Eppendorf tube. RNAs were weighted out as powder and the mass concentration was

468 calculated. The Tau:RNA mass ratio, the total concentration of Tau and RNA, as well as the

469 NaCl salt concentration were optimized to maximize droplet formation, while choosing a total

470 biopolymer density to avoid overlapping of droplets in the images to simplify the calculation of

471 droplet coverage. Microscopy images were acquired at 10 minutes after mixing. A concentration

472 of 19% v/v for the viscogen glycerol was determined to be an optimal concentration to ensure

473 cryoprotection for DEER measurements carried out at ~80 K, while also ensuring maximal

474 droplet formation at room temperature (Fig. S5b).

475 The charge of a peptide at a given pH was estimated by applying an algorithm adapted from

476 Innovagen's Peptide Property Calculator (http://pepcalc.com/). All residues were assumed to

477 have pKa values that are equivalent to the isolated residues (CRC Handbook of Chemistry and

478 Physics, 87th ed). Charges of the C-terminus or N-terminus were estimated as -1 and +1,

479   respectively at both pH 6.0 and pH 7.0. The processing code is made available as supplementary

480   files on the free web (https://github.com/yanxianUCSB/PeptideChargeCalculator).

481

Bright-field microscopy of Tau-RNA droplets

483   Immediately after mixing Tau in a 0.6 ml Eppendorf tube with RNA under droplet forming

484   conditions (established above) and ensuring thorough mixing, 1 µl of this mixture was applied to

485   a microscope slide that is closed with a cover slide gapped by two layers of double-side sticky

486   tape to generate a liquid sample region with consistent thickness. The microscope slide was kept

487   at room temperature for 10 minutes with the cover slide facing down, during which the particles

488   within the liquid sample region settled down onto the surface of the cover slide. Images were

489   taken with a 12-bit CCD camera across the entire sample liquid region near the surface of the

490   cover slide using an inverted compound microscope (Olympus IX70). Before imaging, Köhler

491   illumination was applied and the focus close to the surface of the cover slide optimized to

492   enhance the contrast between the dark droplets and the bright background.

493

Confocal microscopy of Tau-RNA droplets

495   For confocal microscopy, Δtau187/322C was fluorescently labeled (Δtau187/322C-FL) with

496   Alexa Fluor 488 C_5 Maleimide (Thermo Fisher) at the same 322 site as Δtau187/322C-SL. 50

497   µM of Δtau187/322C-FL was mixed with 350 µM Δtau187/322C-SL at a 1:7 molar ratio in order

498   to prevent saturation. 800 µg/ml of poly(A) RNA was further added to this Tau solution,

499   resulting in droplet formation in the 20 mM ammonium acetate buffer and in the presence of 20

500   mM NaCl. 10 µL of the mixture was pipetted and put on a microscope slide with a cover slide

501 gapped by double-sided sticky tape. Confocal images were acquired using a spectral confocal

502 microscope (Olympus Fluoview 1000).

503

504 **Droplet quantification from image analysis**

505 To quantify the amount of droplet formed under the given experimental condition of interest,

506 images were taken by a 12-bit CCD camera of an inverted compound microscope (Olympus

507 IX70), and recorded in TIF format. With illumination and focus optimized, droplets settling on

508 the cover slide have lower intensity than their surrounding on the images. An image of the 20

509 mM ammonium acetate buffer was taken to calculate the average intensity to set as threshold in

510 order to classify different parts of the image into droplets and buffer. For each image, the area of

511 the droplets was divided by the total area of the image, generating a % droplet coverage value on

512 the cover slide. Droplets with eccentricity above 0.9 or equivalent diameter below 1 μm were

513 filtered out in order to reduce false reading. The MATLAB code is made available as

514 supplementary files on the free web (https://github.com/yanxianUCSB/DropletAnalysis).

515

516 **Continuous wave (cw) Electron Paramagnetic Resonance (EPR)**

517 Cw EPR relies on the anisotropy of nitroxide radical's Larmor frequency and hyperfine coupling

518 that makes its lineshape highly sensitive to the local dynamics, orientation and confinement of a

519 nitroxide-based spin label tethered to the protein. Cw EPR measurements were carried out with

520 Δtau187/322C-SL using a X-band spectrometer operating at 9.8 GHz (EMX, Bruker Biospin)

521 and a dielectric cavity (ER 4123D, Bruker Biospin). Samples were prepared by either mixing

522 200 μM Δtau187/322C-SL with 300 μM unlabeled Δtau187/322C (to generate 40% spin labeled

523 sample) or by using 500 μM Δtau187/322C-SL (100% labeled). Viscogen was added to the

524   sample to achieve either 19% v/v glycerol (for the droplet samples) or 30% v/v sucrose (for the

525   aggregated samples) matching the DEER conditions. Tau samples under droplet forming

526   condition were prepared by adding 1.5 mg/ml RNA, and Tau samples under aggregation-

527   inducing conditions prepared by adding 125 μM heparin (11 kDa average MW, Sigma-Aldrich).

528   A sample of 3.5 μL volume was loaded into a quartz capillary (VitroCom, CV6084) and sealed

529   at one end with critoseal and the other with beeswax, and then placed in the dielectric cavity for

530   measurements. Cw EPR spectra were acquired using 2 mW of microwave power, 0.3 gauss

531   modulation amplitude, 150 gauss sweep width and 25 scans for signal averaging.

532

533   **Double Electron Electron Resonance (DEER)**

534   DEER measurements were performed on a Q-band pulsed EPR spectrometer operating at 32

535   GHz (E580, Bruker Biospin) equipped with a QT2 resonator (measurements done by courtesy of

536   Bruker Biospin). Samples were prepared by mixing 50 μM Δtau187G272C/S285C-SL$_2$ with 500

537   μM analog-labeled Δtau187G272C/S285C-DL$_2$ at a 1:10 molar ratio to achieve spin-dilution and

538   avoid artifacts from unwanted inter-protein spin distances. For DEER, Tau samples under droplet

539   forming condition were prepared by adding 1.65 mg/ml RNA and ensuring 19% v/v glycerol

540   concentration, and Tau samples under aggregation-inducing conditions prepared by adding 137.5

541   μM heparin and ensuring 30% v/v sucrose concentration. 40 μL samples containing 550 μM

542   concentration of Tau were loaded into a quartz capillary (2.4 mm od x 2 mm id) and flash frozen

543   in liquid nitrogen after 20 minutes of incubation at room temperature. DEER measurements were

544   conducted using the dead-time free four-pulse DEER sequence at 80 K, using 22 ns (π/2) and 44

545   ns (π) observe pulses and a 30 ns (π) pump pulse. The raw DEER data was processed using

546   Gaussian fitting via DeerAnalysis2013 [47].

547

Quantification of fibril using Thioflavin T assay

549   18 μM Δtau187 was mixed with 100 μg/ml poly(U) RNA and incubated at room temperature at

550   presence of 4 μM Thioflavin T for over 3 days with or without additional 100 mM NaCl.

551   Fluorescence at 485 nm was measured via Infinite 200 Pro plate reader (Tecan).

552

Transfer RNA transfection

554   Neuronal cultures were transfected with 20U of bovine liver tRNA (Sigma-Aldrich) per six well

555   plate using lipofectamine 2000 transfection reagent (Thermo Fisher) following the

556   manufacturer's protocol. Control cells were transfected in equal conditions in the absence of

557   nucleic acid (Mock transfection). Mock transfected cells were lysed as described below, with or

558   without 20U tRNA added to the lysis buffer.

559

Sarkosyl insolube Tau isolation and western blotting

561   Separation of sarkosyl insoluble Tau was done as described in the literature [48, 49]. Briefly,

562   adherent neuronal cell cultures were lysed with an ice-cold high salt/high sucrose Tris HCl buffer

563   (0.8 M NaCl, 10% Sucrose, 10 mM Tris HCl pH 7.4) containing a 1X Protease Inhibitor Cocktail,

564   and a 1X Phosphatase Inhibitor Cocktail. Lysis proceeded at 4°C for 30 min before detachment

565   with a cell scraper, followed by mechanical dissociation using a micropipette. Immediately

566   afterwards, the lysates were centrifuged at 4°C 3000 x g for 15 min in a microcentrifuge. The

567   clear supernatants were collected and sampled (Input). Sodium lauroyl sarcosinate (Sigma-

568   Aldrich) was then added to the supernatants to a final concentration of 1%, followed by a brief

569   vortexing. Samples were incubated at 4°C with continuous rocking. Samples were then

570   centrifuged at 4°C for 2 h at 170000 x g in a Beckman Coulter 70.1 Ti rotor. Sarkosyl soluble

571   supernatants (Sol.) were collected. Sarkosyl insoluble (Ins.) pellets were resuspended in 2X

572   sample loading buffer (250 mM Tris HCl pH 6.8, 10% Glycerol, 10% SDS, 0.5% bromophenol

573   blue, 20 mM DTT) and heated to 95°C for 10 min. The previously collected input and the

574   sarkosyl soluble fractions were diluted with the same sample loading buffer, and heated under

575   similar conditions. Proteins were separated on a 10% SDS-PAGE, transferred to Nitrocellulose

576   membranes, and blotted with either PHF-1 or β–actin antibody.

577

578   **Data availability**

579   The data that support the findings of this study are available from the corresponding authors on

580   request.

Figure 3

**Fig. 3: Tau tRNA binding by gel shift assay and ITC.** (a) Direct titration experiment shows

full length protein Tau induces a mobility shift in tRNA^{Lys}. (b) The fraction of bound tRNA

plotted as a function of the monomeric Tau concentration and fit to the Hill equation, y = 1/ [1+

623 $(K_d / x)^n$. (c) Yeast tRNA was titrated into solutions of K18 Tau in an ITC experiment. The top

624 panels show the raw incremental-titration. The area under each peak is integrated and plotted

625 against the molar tRNA:Tau ratio and fitted to an independent binding model (the bottom panel).

626 (b-c) Standard error of the mean (SEM) is reported, n=3. (d) Stoichiometry shift assay varying

627 full length protein Tau:RNA molar ratio while tRNA in 2.6 µM. (e) Fraction of bound tRNA in d

628 is plotted over the molar Tau:tRNA ratio. (f) Fraction of bound Tau plotted as a function of

629 Tau:tRNA molar ratios and compared to the theoretical saturation binding curves (dotted

630 lines) with 1:1 to 6:1 protein:RNA molar stoichiometry.

Figure 4
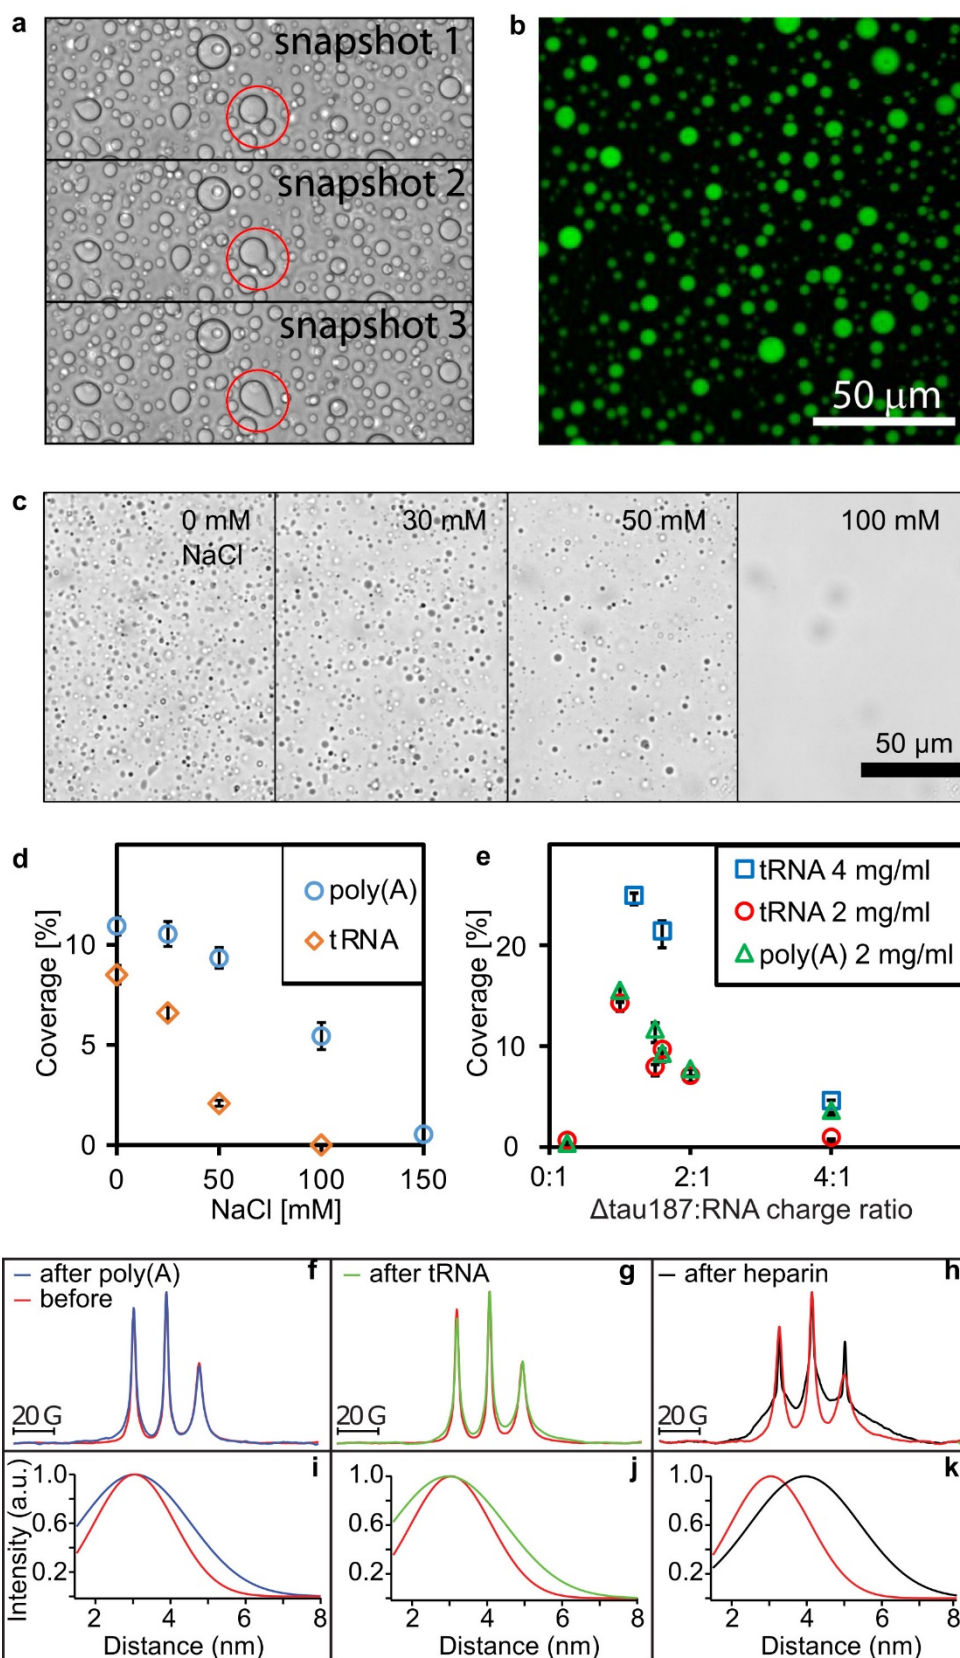

632   **Fig. 4: Tau and RNA forms droplet *in vitro*.** (a) Bright field snapshots of droplets from

633   Δtau187 and poly(A) showing two droplets seamlessly fusing (highlighted with red circle). (b)

634   Confocal microscopy image of Δtau187 labeled with Alexa-488 in the droplets as in (a). c)

635   Representative bright-field images of Tau-RNA droplet with varying [NaCl]. d) Droplet

636   coverage with poly(A) or tRNA with varying [NaCl] and e) varying Δtau187: RNA charge ratios.

637   Δtau187:RNA in c-d were maintained at a charge ratio of 1.2:1 and a total mass concentration of

638   2 mg/ml. Error bars in (d) and (e) represent the standard deviation from n=3. (f-k) CW EPR

639   spectra obtained at room temperature of Δtau187 in droplets formed with 1.5 mg/ml poly(A)

640   RNA (f) and 1.5 mg/ml tRNA (g) is unaltered from solution before adding RNA. CW EPR line

641   shape upon adding 125 μM heparin (h) show dramatic line broadening. DEER of Δtau187-SL$_2$ in

642   droplets formed with 1.5 mg/ml poly(A) RNA (i) and 1.5 mg/ml tRNA (j), as well as upon

643   incubation with 137.5 μM heparin (k).

644

644

Figure 5
645

646 **Fig. 5: tRNA transfection accumulates sarkosyl insoluble Tau in hiPSC derived neurons.** (a)

647 Cells transfected with tRNA but not cells transfected in the absence of nucleic acids (Mock, lane

648 3) present an evident accumulation of sarkosyl insoluble Tau (tRNA, lane 9). Addition of tRNA

649 to the lysis buffer is insufficient to increase the Tau present in the insoluble fractions (Mock +

650 tRNA, lane 6). (b-c) Quantification of PHF-1 Tau (b) and β-actin (c) level are shown. Error bar

651 represents standard error of the mean. * p < 0.05, n=5.
