20
21   **Summary**

22   The bacterial flagellum is the proto-typical protein nanomachine and comprises a

23   rotating helical propeller attached to a membrane-embedded motor complex[1]. The motor

24   consists of a central rotor surround by stator units that couple ion flow across the cytoplasmic

25   membrane to torque generation. Here we present the structures of stator complexes from

26   multiple bacterial species, allowing interpretation of the extensive body of data on stator

27   mechanism. The structures reveal an unexpected asymmetric A_5B_2 subunit assembly in which

28   the five A subunits enclose the two B subunits. Comparison to novel structures of other ion-

29   driven motors indicates that this A_5B_2 architecture is fundamental to bacterial systems that

30   couple energy from ion-flow to generate mechanical work at a distance, and suggests that

31   such events involve rotation in the motor structures.

32

33   **Main**

34   A motor is a machine that supplies motive power for a device with moving parts.

35   Biological systems use both linear and rotary motors to generate a variety of outputs. One of

36   the most fascinating and complex biological rotary motors is the flagellar apparatus used by

37   bacteria to propel themselves through fluid environments. Although bacterial swimming was

38   first observed in the 17th century[2], a mechanistic understanding of how the bacterial flagellum

39   generates rotation is still lacking. The core of the flagellum is a highly conserved motor (Fig.

40   1a) consisting of a cytoplasmic-membrane embedded rotor complex surrounded by varying

41   numbers of stator complexes (hereafter termed simply stators) that generate torque[3]. While

42   high resolution information has recently been obtained for the rotor component[4], structural

43   detail of the stators has thus far been limited to modelling studies[5].

44   Stators harvest energy from either H^+ or Na^+ ion flow across the cytoplasmic

45   membrane, generating torque in the cytoplasmic portion (C-ring) of the rotor complex[6-9].

46   Chimeras between H^+- and Na^+-dependent stators are functional, implying that the

47   mechanism converting ion flow into work is the same for the two coupling ions[10]. Stators are

48   built from two cytoplasmic membrane proteins, which for simplicity are generically referred

49   to here as MotA and MotB. MotA is predicted to contain four transmembrane helices (TMH)

50   with a large cytoplasmic insertion between TMH2 and TMH3. MotB is predicted to contain a

51   short cytoplasmic sequence, a single TMH, and a C-terminal peptidoglycan binding (PGB)

52   domain. Early biochemical work defined the stator stoichiometry as $MotA_4B_2$[11], and this

53   subunit composition has informed attempts to derive mechanism for conversion of ion flow

54   into rotation (reviewed in [12]). Extensive experimental studies have led to a model of stator

55   function in which docking of the MotA cytoplasmic loop to the rotor C-ring simultaneously

56   induces ion permeation through the stator and release of the MotB-PGB domain to bind to

57   the peptidoglycan (PG) surrounding the flagellar basal body[13,14]. Ion flow is proposed to lead

58   to conformational changes in the cytoplasmic domain of MotA that generate torque in the

59   rotor[15-17]. In the absence of a stator structure various mechanistic hypotheses have been

60   proposed to explain the coupling of ion flow to conformational change, most of which

61   explicitly use the predicted 2-fold symmetry of a $MotA_4B_2$ complex[17-19].

62

Flagellar stators are $MotA_5B_2$ complexes

64   We used cryo-electron microscopy (cryo-EM) to study stator complexes from a range

65   of bacterial species with different ion specificities (Extended Data Fig. 1). Two-dimensional

66   class averages of the complexes from three species (*Vibrio mimicus, Clostridium sporogenes*

67   and *Bacillus subtilis)* clearly showed a distorted, pentagonal, structure (Fig. 1b). 3D

68   reconstructions of these complexes yielded volumes that could only be interpreted as

69    $MotA_5B_2$ assemblies (Fig. 1c; Extended Data Fig. 2), with five copies of MotA fully enclosing

70   the TMHs of two copies of MotB (Fig. 2a). Although we do not observe the PGB-domains of

71   MotB in the resolved structures, these domains must be present in the imaged complexes

72   because the stators were purified using an affinity tag located after the PGB domain. Thus,

73   the PGB-domain of MotB has no fixed location with respect to the core complex in the context

74   of the isolated protein. The stator structures are compatible with sequence conservation

75   data, with inter- and intra-molecular co-evolution data, and with published cysteine

76   crosslinking[20,21] and tryptophan scanning mutagenesis[22,23] (Extended data Fig. 3).

3

77   The four TMHs of MotA are arranged in two layers. TMH3 and TMH4 line the central

78   pore, while TMH1 and TMH2 form a surrounding outer layer of helices (Fig. 2a,b). TMH1 and

79   TMH2 are not in contact with each other within a single subunit but instead interact between

80   adjacent subunits, thereby stabilising the MotA assembly. Immediately following TMH2 there

81   is an amphipathic helix (AMPH) running perpendicular to the TMHs at the cytoplasmic

82   membrane surface, with the five copies of this helix forming a belt around the outside of the

83   structure. TMH3 and TMH4 extend 30 Å outside the membrane to form the core of the MotA

84   cytoplasmic domain, with the rest of the domain built from helices inserted in the loop

85   between the AMPH and TMH3. Both within and outside the membrane domain the

86   pentameric arrangement of MotA is distorted (Fig. 2c). Charged residues shown to be

87   essential for the interaction of the stator with the rotor C-ring[24] are located towards the base

88   of this domain, forming a ring that decorates the surface of the pentamer (Extended data Fig.

89   4).

90   The TMHs of the two copies of MotB are located in the central pore of the distorted

91   MotA pentamer, with their hydrophobic sidechains completely buried within the MotA ring.

92   From the N-terminal ends of the MotB TMHs clear densities extend down to contact the inner

93   surfaces of TMH3 and TMH4 in the cytoplasmic domains of MotA (Fig. 3a,b; Extended Data

94   Fig. 5a,b). Although the densities are too weak for the sequence to be traced, they are of

95   sufficient length to account for most of the MotB N-terminus, including a cluster of positive

96   charges essential for motor function[25]. At the non-cytoplasmic face of the complex the MotB

97   TMHs emerge vertically from the MotA pentamer and are followed by another short helical

98   section that packs down between the TMH3-TMH4 loops of the MotA chains. The connectivity

99   of these densities defines them as the plug helices previously implicated by mutagenesis as

100   critical to sealing the complexes in an off state[26].

101   Prior mutagenesis studies have established that a series of conserved residues in the

102   TMHs of MotA and MotB are important for flagellar motion and/or ion-flow through the

103   stator (reviewed in [3]). Invariant $MotB_{D32}$ (using the *Escherichia coli* numbering system) is the

104   key protonatable residue and both copies are seen to lie within a ring formed by the five

105   copies of another invariant polar residue, $MotA_{T209}$ (Fig. 3c). A second Thr residue (at a

106   position corresponding to residue A180 in *E. coli* MotA) that is conserved in the Na^+-

107   dependent stators also contributes to this ring, and forms part of a track of Na^+/H^+ specificity

108   determining residues that line the inner surface of the MotA pore (Extended data Fig. 1b).

109   Two conserved Pro residues in MotA have been shown to be important for torque

110   generation[27]. One of these, $MotA_{P222}$ can now be seen to be required for contacts between

111   neighbouring MotA monomers. The other, $MotA_{P173}$, forms a second ring of conserved

112   residues with invariant $MotA_{Y217}$, two helical turns down from the Thr ring. This hydrophobic

113   ring contacts MotB at the completely conserved $MotB_{W26}$. A $MotB_{W26A}$ substitution

114   completely abolished motility confirming the importance of this contact (Fig. 3d).

115

116   **Asymmetry and the implications for activation of ion flow**

117   The 5:2 stoichiometry of the stator complex leads to multiple levels of asymmetry in

118   the structure (Fig. 2c; Extended Data Fig. 5c). The pentagon formed by the MotA subunits

119   within the membrane is distorted to accommodate and seal around the two MotB TMHs. The

120   asymmetry of this part of the complex is also driven by the two MotB plug helices sitting

121   between the MotA loops, which divide the MotA chains into two groups separated in the

122   extracytoplasmic region. Removal of the MotB plug has been shown to lead to uncontrolled

123   ion flow through the MotAB channel[26]. However, our structures show that the plug helices

124   are not the sole block to ion permeation since there are no detectable channels across the

125   cytoplasmic membrane compartment (Fig. 3e; Extended Data Fig. 5d). Embedding plug-free

126   structures in full lipid bilayer models and running extended simulations demonstrated the

127   observed structures are stable, low energy, states (Extended Data Fig. 6). No ion permeation

128   across the bilayer was seen in any simulation, supporting the idea that the complexes

129   currently seen will require rearrangement for activity.

130   Activation of ion flow is proposed to be triggered by docking of the inactive stator onto

131   the flagellar C-ring via the MotA cytoplasmic domains resulting in signal propagation from the

132   cytoplasm to the plug region and plug release[13,14]. Our structures reveal two potential routes

133   for such a signal. The first involves the cytoplasmic N-termini of the MotB subunits which

134   contain functionally essential residues[25] that interact with the inside of the MotA pentamer

135   through highly evolutionarily coupled contacts (Extended data Fig. 3d). C-ring-induced

136   movement of MotA would be communicated to MotB at this site leading to alterations at the

137   opposite end of the MotB TMHs. The second possible route of signal propagation is directly

138   through the MotA subunits, with hinging of the long TMH3 and TMH4 helices altering the

139   conformation of the plug helix binding loops to allow plug release. Our structures provide

140   insight into the conformational changes that the MotA cytoplasmic domains can undergo. The

141   structures show differing degrees of hinging of the MotA cytoplasmic domains relative to the

142   membrane embedded helices (Fig. 3f; Extended Data Fig. 5e) suggesting changes in the

143   degree of asymmetry may link to functional state. Our structures also reveal that the two

144   MotA residues known to be essential for interaction with the C-ring protein FliG[24] are located

145   on opposite sides of the MotA cytoplasmic domain, with $MotA_{R90}$ from one copy facing

146    $MotA_{E98}$ from the neighbouring copy (Extended data Fig. 4). Therefore docking of the C-

147   terminal domain of FliG between two MotA subunits could trigger conformational change in

148   the stator.

6

149

150 **Coupling of ion-flow to flagellar rotation**

151 The most striking feature of the asymmetry of the 5:2 subunit stoichiometry is that it

152 places the TMHs of the two copies of MotB, including the critical $MotB_{D32}$ residue, in different

153 environments within the distorted MotA pentagon. The system is therefore primed for

154 differential binding of H^+ or Na^+ at the critical $MotB_{D32}$ residue to induce changes in the

155 relative positioning of the MotB and MotA helices, most likely by rotation of one relative to

156 the other. Because MotB becomes tethered to the PG upon stator activation[13] (Fig. 4a) it

157 follows that the MotA ring rotates around the MotB dimer. The 5:2 subunit stoichiometry

158 implies a model whereby a single channel opens to allow ion binding to $MotB_{D32}$ on one MotB

159 triggering rotation of the MotA ring by ~36° (Fig. 4b). This motion would bring the second

160 MotB chain into the same position relative to the surrounding MotA subunits as the starting

161 arrangement of the first MotB chain, closing the first channel and opening the second. Each

162 subsequent ion binding event would trigger a further ratchet motion of 36°, with each turn

163 of the MotA cytoplasmic domains providing a "power stroke" to the rotor. An alternative

164 model in which the second ion binding event leads to a reset to the original position and full

165 rotation does not occur, would also be compatible with the structure. Such a mechanism

166 would still be capable of driving full rotation of the rotor component, acting like an energised

167 escapement mechanism.

168 Any mechanism for coupling ion flow to flagellar rotation must also explain how the

169 direction of rotation of the flagellum can reverse in response to chemotactic stimuli. All

170 experimental evidence (reviewed in [28]) shows that the chemotaxis machinery acts on the FliG

171 subunit of the C-ring rather than the stator. Our unidirectional rotation model for the stator

172 mechanism can account for flagellar reversal if the chemotaxis-linked conformational

7

173   changes induced in the C-ring lead to an alteration in the side of the stator that is driving the

174   rotation (Fig. 4c). Consistent with this proposal large conformational changes in the stator-

175   interacting FliG component of the C-ring have been observed in crystal structures of FliG

176   fragments, where 180° rotations of the C-terminal domain relative to the middle domain have

177   been observed[29]. The model also predicts that any reversal of the ion flow through the stator

178   would have the potential to reverse the direction of flagellar rotation even in the absence of

179   switching by the chemotaxis machinery, and this phenomenon has been observed in

180   *Streptococcus* species assayed under high pH conditions[30,31].

181

182   **Common architecture across multiple bacterial ion-driven machines**

183   The MotAB system is related at the sequence level to the ExbBD complex found in

184   Gram-negative bacteria that uses ion-flow across the cytoplasmic membrane to power

185   transport processes at the outer membrane via the trans-periplasmic TonB protein[32]. We

186   determined cryo-EM structures of ExbBD complexes from *E. coli* and *Pseudomonas savastanoi*

187   (Extended Data Fig. 7). Both displayed a 5:2 ExbB:ExbD stoichiometry that differs from the

188   subunit composition of earlier structures[33,34], but agrees with the subunit stoichiometry of a

189   novel structure of the *E. coli* ExbBD reported whilst this manuscript was in preparation[35].

190   Comparison of these new ExbB$_5$D$_2$ structures to the stator complexes reveals a high level of

191   structural conservation, particularly within the membrane domain (Extended Data Fig. 8a,b).

192   Both the flattened pentagon geometry and the alignment of mechanistically important

193   residues, such as the conserved Asp within a ring of Thr residues, suggest that the two systems

194   use the same molecular mechanism. We therefore predict that the ExbB will rotate relative

195   to the ExbD helices in response to proton flow. Outside the core TMH region there are

196   structural differences between the systems that presumably reflect their very different

8

197 biologies. ExbB is very differently elaborated relative to MotA, with only one TMH packing

198 across the pair of helices that form the core inner ring and no bracing helices strengthening

199 packing between subunits (Extended Data Fig. 8c). The ExbB cytoplasmic domains are only

200 superficially related to the corresponding MotA domain and lack the short pair of C-terminal

201 helices found in MotA (Extended Data Fig. 8d).

202   *P. savastanoi* ExbB and ExbD were purified as a complex with TonB when all three

203 proteins were co-expressed (Extended data Fig. 9a). However, no extra density was observed

204 in the cryo-EM maps of this complex relative to the ExbBD complex alone, suggesting that

205 TonB is located on the outside of the ExbBD complex and dissociates upon sample freezing. A

206 peripheral   location   for   TonB   is   consistent   with   both   co-evolution   and

207 mutagenesis/suppressor data[36], which suggest that the TonB binding site is on the outside of

208 the ExbB transmembrane domain (Extended data Fig. 9b). TonB consists of a single pass TMH,

209 followed by an extended periplasmic region that interacts with the periplasmic domain of

210 ExbD[37], and terminates in a folded domain that links with outer-membrane receptor

211 proteins[38]. We speculate that the TonB TMH packs against the exterior of the ExbBD complex

212 so that conformational change in TonB is driven by rotation of the ExbB component relative

213 to ExbD. By extension, the homologous TolQRA system will also share this architecture and

214 be mechanistically related[39].

215   Bacteria from the *Bacteroidetes* phylum possess a motor complex that harvests

216 energy from ion-flow to drive protein secretion and to power bacterial motility via a non-

217 flagellar mechanism termed gliding motility[40]. The structure of this complex is described in a

218 companion paper (Hennell-James et al, companion paper). Although the constituent GldL

219 and GldM subunits of this motor have no sequence similarity to the subunits of the MotAB or

220 ExbBD complexes, the *Bacteriodetes* motor complex exhibits the same 5:2 subunit

221   stoichiometry as these complexes (Fig. 5a). All three complexes have an intramembrane core

222   consisting of a central subunit TMH dimer surrounded by a 10 TMH ring. Structural

223   comparisons demonstrate the similarity between the three motors in the arrangement of this

224   intramembrane core and of the height within the membrane at which charged residues

225   critical to function are located (Fig. 5b,c). Such shared underlying architecture between

226   otherwise highly dissimilar motors (Fig. 5d) implies an unexpected commonality in their

227   mechanism.

228

229   **Acknowledgements**

249

250   **Author contributions**

251   J.C.D carried out all biochemical work except as credited otherwise, prepared cryo-EM grids,

252   collected and processed EM data and determined the structures. J.C.D., S.J., and S.M.L

253   designed the project, interpreted the data, built models, and wrote the first draft of the

254   paper. S.J. also performed MALS experiments. O.V. and P.J.S. performed molecular dynamics

255   simulations. A.M., H.M., and T.G. carried out biochemical work on *Pseudomonas* TonB-ExbB-

256   ExbD. R.H.J. and B.C.B. contributed the GldLM structure. J.W.C. initiated and provided

257   materials for the ExbBD project. All authors commented on drafts of the manuscript.

341 **Methods**

342

343 **Bacterial strains and plasmids**

344 Bacterial strains and plasmids used in this study are listed in Supplementary Table 1.

345 The pT12 backbone used for all protein expression was derived from Kuhlen *et al* [41]. Plasmids

346 were generated by Gibson assembly of PCR fragments using the NEBuilder HiFi Master Mix

347 (NEB). Fragments were created by PCR with the relevant primers (listed in Supplementary

348 Table 2) using Q5 polymerase (NEB) and genomic DNA templates obtained from the Liebniz

349 Institute [dsmz.de]: *Vibrio mimicus* (DSM 19130), *Bacillus subtilis* 168 (DSM 402), *Clostridium*

350 *sporogenes* 388 (DSM 795), *Escherichia coli* W (DSM 1116), *Pseudomonas savastanoi*, pv.

351 phaseolicola 1448A (DSM 21482). Gibson assembly and PCR were carried out following the

352 manufacturer's recommendations. *E. coli* RP6894 ($\Delta motAB$) for motility assays was generated

353 by J. S. Parkinson and gifted by D.F. Blair.

354

355 **Purification of MotAB/PomAB and ExbBD complexes**

356 *V. mimicus* PomAB, its derivative PomAB$_{\Delta 61-120}$ lacking unstructured periplasmic

357 residues of PomB, *B. subtilis* MotAB, *C. sporogenes* MotAB, *E. coli* ExbBD, and *P. savastanoi*

358 TonB-ExbBD complexes were expressed in *E. coli* MT56 as a single operon from a pT12 vector

359 encoding a C-terminal twin-strep tag. Purification steps were similar across all constructs and

360 carried out at 4 °C. Briefly, cells were grown at 37 °C for 16 h in TB media containing

361 kanamycin (50 μg/mL) and rhamnose monohydrate (0.1% w/v) then collected by

362 centrifugation at 4,000*g*. Cell pellets were resuspended in TBS (100 mM Tris, 150 mM NaCl,

363 1 mM EDTA pH 8.0) plus 30 μg/mL DNase I and 400 μg/mL lysozyme for 30 mins before

364 passage through an EmulsiFlex C5 homogenizer (Avestin) at 15,000 psi. Unbroken cells were

365   removed by centrifugation at 24,000g for 20 min. The supernatant was recovered and total

366   membranes were collected by centrifugation at 200,000g for 1.5 h. Membranes were

367   resuspended in TBS and solubilized by incubation with 1% (w/v) lauryl maltose neopentyl

368   glycol (LMNG; Anatrace) for 2 h. Insoluble material was removed by centrifugation at

369   100,000g for 30 min. Solubilized membranes were then applied to a Streptactin XT column

370   (IBA Lifesciences). The resin was washed with 10 column volumes (CV) of TBS containing

371   0.02% (w/v) LMNG and proteins were eluted in 5 CV of TBS supplemented with 0.01% (w/v)

372   LMNG and 50 mM D-biotin (IBA Lifesciences). Eluates were concentrated using a 100-kDa

373   molecular weight cutoff (MWCO) Vivaspin 6 (GE Healthcare) centrifugal filter unit and

374   injected onto a Superose 6 Increase 10/300 GL size exclusion column (GE Healthcare) pre-

375   equilibrated in TBS plus 0.01% (w/v) LMNG. Peak fractions were collected and concentrated

376   using a 100-kDa MWCO Vivaspin 500 (GE Healthcare) centrifugal filter unit.

377   For *P. savastanoi* TonB-ExbBD and ExbBD complexes, SEC-MALS analysis was carried

378   out by injecting 100 μL (A_{280nm} = 1.0) of either sample onto a Superose 6 increase 10/300 GL

379   (GE Healthcare) equilibrated in TBS containing 0.02% (w/v) LMNG. Light scattering and

380   refractive index changes were measured using a Dawn Heleos-II light-scattering detector and

381   an Optilab-TrEX refractive index monitor. Analysis was carried out using ASTRA 6.1.1.17

382   software using a theoretical extinction coefficient of 1.02 ($Abs_{0.1\%}$) and a protein dn/dc value

383   of 0.186 mL/g and a detergent dn/dc value of 0.143 mL/g.

384

385   **Cryo-EM sample preparation and imaging**

386   Purified complexes (4 μL each) of *V. mimicus* PomAB (A_{280nm} = 0.5), PomAB$_{\Delta61-120}$

387   (A_{280nm} = 0.55), *B. subtilis* MotAB (A_{280nm} = 1.0), *C. sporogenes* MotAB (A_{280nm} = 0.8), *E. coli*

388   ExbBD (A_{280nm} = 3.2), or *P. savastanoi* TonB-ExbBD (A_{280nm} = 2.0) were adsorbed to glow-

21

389   discharged holey carbon-coated grids (Quantifoil 300 mesh, Au R1.2/1.3) for 10 s. Grids were

390   then blotted for 2 s at 100% humidity at 8°C and frozen in liquid ethane using a Vitrobot Mark

391   IV (FEI). Alternatively, specimens were prepared by supplementing *V. mimicus* PomAB (A_{280nm}

392   = 2.3), $PomAB_{\Delta 61-120}$ (A_{280nm} = 3.7), *B. subtilis* MotAB (A_{280nm} = 7.2), *C. sporogenes* MotAB

393   (A_{280nm} = 8.6), *E. coli* ExbBD (A_{280nm} = 4.2) with 0.7 mM fluorinated octyl maltoside (fluo OM;

394   Anatrace) prior to grid preparation.

395   Data were collected in counting mode on a Titan Krios G3 (FEI) operating at 300 kV

396   with a GIF energy filter (Gatan) and K2 Summit detector (Gatan) using a pixel size of 0.822 Å

397   and a total dose of 48 $e^-/Å^2$ spread across 20 or 32 fractions. Except for *P. savastanoi* TonB-

398   ExbBD, all datasets included movies from grids prepared with and without the presence of

399   fluo OM to improve distribution of particle orientations.

400

401   **Cryo-EM data processing**

402   Motion correction and dose weighting were performed using MotionCor

403   implemented in Relion 3.0[42]. Contrast transfer functions were calculated using CTFFIND4[43].

404   Particles were picked in Simple[44] and processed in Relion 3.0[42]. Gold standard Fourier shell

405   correlations using the 0.143 criterion and local resolution estimations were calculated within

406   Relion[42] (Extended Data Fig. 2).

407   *V. mimicus* PomAB particles (1,172,445) underwent one round of reference-free 2D

408   classification, from which 253,681 particles were selected and used to generate an *ab initio*

409   initial model. This model was low-pass filtered to 30 Å and used as reference for 3D

410   classification, generating a class that refined to 6.8 Å from 155,280 particles.

411   For the deletion construct $PomAB_{\Delta 61-120}$ that improved particle orientations and data

412   quality, particles (2,383,062) were extracted from 13,980 movies. Following one round of

413   reference-free 2D classification, 800,844 particles were classified in 3D (4 classes) against a

414   40 Å low-pass filtered map of PomAB. A class containing 244,654 particles was further

415   subjected to masked refinement yielding a 4.8 Å map. Refinement after Bayesian particle

416   polishing and per-particle defocus with beamtilt estimation further improved map quality to

417   4.2 Å.

418   *B. subtilis* MotAB particles (1,532,430) were extracted over 11,588 movies. After 2D

419   classification, selected particles (397,584) underwent two rounds of 3D classification (3

420   classes each) using a 40 Å low-pass filtered map generated from a subset of particles refined

421   against a 60 Å low-pass filtered map of PomAB$_{\Delta 61-120}$. A class made up of 122,615 particles

422   was refined to 3.9 Å. Bayesian particle polishing further improved map resolution by 0.2 Å,

423   and subsequent CTF refinement using per-particle defocus with beamtilt estimation

424   generated a 3.5 Å map. To improve MotB N-terminal and plug densities, a subset of

425   fluorinated particles (43,375) was selected and refined against the 3.5 Å reconstruction,

426   generating a 5.0 Å map that was used to depict these regions in Extended Data Fig. 5.

427   *C. sporogenes* MotAB particles (1,998,900) were extracted from 9,148 movies and

428   subjected to a round of reference-free 2D classification. Initial 3D classification performed

429   against a 60 Å low-pass filtered map of *B. subtilis* MotAB revealed two prominent classes

430   which represented a monomeric MotAB complex and a non-physiological end-to-end dimer

431   of MotAB. These classes were used as references in a supervised multi-reference 3D

432   classification against the full 1,137,357 particle set to exclude dimeric particles. Unsupervised

433   3D classification (4 classes) performed against 865,446 monomeric particles and further

434   refinement yielded 3.8 Å from 314,230 particles. Bayesian particle polishing followed by per-

435   particle defocus with beamtilt estimation further improved map quality to 3.4 Å.

23

436   Movies (6,902) were collected for *E. coli* ExbBD, resulting in the extraction of

437   2,045,350 particles. Following one round of reference-free 2D classification, an initial model

438   of ExbBD was generated by 3D classification and refinement of a particle subset against a 40

439   Å low-pass filtered 5:1 ExbBD complex[34] (EMD-6928). The resulting map was used as initial

440   model for multiple rounds of 3D classification against the full 2D-classified particle set

441   (755,677). After refinement of 227,700 particles, this protocol generated a 5.8 Å map,

442   improving to 4.6 Å following Bayesian particle polishing and per-particle defocus plus beamtilt

443   estimation.

444   Movies (4,232) were collected for *P. savastanoi* TonB-ExbBD and 1,342,900 particles

445   were extracted. Particles were subjected to two rounds of 2D classification with centered re-

446   extraction between classifications. The cleaned 499,697 particles were subjected to C5-

447   symmetric 3D classification against a 40 Å low-pass filtered 5:2 ExbBD map from *E. coli*. The

448   resultant 202,356 particles were refined with C5 symmetry to generate a 3.5 Å map that

449   lacked density for the transmembrane helices (TMHs) of ExbD. Particles were polished and

450   subjected to an additional round of 2D classification followed by 3D classification with C1

451   symmetry, resulting in 3.9 Å map from 110,164 particles after refinement in C1. An additional

452   round of Bayesian polishing and refinement (C1) yielded a 3.8 Å map. Per-particle defocus

453   and beamtilt estimation followed by alignment-free 3D classification and subsequent local

454   refinement (C1) yielded a 3.8 Å map with improved density for the TMHs of ExbD from 65,617

455   particles.

456

457   **Model building and refinement**

458   Atomic models were built using Coot[45]. Multiple rounds of rebuilding (in both the

459   globally sharpened and local-resolution filtered maps) and real-space refinement in Phenix[46]

24

460   using secondary structure, rotamer and Ramachandran restraints yielded the final models

461   described in Table 1. All models were validated using Molprobity[47]. Conservation analysis was

462   carried out using the Consurf server[48]. A homology model of *E. coli* MotAB was generated by

463   sequence threading against the *Clostridium* model using Phyre2[49]. Figures were prepared

464   using UCSF ChimeraX[50] and Pymol (The PyMOL Molecular Graphics System, Version 2.0

465   Schrödinger, LLC). All models depicted in figures are based on the highest resolution

466   *Clostridium* model, unless otherwise specified. Residue numbering adopts the reference *E.*

467   *coli* sequence and model; a residue conversion table is provided (Supplementary Table 3).

468

469   **Evolutionary covariance analysis**

470   Coevolutionary contacts for *E. coli W* MotA were determined by the Gremlin web-

471   server[5]. Searches used the Jackhmmer algorithm for multiple sequence alignment, an E-value

472   threshold of 10^{-10} and a minimum coverage of 75%. Intra- and intermolecular contacts were

473   mapped to the *E. coli* MotA structure using Gremlin beta[5] . Intermolecular contacts between

474   MotA and MotB (residues 1-120) were determined using an E-value threshold of 10^{-20} and 10^{-}

475   ^{2}, respectively. Intermolecular contacts between TonB and ExbB were determined using an E-

476   value threshold of 10^{-20}. Contacts with a probability score greater than 0.9 were regarded as

477   significant and listed in Supplementary Table 4.

478

479   **Simulation setup**

480   All simulations were run using GROMACS 2018[51]. The systems were initially setup

481   using the Martini 2.2 coarse-grain (CG) force field and solvated with water and 0.15 M NaCl

482   to neutralise the system[52]. The membranes were constructed using INSANE with a 4:1 ratio

483   of POPE:POPG lipids[53]. An elastic network of 1000 kJ mol^{-1} nm^{-2} was applied between all

25

484   backbone beads between 0.5 and 1 nm. Electrostatics were described using the reaction field

485   method, with a cut-off of 1.1 nm using the potential shift modifier and the van der Waals

486   interactions were shifted between 0.9-1.1 nm. The systems were first energy minimised by

487   steepest descent algorithm to 1000 kJ mol^{-1} nm^{-1} and then simulated for a total of 1 µs. The

488   temperature and pressure were kept constant throughout the simulation at 310 K and 1 bar

489   respectively, with protein, lipids and water/ions coupled individually to a temperature bath

490   by the V-rescale method[54] and a semi-isotropic Parrinello-Rahman barostat[55]. The final

491   snapshots from the CG simulations were then converted back to an atomistic description

492   using CG2AT[56].

493

494   **Atomistic simulations**

495   The charged N- and C- termini of the converted protein were capped using acetyl and

496   methyl moieties, respectively. All ionisable groups were simulated with default protonation

497   states, unless otherwise mentioned. The virtual site model for hydrogen atoms[57], adapted for

498   the charmm36 forcefield[58] was employed, allowing the use of a 4 fs timestep during the

499   simulations. Electrostatics were described using PME, with a cut-off of 1.2 nm and the van

500   der Waals interactions were shifted between 1-1.2 nm. The tip3p water model was used, the

501   water bond angles and distances were constrained by SETTLE[59]. All other bonds were

502   constrained using the LINCS algorithm[60]. The systems were then equilibrated for a further 1

503   ns using a 4 fs timestep with positional restraints of 1000 kJ mol^{-1} nm^{-2} on the heavy atoms,

504   in a NPT ensemble with temperature V-rescale coupling at 310 K[54] and semi-isotropic

505   Parrinello-Rahman barostat at 1 bar with protein, lipids and water/ions coupled individually[55].

506   The Production simulations were performed without position restraints for a total of 200 ns

507   and were run in triplicate.

508

Motility assay

510   *E. coli* RP6894 (Δ*motAB*) was transformed with pT12-derived plasmids encoding C-

511 terminal twin-strep tagged MotAB containing point mutations or appropriate controls.

512 Saturated overnight cultures (2 µL) were injected into soft agar plates (0.3% w/v agar in

513 tryptone broth) containing kanamycin (30 µg/mL) plus rhamnose monohydrate (0.5% w/v)

514 and incubated in a humidified chamber for 23 h at 25 °C.

515

Pulldowns

517   *E. coli* MT56 was transformed with pT12-derived plasmids encoding C-terminal twin-

518 strep tagged MotAB harbouring point mutations or appropriate controls. Small scale (5 mL)

519 cultures were grown at 37 °C for 16 h in TB media containing kanamycin (50 µg/mL) and

520 rhamnose monohydrate (0.1% w/v). OD_{600}-normalized cell counts were centrifuged at 4,000g

521 for 5 min and pellets frozen at -80 °C. After thawing, cells were lysed by resuspension in 200

522 mM Tris pH 8.0, 300 mM NaCl, 2 mM EDTA plus 30 µg/mL DNase I and 400 µg/mL lysozyme

523 for 30 min, then solubilized in 1.5 % w/v LMNG for 1 h. Insoluble material was removed by

524 centrifugation at 18,000g for 30 min. LMNG-solubilized lysates were added to 5 µg of TBS-

525 prewashed MagStrep XT magnetic beads (IBA Lifesciences) for 1 h with mild shaking. Beads

526 were isolated and washed twice with TBS plus 0.025% w/v LMNG followed by elution with

527 TBS plus 0.025% w/v LMNG and 50 mM D-biotin. Eluates were diluted in SDS-PAGE sample

528 buffer and run on a 4–20% polyacrylamide gel (NuSep). The gel was stained with InstantBlue

529 (Expedeon) to determine the presence of MotA and MotB.

530

Reporting summary

532

Data availability

534 The data that support the findings of this study are available from the corresponding author

535 upon reasonable request. Cryo-EM volumes and atomic models have been deposited to the

536 EMDB (accession codes EMD-10895, EMD-10899, EMD-10901, EMD-10902, EMD-10897) and

537 PDB (accession codes 6YSF and 6YSL), respectively. Source data for gel shown in Extended

538 Data Fig. 10 are provided with the paper.

Extended data figures and tables

Extended Data Fig. 1. Ion specificity of stator complexes. a-c, Sequence alignment of the (a) transmembrane and plug helices of MotB and (b) transmembrane helices (TMHs) 3 and 4 of MotA from *E. coli* and other relevant bacterial species. Species are classified based on ion specificity (red, H⁺-driven; blue, Na⁺-driven). Residues that are conserved just within either the H⁺ or Na⁺-driven classes of stator and map to the MotA-MotB interface (c) are indicated with orange asterisks in the alignment and same residue colouring across H⁺-driven (Left) and Na⁺-driven (Right) models (using *E. coli* MotAB numbering equivalents) . The threonine ring is highlighted with light blue asterisks (a,b) or residues (c).

Extended Data Fig. 2. Cryo-EM map quality and resolution estimates of stators. a, Gold-standard Fourier shell correlation (FSC) curves of RELION-postprocessed stator volumes. Resolution at the gold-standard cutoff (FSC = 0.143) is indicated. Curves: red, phase-randomized; green, unmasked; blue, masked; black, MTF-corrected. **b**, Local resolution estimates (in Å) of the sharpened volumes. **c**, Representative modelled densities.
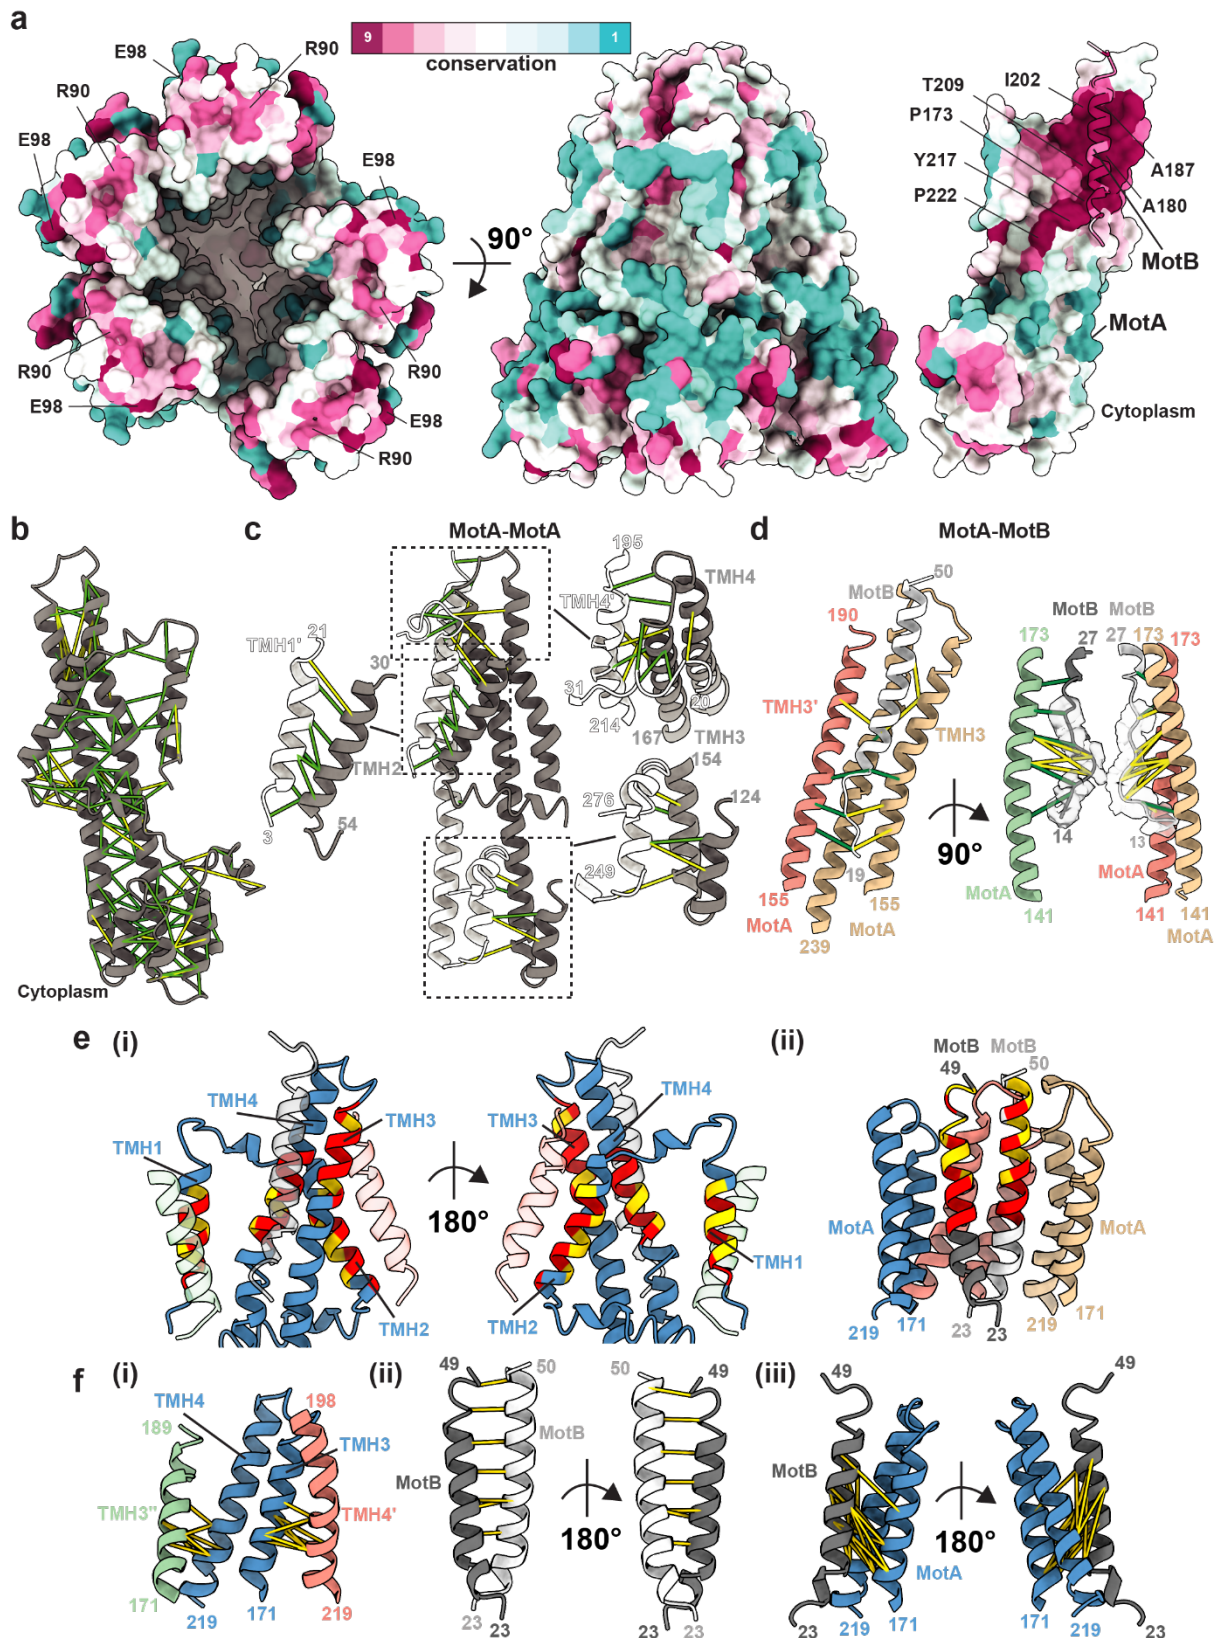

Extended Data Fig. 3. Conservation, covariance, and prior mutagenesis data mapped onto the stator structure. a, Surface conservation as determined by Consurf[48] (maroon high conservation, cyan low conservation). (Left) View from the cytoplasm showing conservation

749   at the cytoplasmic MotA domains, including residues previously identified to be important for
750   torque generation[24] (R90 and E98). (Centre) Side view showing poor conservation within
751   membrane-interfacing residues of MotA. (Right) Cutaway displaying high level of
752   conservation at the MotA-MotB interface; MotA shown as surface representation, MotB as
753   ribbon. **b-d**, Evolutionary co-variation of residues (b) within MotA, (c) between MotA
754   subunits, with boxes highlighting regions of strong covariance that are illustrated in more
755   detail in the adjacent fragments, or (d) between MotA and MotB with the left hand side
756   showing contacts for modelled MotB regions and the right hand side showing contacts in the
757   unmodelled N-terminal MotB density represented here as a poly-alanine backbone.
758   Predictions were carried out in Gremlin[5] and contacts with a probability score of > 0.9 are
759   shown. Contacts are coloured by Cα-Cα distance (≤10 Å in green, ≤15 Å in yellow). **e**, Mapping
760   previous tryptophan scanning mutagenesis performed on MotA TMHs[22] (i) or MotB[23] (ii) to
761   the stator structure. MotA and MotB are coloured as in Fig. 2,3 with targeted residues
762   coloured according to toleration to mutagenesis; yellow corresponds to tolerated mutants
763   (relative swarm rates > 0.5), red are poorly tolerated mutants (relative swarm rates of ≤ 0.5).
764   In (i), TMH4 (green) and TMH2 (red) of neighbouring MotA subunits and MotB (white) are
765   shown as transparent silhouettes. Poorly tolerated mutants cluster at subunit interfaces. In
766   (ii) only TMH3-TMH4 of three MotA subunits are shown for clarity. **f**, Mapping previously
767   determined cysteine crosslinks between (i) MotA-MotA[20], (ii) MotB-MotB[21], or (iii) MotA-
768   MotB[20] to our structure. For displaying crosslinks, a yield of ≥ 30% disulfide-linked adduct
769   under iodine oxidizing conditions was used as threshold, except for $MotA_{TMH4}$-MotB crosslinks
770   which used a ≥ 10% threshold. All analyses in this figure were performed using an *E. coli*
771   MotAB structure generated by homology threading onto *C. sporogenes* MotAB.
**Extended Data Fig. 4. Residues that interact with the flagellar C-ring form a charged ring on the cytoplasmic face of MotA. a,** An isolated MotA subunit with the essential torque-generating charged residues R90 and E98[24] displayed in yellow spheres representation. **b,** The full *C. sporogenes* stator complex viewed from the side (Left) or from the cytoplasm (Right), coloured as in Figs. 2-3, and with the torque-generating charged residues represented as in (a) using *E. coli* MotAB numbering scheme.

10
Extended Data Fig. 5. Structural elements of the *B. subtilis* stator. a, Structure of the *B. subtilis* stator depicting unmodeled density for the MotB N-terminal extensions (Left) and plug helices (Right). **b**, (i) Isolated *B. subtilis* MotB dimer represented as in (a), and (ii) superposition of the TMHs of the two MotB chains showing the relative rotation of the plug helices. **c**, Slabs at the heights indicated through *B. subtilis* MotAB show distortion from a regular pentagon (arrow indicates the cytoplasmic side of the complex) as viewed from the cytoplasm). **d**, Surface representation of *B. subtilis* MotAB showing tight packing. (Top) Side view with the front of the complex removed. (Bottom) Top-down view of the slab indicated by dashed lines. **e**, Structural alignment of the five *B. subtilis* MotA chains reveal they fall into two conformational classes which differ in the degree of flexing at the highlighted prolines.

796
Extended Data Fig. 6. Molecular dynamics simulations of stator structures in lipid bilayers.
a, Side (*top*) and top-down (*bottom*) views of (i) *C. sporogenes* and (ii) *B. subtilis* MotAB inserted within a lipid bilayer after extended simulations (coarsegrain for 1 µs then atomistic for a further 200 ns). **b**, Cartoon representation of (i) *Clostridium* MotAB and (ii) *Bacillus* MotAB coloured (blue to red) by the average rmsf of the 3 replica simulations performed.

802
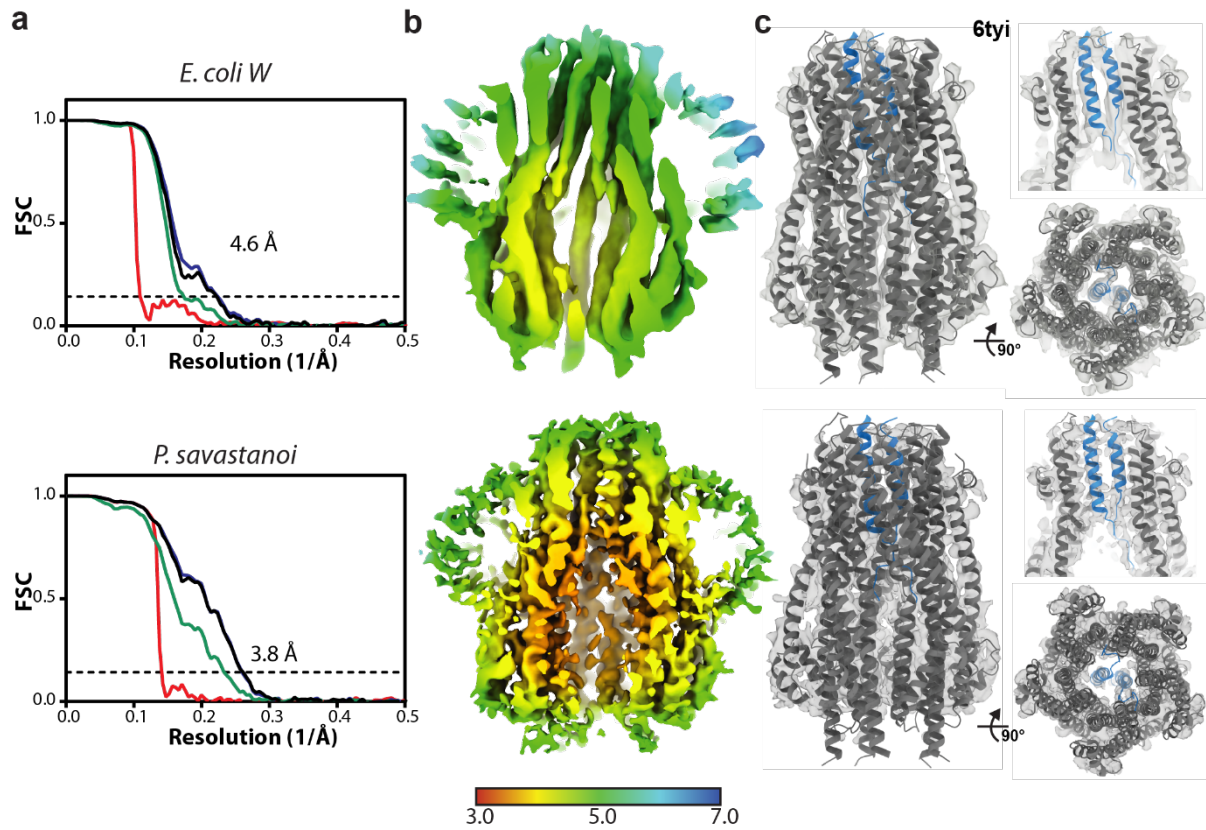

Extended Data Fig. 7. Cryo-EM map quality and resolution estimates of ExbBD complexes a, Gold-standard Fourier shell correlation (FSC) curves of RELION-postprocessed ExbBD maps. Resolution at the gold-standard cutoff (FSC = 0.143) is indicated. Curves: red, phase-randomized; green, unmasked; blue, masked; black, MTF-corrected. **b**, Local resolution estimates (in Å) of the sharpened maps. **c**, Structure of the 5:2 ExbBD complex from *E. coli*[35] (PDB 6tyi) fit into the *E. coli* W (top) and *P. savastanoi* ExbBD (bottom) maps. ExbB is coloured dark grey and ExbD is coloured blue. Top right panels have three ExbB subunits removed to demonstrate density for the two TMHs of ExbD. Bottom right panels reveal the 5:2 ExbB:ExbD arrangement as viewed from the cytoplasm.

818
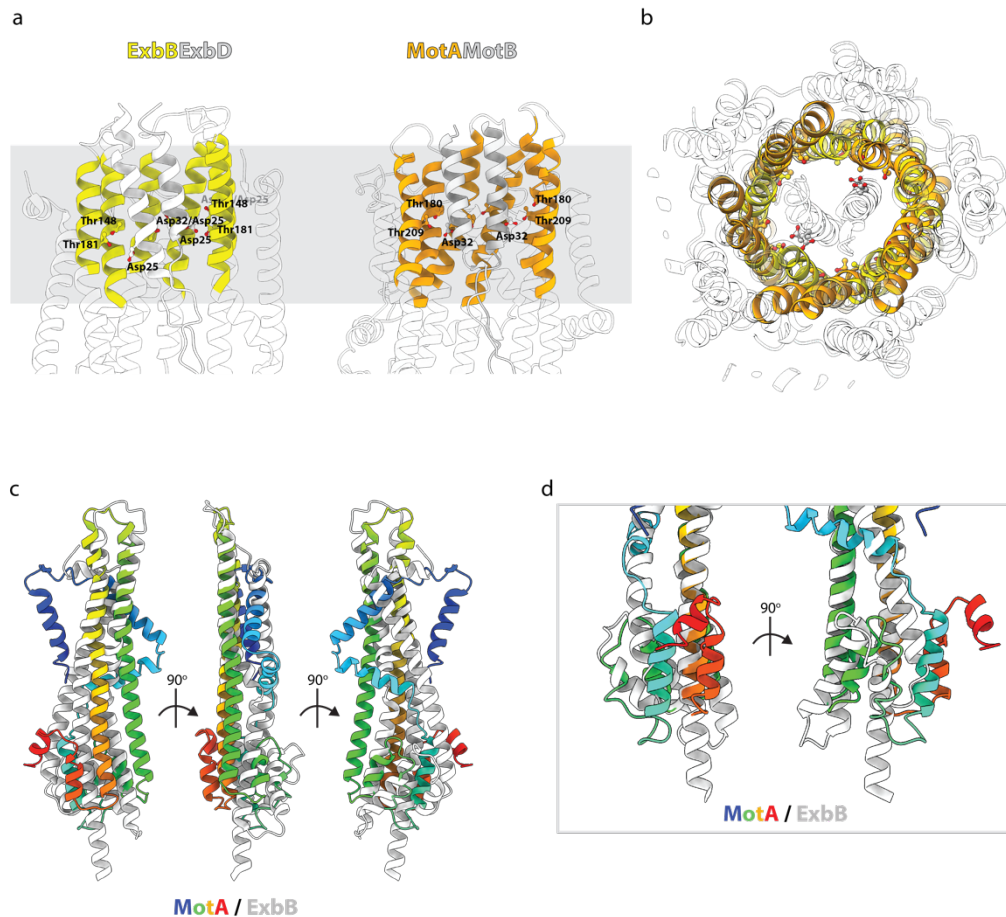

Extended Data Fig. 8. Structural alignment of MotAB and ExbBD.
a, side views of the cores of the *C. sporogenes* MotAB (orange) and *E. coli* ExbBD[35] (yellow) complexes with two front MotA/ExbB subunits removed showing the conserved Asp residues lying at the same height with respect to a ring of Thr on the MotA/ExbD components **b,** Overlaying the cores of *C. sporogenes* MotAB (orange) and *E. coli* ExbBD (yellow) by alignment of the MotA/ExbB helices demonstrates alignment of the critical polar residues between the two systems. Regions outside the core shown as transparent grey; MotB/ExbD shown in grey. **c,** Aligning a single subunit of MotA (rainbow colouring) with ExbB (white) via the pore lining helices reveals the different elaborations of this core unit in each protein. **d,** Aligning a single subunit of MotA with ExbB via the cytoplasmic extensions of the two core helices reveals the different folding of the rest of the cytoplasmic regions. Proteins coloured as in (**c**).

830

41

831

832
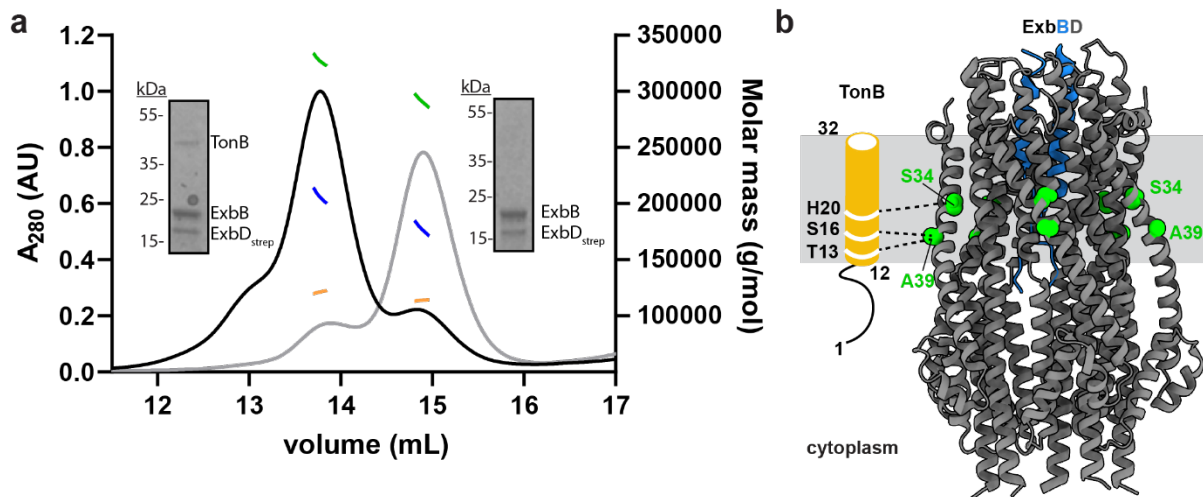

833 **Extended Data Fig. 9. TonB recruitment to the ExbBD complex. a,** SEC-MALS profile of
834 purified *Pseudomonas* TonB-ExbBD (black absorption curve) and ExbBD (grey absorption
835 curve) with SDS-PAGE analysis of each sample inlayed. Total protein-detergent complex molar
836 mass (green) and deconvoluted protein (blue) and detergent (orange) molar masses are
837 shown. A ~30 kDa difference in molar mass is observed between the complexes consistent
838 with the the TonB-ExbBD complex containing one TonB subunit. **b,** Evolutionary co-variation
839 of residues between TonB and ExbB displayed on the *E. coli* ExbBD structure[35] (PDB 6tyi). For
840 clarity, a topological model of the TMH of TonB is shown in orange with TonB-ExbB contacts
841 indicated as dashed lines. Covarying residues decorating the periphery of ExbB are displayed
842 in green. ExbB (grey) and ExbD (blue) are displayed as ribbon cartoons. Contacts shown were
843 generated by Gremlin[5] and have a probability score of > 0.9.
