Vibrio natriegens has recently emerged as an alternative to *Escherichia coli* for molecular biology and biotechnology, but low-efficiency genetic tools hamper its development. Here, we uncover how to induce natural competence in *V. natriegens* and describe methods for multiplex genome editing by natural transformation (MuGENT). MuGENT promotes integration of large genome edits at high-efficiency on unprecedented timescales, which will extend the utility of this species for diverse applications.

V. natriegens is the fastest growing organism known, with a doubling time of <10 min[1,2]. With broad metabolic capabilities, lack of pathogenicity, and its rapid growth rate, it is an attractive alternative to *E. coli* for diverse molecular biology and biotechnology applications[3]. Methods for classical genetic techniques have been developed for *V. natriegens*, but these are relatively laborious, require multiple steps, and must be used sequentially to generate multiple genome edits[3]. The challenges of these techniques contrast with the ease of genetics in *Vibrio* species that are naturally transformable. Competent *Vibrio*s can take up DNA from the environment and integrate it into their genome by homologous recombination; processes known as natural competence and natural transformation, respectively[4-7]. The inducing cue for natural transformation in competent *Vibrio*s is growth on the chitinous shells of crustacean zooplankton, which are commonly found in the aquatic environment where these microbes reside[4]. Chitin induces

1   the expression of the competence regulator TfoX[8,9]. In fact, overexpression of TfoX obviates

2   the need for chitin induction, allowing competent *Vibrios* to be naturally transformed in

3   rich media[4,8].

4

5   As no reports of natural transformation existed for *V. natriegens*, we first sought to

6   establish whether this was possible. Unlike naturally competent *V. cholerae*, incubation on

7   chitin did not lead to detectable transformation in *V. natriegens* (data not shown). However,

8   ectopic expression of TfoX (either the endogenous *tfoX* gene or one from *Vibrio cholerae*)

9   on an IPTG-inducible plasmid (pMMB) supported high rates of natural transformation (**Fig.**

10   **1a**). This was tested using a linear PCR product that replaces the gene encoding the DNA

11   endonuclease Dns with an antibiotic resistance (Ab^R) marker. The *dns* locus was used as a

12   target for transformation assays throughout this manuscript because loss of this gene does

13   not impact growth or viability in rich medium. Under optimal conditions ~1-10% of the

14   population had integrated the transforming DNA (tDNA), which matches the highest rates

15   of transformation observed among competent species[10] (**Fig. 1a-c**). Natural transformation

16   of *V. natriegens* required very little transforming DNA (tDNA) (highly efficient with even 1

17   ng / 10^8 CFU) and was dependent on the length of homologous sequence surrounding the

18   mutation (**Fig. 1b and c**). This method could also be used to introduce point mutations into

19   *V. natriegens* (tested with tDNA containing an *rpsL* K43R Sm^R allele); however, this activity

20   was partially suppressed by the mismatch repair system (**Fig. 1d**).

21

22   Having demonstrated *V. natriegens* is naturally competent, we sought to determine if we

23   could use natural transformation to perform scarless multiplex genome editing by natural

24   transformation (MuGENT)[11]. MuGENT operates under the premise that under competence

25   inducing conditions, only a subpopulation of cells is transformable. Those cells that can be

26   transformed, however, have the capacity to take up and integrate multiple tDNAs[11,12]. Thus,

27   during MuGENT, cells are incubated with two types of linear tDNA; (1) a selected product

28   that introduces an antibiotic resistance marker into the genome and (2) unselected

29   products that introduce scarless genome edits of interest at one or more loci.

30

1   We first tested the ability of MuGENT to introduce a single unmarked genome edit (also

2   known as cotransformation). To facilitate measurement of cotransformation, we noted this

3   species forms opaque colonies on agar plates (**Fig. S1**), which could be due to the

4   production of a capsular polysaccharide. Consistent with this, inactivating a homolog of the

5   essential capsule biosynthesis gene *wbfF*[13] resulted in the formation of transparent

6   colonies on agar plates and loss of expression of a high molecular weight polysaccharide

7   (**Fig. S1**). Thus, to test cotransformation we used an unselected product to replace ~500 bp

8   of the 5' end of the *wbfF* gene with a premature stop codon and scored cotransformation

9   via colony morphology (opaque vs. transparent) on agar plates. We found that

10   cotransformation was remarkably efficient in *V. natriegens* (up to ~80%), even with low

11   amounts (~25-50 ng / 10^8 CFU) of the unselected product (**Fig. S2a**). Also,

12   cotransformation with 1 kb flanks on the unselected product was possible, but at ~6-fold

13   lower frequencies than with 3 kb flanks (**Fig. S2a**).

14

15   We next tested the full multiplex genome editing capacity of MuGENT to simultaneously

16   cotransform multiple scarless genome edits into the genome in a single step[11,14]. Since

17   there is no selection for integration of the unselected genome edits *in cis* during MuGENT,

18   output populations are highly heterogeneous and individual mutants contain any number

19   and combination of the multiplexed genome edits. Also, this process can be carried out in

20   multiple iterative cycles to further increase the complexity of genome edits in the

21   population (**Fig. 2a**)[11].

22

23   As an initial test of multiplex genome editing, we targeted 5 genes whose mutagenesis was

24   considered unlikely to affect viability or growth in LB. These targets included four

25   carbohydrate transporters (specific for mannitol, fructose, sucrose, and trehalose – all of

26   which are absent in LB) and the *dns* gene. All genes were targeted for inactivation by

27   replacing ~500 bp of the 5' end of each gene with a premature stop codon. Integration of

28   genome edits was determined by multiplex allele-specific colony PCR (MASC-PCR)[15] (**Fig.**

29   **S2b**). Following one cycle of MuGENT, we found that ~70% of the population contained at

30   least 1 genome edit, with ~25% of the population containing 3-4 genome edits (**Fig. S2c**). A

31   quadruple mutant from this experiment was isolated and whole genome sequencing did

1   not reveal any off target mutations in this strain. Thus, MuGENT rapidly generated *V.*

2   *natriegens* strains with multiple large (0.5 kb) scarless genome edits at high-efficiency

3   without off-target effects, and can be used to make highly complex mutant populations.

4

5   As a second demonstration of multiplex genome editing, we demonstrated its utility in

6   metabolic engineering by attempting to rapidly enhance production of a value-added

7   chemical in *V. natriegens*. This species naturally accumulates low levels of the bioplastic

8   precursor poly-β-hydroxybutyrate (PHB) as a storage polymer[16]. PHB is derived from the

9   condensation and subsequent NADPH-dependent reduction of acetyl-CoA precursors[17].

10 Thus, for our targets, we tuned the expression (swap P_{native} for IPTG-inducible P_{tac}) or

11 inactivated genes that we hypothesized would affect NADPH and/or acetyl-CoA availability.

12 The targets for promoter swaps were the PHB synthesis operon (*phaBAC*), NAD kinase

13 (*nadK*), and two transhydrogenases (*pntAB* and *udhA*), while targets for inactivation were

14 phosphoglucose isomerase (*pgi*), citrate synthase (*gltA*), phosphotransacetylase (*pta*),

15 isocitrate lyase (*aceA*), and lactate dehydrogenase (*ldhA*) (**Fig. 2b**). Thus, there were 512

16 possible combinations for these 9 genome edits. We performed multiple cycles of MuGENT

17 to introduce these genome edits into a competent population of *V. natriegens*. At each cycle,

18 the selected product was designed to swap the Ab[R] marker at the *dns* locus to maintain

19 coselection at each step. Following four cycles of MuGENT, which took just 5 days to

20 perform, ~50% of the population had 3 or more genome edits and ~10% contained 5+

21 genome edits (**Fig. 2c**). To select mutants with increased PHB production, we then plated

22 this output population onto media containing Nile red, which stains PHB granules[18]. Nile

23 red fluorescence on these plates was highly heterogeneous, suggesting that some

24 genotypes produced more PHB than the parent isolate (**Fig. 2d**). A number of highly

25 fluorescent colonies were picked and the genotypes determined by MASC-PCR. Also, PHB in

26 these select strains was directly measured by HPLC. Cumulatively, these analyses rapidly

27 revealed genotypes that produced ~100-fold more PHB than the parent and ~3.3-fold

28 more than a strain with just the P_{tac}-*phaBAC* mutation (**Fig. 2e**).

29

30 While many methods for multiplex genome editing in bacterial systems have been

31 described[19], many of these are limited to small changes such as SNPs. MuGENT, on the

1   other hand, can efficiently swap, insert, or remove whole promoters or coding sequences as

2   demonstrated above. Furthermore, one of the major limitations to other multiplex genome

3   editing methods is that mutagenesis must be performed in strains lacking DNA repair

4   pathways to allow for high-efficiency integration of genome edits, which results in a large

5   number of off-target mutations[15,19]. MuGENT in *V. natriegens* is performed in DNA repair

6   sufficient backgrounds, thus, little to no off target mutations are introduced during the

7   procedure as indicated above. Also, unlike other multiplex editing approaches, MuGENT

8   requires no specialized equipment and, thus, has the potential to make multiplex genome

9   editing commonplace.

10

11 In conclusion, this study demonstrates that MuGENT is a rapid, efficient, and simple tool for

12 engineering the *V. natriegens* genome. This microbe is already being developed as an

13 alternative to *E. coli*, and we believe that the ease and speed of MuGENT will extend the use

14 of *V. natriegens* as a novel chassis for diverse molecular biology and biotechnology

15 applications.

SUPPLEMENTARY ONLINE INFORMATION

ONLINE METHODS

Bacterial strains and culture conditions

The parent *V. natriegens* strain used throughout this study was a spontaneous rifampicin-resistant derivative of ATCC14048[1]. For a list of all strains used / generated in this study, see **Table S1**. Strains were routinely grown in LB+v2 salts (LBv2)[2], which is LB Miller broth (BD) supplemented with 200 mM NaCl, 23.14 mM MgCl$_2$, and 4.2 mM KCl. LBv2 was supplemented with 100 µM IPTG, 50 µg/mL kanamycin (Kan), 200 µg/mL spectinomycin (Spec), 100 µg/mL rifampicin (Rif), 100 µg/mL streptomycin (Sm), or 100 µg/mL carbenicillin (Carb) as appropriate.

Generation of mutant strains and constructs

Mutant constructs were generated by splicing-by-overlap extension (SOE) PCR exactly as previously described[3]. Briefly, for three-piece mutant constructs (i.e. for constructs where a gene of interest is replaced with an Ab^R cassette or where the native promoter is swapped for a P$_{tac}$ promoter) segments were designated UP, MIDDLE, and DOWN and correspond to: (1) UP = the upstream region of homology amplified with F1 and R1 primers, (2) DOWN = the downstream region of homology amplified with F2 and R2 primers, and (3) MIDDLE = the Ab^R marker or promoter swap fragment. For two-piece mutant constructs (i.e. for constructs where ~501 bp of the 5' end of a gene is replaced with a stop codon), the mutation of interest is incorporated into the R1 and F2 primers used to amplify the upstream and downstream regions of homology, respectively. Gel purified segments were then mixed in equal ratios and used as template for a SOE PCR reaction with the F1 and R2 primers. All mutant constructs were made using Phusion polymerase. These were introduced into the *V. natriegens* genome via natural transformation as described below. All primers used to generate mutant constructs are listed in **Table S2**.

Natural transformation / MuGENT assays

Strains harboring pMMB-*tfoX* (Vn *tfoX* or Vc *tfoX*) were induced to competence by growing overnight (12-18 hours) in LBv2+100 µg/mL carbenicillin+100 µM IPTG in a rollerdrum at 30°C. Then, ~10^8 CFUs of this overnight culture (~3.5 µL) were diluted directly into 350 µL of instant ocean medium (28 g/L; Aquarium Systems Inc.) supplemented with 100 µM IPTG. Transforming DNA (tDNA) was then added as indicated, and reactions were incubated statically at 30°C for 5 hours. Next, 1 mL of LBv2 was added and reactions were outgrown at 30°C with shaking (250 rpm) for ~1-2 hrs. Then, reactions were plated for quantitative culture onto media to select for integration of tDNA (i.e. LB+drug = transformants) and onto nonselective media (i.e. plain LB = total viable counts). Transformation efficiency is shown as: transformants / total viable counts.

For MuGENT, transformation assays were conducted exactly as described above. Unless otherwise specified, ~50 ng of the selected product was incubated with cells along with ~200 ng of each unselected product. After outgrowth, 1/10th of the reaction was removed and plated for MASC-PCR analysis (described below). If multiple cycles of MuGENT were performed, the rest of the reaction was grown overnight in LBv2 supplemented with 100 µM IPTG, 100µg/mL carbenicillin (to maintain pMMB-*tfoX*), and the antibiotic to select for

integration of the selected product. The following day, the population was then subjected to another round of MuGENT as described above using a selected product containing a different AbR marker to maintain coselection at each cycle.

Integration of genome edits was detected via MASC-PCR exactly as previously described[4, 5]. Briefly, colonies were boiled in 50 µL of sterile water, vortexed, and then 2 µL were used as template in a 25 µL PCR reaction. PCR was conducted with Taq polymerase (SydLabs) using a modified 5X Taq buffer: 200 mM Tris pH 8.8, 100 mM KCl, 100 mM $(NH_4)_2SO_4$, 30 mM $MgSO_4$, and 1% Triton X-100. The total primer used in each MASC-PCR reaction (regardless of the number of multiplexed products being detected) was 1200 nM (i.e. for detection of 4 multiplexed genome edits, 300 nM of each genome edit-specific primer pair was used). The cycling conditions used were: 95°C 3 min; 26 × [95°C 40s, 58°C 30s, 72°C 3 min]; 72°C 3 min; 12°C hold. Reactions were then run on 2% agarose gels and imaged with GelGreen dye according to manufacturer's instructions (Biotium). For a list of all primers used for MASC-PCR see **Table S2**.

Alcian blue stained gels
To prepare cell lysates, ~10^9 cells of the indicated *V. natriegens* strains were pelleted and then resuspended in 180 µL of Buffer ATL (Qiagen). Then, 20 µL of a 20 mg/mL proteinase K stock solution was added to each reaction and incubated at 56°C for 20 mins. Samples were then boiled in 2X SDS PAGE sample buffer and separated on 4-12% SDS PAGE gels. Gels were then stained with 0.1% Alcian Blue 8GX in 40% ethanol/3% acetic acid as previously described[6]. The gel was then destained in a 40% ethanol/3% acetic acid and imaged on a Biorad ChemiDoc MP Imaging system.

Whole genome sequencing
Genomic DNA was prepped from strains and sequencing libraries were prepped via homopolymer-tail mediated ligation exactly as previously described[7]. Single-end 50 bp reads were collected on the Illumina platform. Then, data was analyzed for small indels and single nucleotide variants using CLC Genomics Workbench exactly as previously described[8, 9].

Qualitative and quantitative assessment of PHB production
PHB was qualitatively assessed in MuGENT edited populations of *V. natriegens* by plating onto Nile red containing medium with excess glucose as a carbon source and 100 µM IPTG to induce P_{tac}-containing genome edits = recipe per L: 28 g instant ocean, 2.5 g tryptone, 1 g yeast extract, 20 g glucose, 15 g agar, and 1 mg Nile red. Fluorescence of colonies was detected using a PrepOne Sapphire LED blue light base (475 nm ± 30 nm) and amber filter (530 nm long pass) (Embi Tec).

For quantitative assessment of PHB levels, the indicated strains were grown overnight in M9 minimal medium (BD) supplemented with 2 mM $MgSO_4$, 100 µM $CaCl_2$, 200 mM NaCl, 30 µM $FeSO_4$, 100 µM IPTG, 1% tryptone, and 2% glucose. Approximately 8×10^9 cells were then pelleted, resuspended with 50 µL water and transferred to pre-weighed glass screw-cap tubes. Cell suspensions were dried for 5 h at 80°C and then the tubes were weighed again to determine dry cell weights. PHB was then hydrolyzed and extracted as crotonic

acid by boiling the dried cells in 1 ml of pure sulfuric acid. Extracts were chilled on ice and diluted with 4 ml ice-cold water. Aliquots were further diluted 10-fold with water, centrifuged, filtered, and then crotonic acid was quantified by HPLC as described[10].

SUPPLEMENTARY FIGURES
Fig. S1 – V. natriegens *produces a WbfF-dependent capsular polysaccharide.* Colony morphologies of WT (white arrow) and Δ*wbfF* (black arrow) strains, which demonstrate the phenotypes screened for in cotransformation assays. Cell lysates of the indicated strains were run on a 4-12% SDS PAGE gel and stained with the carbohydrate stain Alcian blue. The presence of a high molecular weight polysaccharide in the WT is indicated by a red arrow.
Fig. S2 – *Cotransformation is highly efficient in* V. natriegens. (**A**) Cotransformation was tested using a Δ*dns*::Kan^R (3 kb/3 kb) selected product and an unselected product that deleted ~500 bp of the 5' end of *wbfF* gene. Cotransformation assays were performed using 50ng of the Δ*dns*::Kan^R (3 kb/3 kb) selected product and (**B**) the indicated amount of the Δ*wbfF* (3kb/3kb) unselected product or (**C**) 200 ng of Δ*wbfF* unselected products containing the indicated length of homology on each side of the mutation. (**D** and **E**) MuGENT was performed with 5 unselected genome edits. The selected product was Δ*wbfF*::Kan^R, while the unselected products targeted four carbohydrate transporters and *dns* for inactivation by replacing ~500 bp of the 5' end of each gene with a premature stop codon. (**D**) A representative MASC-PCR gel of 24 colonies from the edited population. The targets of each genome edit are indicated on the left and the presence of a band indicates integration of the indicated genome edit. Strains containing 4 genome edits are indicated by the green arrows. (**E**) Distribution of genome edits in the population determined by MASC-PCR analysis of 48 random mutants.

SUPPLEMENTARY TABLES

Table S1 – *Strains used in this study*

Strain name	Genotype and antibiotic resistances	Description	Reference / (strain#)
WT	Rif^R	Spontaneous Rif^R derivative *V. natriegens* ATCC14048 that is the parent isolate for all strains used in this study.	This study (SAD1304)
pMMB-tfoX (Vc)	pMMB-*tfox* (Vc) Carb^R	SAD1304 containing pMMB-*tfoX* (Vc), a vector containing the *tfoX* gene from *V. cholerae* (VC1153) under the control of an IPTG-inducible P$_{tac}$ promoter. Vector is derived from pMMB67EH and has a Carb^R gene for selection.	This study (SAD1306)
pMMB-tfoX (Vn)	pMMB-*tfox* (Vn) Carb^R	SAD1304 containing pMMB-*tfoX* (Vn), a vector containing the *tfoX* gene from *V. natriegens* (BA890_05980) under the control of an IPTG-inducible P$_{tac}$ promoter. Vector is derived from pMMB67EH and has a Carb^R gene for selection.	This study (TND0322 / SAD1495)
pMMB	pMMB empty vector Carb^R	SAD1304 containing the pMMB67EH empty vector	This study (TND0321 / SAD1496)
WT (Fig. 1D)	pMMB-*tfoX* (Vc) Carb^R, Δ*dns*::Kan^R	SAD1306 with Δ*dns*::Kan^R (ΔBA890_12415)	This study (SAD1313)
Δ*mutS*	pMMB-tfoX (Vc) Carb^R, Δ*dns*::Kan^R, Δ*mutS*	Generated by cotransformation into SAD1306 with Δ*dns*::Kan^R and a product to delete ~500bp of the 5' end of the *mutS* gene (BA890_12150).	This study (TND0362 / SAD1497)
Δ*wbfF*	pMMB-tfoX (Vc) Carb^R, Δ*wbfF*::Kan^R	Introduced a Δ*wbfF*::Kan^R mutation (ΔBA890_01135) into the SAD1306 strain background.	This study (CAH509 / SAD1498)
MuGENT quadruple mutant	pMMB-tfoX (Vc) Carb^R, Δ*wbfF*::Kan^R, ΔBA890_01815 (mannitol transporter), ΔBA890_19540 (sucrose transporter), ΔBA890_16410 (fructose transporter), Δ*dns*	MuGENT into SAD1306 strain with 5 unselected genome edits. This quadruple mutant was whole genome sequenced and no off target mutations were identified.	This study (TND0338 / SAD1499)
Fig. 2E, second bar	pMMB-tfoX (Vc) Carb^R, Δ*dns*::Kan^R, P$_{tac}$-*phaBAC*	MuGENT into SAD1306 to enhance PHB production. The strain contains the genome edits indicated.	This study (TND0364 / SAD1500)
Fig. 2E, third bar	pMMB-tfoX (Vc) Carb^R, Δ*dns*::Kan^R, P$_{tac}$-*phaBAC*, P$_{tac}$-*nadK*, Δ*ldhA*	MuGENT into SAD1306 to enhance PHB production. The strain contains the genome edits indicated.	This study (SAD1501)
Fig. 2E, fourth bar	pMMB-tfoX (Vc) Carb^R, Δ*dns*::Kan^R, P$_{tac}$-*phaBAC*, P$_{tac}$-	MuGENT into SAD1306 to enhance PHB production. The	This study (SAD1502)

	pntAB, Δ*pta*, Δ*gltA*, Δ*aceA*	strain contains the genome edits indicated.	
Fig. 2E, fifth bar	pMMB-tfoX (Vc) Carb^R, Δ*dns*::Spec^R, P$_{tac}$-*phaBAC*, P$_{tac}$-*nadK*, Δ*pta*, Δ*gltA*, Δ*ldhA*	MuGENT into SAD1306 to enhance PHB production. The strain contains the genome edits indicated.	This study (SAD1503)
Fig. 2E, sixth bar	pMMB-tfoX (Vc) Carb^R, Δ*dns*::Spec^R, P$_{tac}$-*phaBAC*, P$_{tac}$-*nadK*, Δ*pta*, Δ*gltA*, Δ*ldhA*, Δ*aceA*	MuGENT into SAD1306 to enhance PHB production. The strain contains the genome edits indicated.	This study (SAD1504)

Table S2 – *Primers used in this study*

Primer Name	Primer Sequence (5'→3')*	Description
