### 31 Abstract

- 32
- 33 Understanding the rate and pattern of germline mutations is of fundamental importance for
- 34 understanding evolutionary processes. Here we analyzed 19 parent-offspring trios of rhesus macaques
- 35 (*Macaca mulatta*) at high sequencing coverage of ca. 76X per individual, and estimated an average
- 36 rate of  $0.73 \times 10^{-8}$  de novo mutations per site per generation (95 % CI:  $0.65 \times 10^{-8} 0.81 \times 10^{-8}$
- $10^{-8}$ ). By phasing 50 % of the mutations to parental origins, we found that the mutation rate is
- 38 positively correlated with the paternal age. The paternal lineage contributed an average of 80 % of
- 39 the *de novo* mutations, with a trend of an increasing male contribution for older fathers. About 1.9
- 40 % of *de novo* mutations were shared between siblings, with no parental bias, suggesting that they
- 41 arose from early development (postzygotic) stages. Finally, the divergence times between closely
- 42 related primates calculated based on the yearly mutation rate of rhesus macaque generally
- 43 reconcile with divergence estimated with molecular clock methods, except for the
- 44 Cercopithecidae/Hominoidea molecular divergence dated at 54 Mya using our new estimate of the
- 45 yearly mutation rate.

### 46 Introduction

47

48 Germline mutations are the source of heritable disease and evolutionary adaptation. Thus, having precise

49 estimates of germline mutation rates is of fundamental importance for many fields in biology, including

- 50 searching for *de novo* disease mutations (Acuna-Hidalgo et al. 2016; Oliveira et al. 2018), inferring
- 51 demographic events (Lapierre et al. 2017; Zeng et al. 2018), and accurate dating of species divergence
- 52 times (Teeling et al. 2005; Ho and Larson 2006; Pulquério and Nichols 2007). Over the past ten years,
- 53 new sequencing techniques have allowed deep sequencing of individuals from the same pedigree,
- 54 enabling direct estimation of the *de novo* mutation rate for each generation, and precise estimation of the
- 55 individual parental contributions to germline mutations across the whole genome. Most such studies have
- 56 been conducted on humans, using large pedigrees with up to 3000 trios (Jónsson et al. 2017; Halldorsson
- et al. 2019), leading to a consensus estimate of  $\sim 1.25 \times 10^{-8}$  de novo mutation per site per generation, with
- 58 an average parental age of ~ 29 years, leading to a yearly rate of  $0.43 \times 10^{-9}$  de novo mutation per site per
- 59 year and most variation between trios explained by the age of the parents (Awadalla et al. 2010; Roach et
- al. 2010; Kong et al. 2012; Neale et al. 2012; Wang and Zhu 2014; Besenbacher et al. 2015; Rahbari et al.
- 61 2016; Jónsson et al. 2017; Maretty et al. 2017).
- 62 The observed increases in the mutation rate with paternal age in humans and other primates (Venn et al.

63 2014; Jónsson et al. 2017; Thomas et al. 2018) has generally been attributed to errors during replication 64 (Li et al. 1996; Crow 2000). In mammalian spermatogenesis, primordial germ cells go through meiotic divisions, to produce stem cells by the time of puberty. After this time, stem cell divisions occur 65 continuously throughout the male lifetime. Thus, human spermatogonial stem cells have undergone 100 66 67 to 150 mitoses in a 20 years old male, and ~ 610 mitoses in a 40 years old male (Acuna-Hidalgo et al. 2016), leading to an additional 1.51 *de novo* mutations per year increase in the father's age (Jónsson et al. 68 69 2017). Female age also seems to affect the mutation rate in humans, with 0.37 mutations added per year 70 (Jónsson et al. 2017). This maternal effect cannot be attributed to replication errors, as different from 71 spermatogenesis, female oocytogenesis occurs during embryogenesis process and is already finished 72 before birth (Byskov 1986). Moreover, there seems to be a bias towards males in contribution to *de novo* 73 mutations, as the paternal to maternal contribution is 4:1 in human and chimpanzee (Venn et al. 2014; 74 Jónsson et al. 2017). One recent study proposed that damage-induced mutations might be a potential 75 explanation for the observation of both the maternal age effect and the male-bias also present in parents 76 reproducing right after puberty when replication mutations should not have accumulated yet in the male 77 germline (Gao et al. 2019). Parent-offspring analyses can also be used to distinguish mutations that are 78 caused by gametogenesis from mutations that emerge in postzygotic stages (Acuna-Hidalgo et al. 2015; 79 Scally 2016). While germline mutations in humans are relatively well studied, it remains unknown how 80 much variability exists among primates on the contribution of replication errors to de novo mutations, the 81 parental effects, and the developmental stages at which these mutations are established (postzygotic or 82 gametogenesis). 83 Up until now, the germline mutation rate has only been estimated using pedigrees in few non-human 84 primate species, including chimpanzee (Pan troglodytes) (Venn et al. 2014; Tatsumoto et al. 2017;

85 Besenbacher et al. 2019), gorilla (*Gorilla gorilla*) (Besenbacher et al. 2019), orangutan (*Pongo abelii*)

86 (Besenbacher et al. 2019), African green monkey (*Chlorocebus sabaeus*) (Pfeifer 2017) and owl monkey

87 (*Aotus nancymaae*) (Thomas et al. 2018). The mutation rate of baboon (*Papio anubis*) (Wu et al. 2019),

rhesus macaque (*Macaca mulatta*) (Wang et al. 2019) and grey mouse lemur (*Microcebus murinus*)

89 (Campbell et al. 2019) have also been estimated in preprinted studies. To precisely call *de novo* mutations

90 in the offspring, collecting and comparing the genomic information of the pedigrees is a first essential

91 step for detecting mutations only present in offspring but not in either parent. Next, the *de novo* mutations

92 need to be separated from sequencing errors or somatic mutations, which cause false-positive calls.

93 Because mutations are rare events, detecting *de novo* mutations that occur within a single generation

94 requires high sequencing coverage in order to cover a majority of genomic regions and identify the false-

95 positives. Furthermore, the algorithms used to estimate the mutation rate should take false-negative calls into account. However, a considerable range of sequencing depth (ranging from 18X (Pfeifer 2017) to 96 97 120X (Tatsumoto et al. 2017)) has been applied in many studies for estimation of mutation rate. Different 98 filtering methods have been introduced to reduce false-positives and false-negatives but the lack of 99 standardized methodology makes it difficult to assess whether differences in mutation rate estimates are 100 caused by technical or biological variability. In addition, most studies on non-human primates used small 101 pedigrees with less than ten trios, which made it difficult to detect any statistically significant patterns 102 over de novo mutation spectra. 103 Studying non-human primates could help us understanding whether the mutation rate is affected by life-104 history traits such as mating strategies or the age of reproduction. The variation in mutation rate among 105 primates will also be useful for re-calibrating the speciation times across lineages. The sister group of 106 Hominoidea is Cercopithecidae, including the important biomedical model species, rhesus macaque 107 (Macaca mulatta), which share 93 % of its genome with humans (Gibbs et al. 2007). This species has a 108 generation time estimate of  $\sim 11$  years (Xue et al. 2016), and their sexual maturity is much earlier than in 109 humans with females reaching maturity around three years old, while males mature around the age of 4 110 years (Rawlins and Kessler 1986). While female macaques generally start reproducing right after maturation, males rarely reproduce in the wild until they reach their adult body size, at approximately 111 112 eight years old (Bercovitch et al. 2003). They are also a promiscuous species, and do not form pair bonds, 113 but reproduce with multiple individuals. These life-history traits, along with their status as the closest 114 related outgroup species of the hominoid group, make the rhesus macaque an interesting species for 115 investigating the differences and common features in mutation rate processes across primates. 116 In this study, we, produced high depth sequencing data for 33 rhesus macaque individuals (76X per individual) representing 19 trios. This particular dataset consists of a large number of trios, each with high 117 118 coverage sequencing, and allowed us to test different filter criteria and choose the most appropriate ones 119 to estimate the species mutation rate with high confidence. With a large number of *de novo* mutations 120 phased to their parents of origins, we can statistically assess the parental contribution and the effect of the 121 parental age. We characterize the type of mutations and their location on the genome to detect clusters 122 and shared mutations between siblings. Finally, we use our new estimate to infer the effective population 123 size and date their divergence time from closely related primate species. 124

## 125 **Results**

#### 126

#### 127 Estimation of mutation rate for 19 trios of rhesus macaques

128 To produce an accurate estimate for the germline mutation rate of rhesus macaques, we generated high 129 coverage (76 X per individual after mapping, min 64 X, max 86 X) genome sequencing data for 19 trios of two unrelated families (Fig. 1). The first family consisted of two reproductive males and four 130 131 reproductive females, and the second family had one reproductive male and seven reproductive females. 132 In the first family, the pedigree extended over a third generation in two cases. The promiscuous mating system of rhesus macaques allowed us to follow the mutation rates in various ages of reproduction, and 133 134 compare numerous full siblings and half-siblings. 135 We developed a pipeline for single nucleotide polymorphisms (SNP) calling with multiple quality control steps involving the filtering of reads and sites (see Methods). For each trio, we considered candidate sites 136 as *de novo* mutations when i) both parents were homozygotes for the reference allele, while the offspring 137

138 was heterozygous with 30 % to 70 % of its reads supporting the alternative allele, and ii) the three

139 individuals passed the depth and genotype quality filters (see Methods). These filters were calibrated to

140 ensure a low rate of false-positives among the candidate *de novo* mutations.

141 We obtained an unfiltered set of 21,246,733 candidate autosomal SNPs, of which 372,549 were potential

142 Mendelian violations. Of these, 685 SNPs passed the filters as *de novo* mutations, ranging from 21 to 56

143 for each trio and an average of 36 *de novo* mutations per trio (se = 2) (see Supplementary Table 1). We

144 manually curated all mutations using IGV on bam files and found that 624 mutations convincingly

displayed as true positives. This leaves a maximum of 8.91 % (61 sites) that could be false-positives due

146 to the absence of the variant in the offspring or presence of the variant in the parents (see Supplementary

147 Fig. 1 and the 61 curated mutations in Supplementary). Most of those sites were in dinucleotide repeat

regions or short tandem repeats (43 sites), while others were in non-repetitive regions of the genome (18

sites). The manual curation may have missed the realignment executed during variant calling. Thus, in the

absence of objective filters, we decided to keep these regions in the estimate of mutation rate but

151 corrected the number of mutations for each trio with a false-positive rate (see equation 1 in Methods

152 section).

153 To confirm the authenticity of the *de novo* mutations, we performed PCR experiments for all candidate *de* 

*novo* mutations from one trio before manual correction. We designed primers to a set of 39 *de novo* 

155 candidates among which 3 *de novo* mutations assigned as spurious from the manual inspection. Of these,

156 24 sites were successfully amplified and sequenced for all three individuals i.e mother, father, and

157 offspring, including 1 of the spurious sites. Among those sequenced sites, 23 were correct, only one was wrong (Supplementary Fig. 2). This invalidated candidate was the spurious candidate removed by manual 158 curation, therefore supporting our manual curation method. The PCR validation results suggested a lower 159 160 false-positive rate of 4.2 % before manual curation. As the PCR validation was done only on 24 161 candidates we decided to keep a strict false-positive rate of 8.91 % found by manual curation. 162 We then estimated the mutation rate, per site per generation, as the number of mutations observed, and 163 corrected for false-positive calls, divided by the number of callable sites. The number if callable sites for 164 each trio ranged from 2,329,878,451 to 2,349,925,275, covering on average 89 % of the autosomal sites of the rhesus macaque genome. A site was defined as callable when both parents were homozygotes for 165 the reference allele, and all individuals passed the depth and genotype quality filters at that site. As 166 callability is determined using the base-pair resolution vcf file, containing every single site of the 167 genome, all filters used during calling were taken into account during the estimation of callability, except 168 169 for the site filters and the allelic balance filter. We then corrected for false-negative rates, calculated as the number of "good" sites that could be filtered away by both the site filters and allelic balance filters -170 estimated at 4.28 % (see equation 1 in Methods section). Another method to estimate the false-negative 171 172 rate is to simulate mutations on the bam files and evaluate the detection rate after passing through all filters. On 552 randomly simulated mutations among the 19 offsprings, 545 were detected as *de novo* 173 mutations, resulting in a false-negative rate of 1.27 %. The 7 remaining mutations were filtered away by 174 175 the allelic balance filter only, which can be explained by the reads filtering in the variant calling step. 176 This result might be underestimated due to the methodological limitation of simulating de novo 177 mutations, yet, it ensures that a false-negative rate of 4.28 % is not out of range. Thus, the final estimated average mutation rate of the rhesus macaques was  $0.73 \times 10^{-8}$  de novo mutations per site per generation 178 (95 % CI  $0.65 \times 10^{-8}$  -  $0.81 \times 10^{-8}$ ). We removed the 61 sites that, based on manual curation, could 179

180 represent false-positive calls from the following analyses (see the 624 *de novo* mutations in

- 181 Supplementary Table 2).
- 182

#### 183 **Parental contribution and age impact to the** *de novo* **mutation rate**

- 184 We observed a positive correlation between the paternal age and the mutation rate in the offspring
- 185 (adjusted R<sup>2</sup> = 0.38; P = 0.003; regression:  $\mu = -8.265 \times 10^{-10} + 6.550 \times 10^{-10} \times age_{paternal}$ ; P = 0.003;
- 186 Fig. 2a). We also detected a positive correlation with the maternal age, though not significant (adjusted
- 187 R<sup>2</sup> = 0.13; P = 0.073; regression:  $\mu = 5.634 \times 10^{-9} + 2.005 \times 10^{-10} \times age_{maternal}$ ; P = 0.073; Fig. 2b). A multiple

regression of the mutation rate on paternal and maternal age resulted in this formula:  $\mu_{Rhesus} = -5.324 \times 10^{-10}$ +7.009×10<sup>-11</sup>×*age<sub>maternal</sub>*+5.840×10<sup>-10</sup>×*age<sub>paternal</sub>* (P=0.01), where  $\mu_{Rhesus}$  is the mutation rate for the species.

We were able to phase 312 mutations to their parent of origin, which accounted for half of the total 191 192 number of *de novo* mutations (624). There is a significant male bias in the contribution of *de novo* 193 mutations, with an average of 79.7 % paternal de novo mutations (95 % CI 76.0 % - 83.4 %; T = 23.76, DF = 36,  $P < 2.2 \times 10^{-16}$ ; Fig. 2c). Moreover, with half of the *de novo* mutations phased to their parent of 194 195 origin, we were able to disentangle the effect of the age of each parent on mutation rate independently 196 (Fig. 2d). By assuming that the ratio of mutations phased to a particular parent was the same in the phased 197 mutations than in the unphased ones, we could predict the total number of mutations given by each 198 parent. For instance, if an offspring had 40 de novo mutations and only half were phased, with 80 % given 199 from its father, we would apply this ratio to the total number of mutations in this offspring, ending up 200 with 32 de novo mutations from its father and eight from its mother. This analysis suggested a stronger male age effect to the number of mutations (adjusted  $R^2 = 0.42$ , P = 0.002), and a similar, non significant 201 maternal age effect (adjusted  $R^2 = 0.10$ , P = 0.100). The two regression lines meet around the age of 202 203 sexual maturity (3 years for females and 4 years for males), which is consistent with a similar 204 accumulation of *de novo* mutations during the developmental process from birth to sexual maturity in 205 both sexes, but the variances on the regression line slopes are large (see Fig. 2c and Supplementary Fig. 3 206 for the same analysis with a Poisson regression). Using these two linear regressions, we can predict the 207 number of *de novo* mutations in the offspring based on the age of each parent at the time of reproduction: 208 *nb of mutations*  $_{Rhesus} = 2.8835 + 0.4827 \times age_{maternal} - 2.2036 + 2.2588 \times age_{paternal}$ , where *nb of mutations* 209 *Rhogus* is the number of *de novo* mutations for the given trio. The expected mutation rates calculated using the two different regression models show similar correlations with the observed mutation rate ( $R^2 = 0.66$ . 210 P = 0.002 for the first regression and  $R^2 = 0.65$ , P = 0.002 for the upscaled one, see Supplementary Fig. 211 4). However, on the first regression on the mutation rate, the maternal age effect may be confounded by 212 213 the paternal age, as maternal and paternal age are correlated in our dataset, yet, non-significantly ( $R^2 =$ 214 0.38, P = 0.106, see Supplementary Fig. 5). The upscaled regression unravels the effect of the parental 215 age independently from each other. This regression can also be used to infer the contribution of each parent at different reproductive age. For instance, if both parents reproduce at 5 years old, based on the 216 217 upscaled regression, the father is estimated to give ~ 9 de novo mutations (95 % CI: 0 - 19) and the mother ~ 5 de novo mutations (95 % CI: 3 - 8), corresponding to a contribution ratio from father to 218 219 mother of 1.8:1 at 5 years old. If they reproduce at 15 years old, this ratio would be 3.2:1 with males

220 giving ~ 32 *de novo* mutations (95 % CI: 28 – 36) and females ~ 10 *de novo* mutations (95 % CI: 6 – 14).

It seems that the male bias increases with the parental age, yet, our model was based on too few data

222 points in early male reproductive ages to reach a firm conclusion. For the two extended trios for which a

second generation is available, we looked at the proportion of *de novo* mutations in the first offspring that

were passed on to the third generation - the third generation inherited a heterozygote genotype with the alternative allele being the *de novo* mutation. In one case, 67 % of the *de novo* mutations in the female

(Heineken) were passed to her daughter (Hoegaarde), while in another case, 39 % of the *de novo* 

227 mutations in the female (Amber) were passed to her son (Magenta). These deviations from the expected

228 50 % inheritance rate are not statistically significant (Binomial test;  $P_{Hoegaarde} = 0.10$  and  $P_{Magenta} = 0.26$ ).

229

#### 230 Characterizations of *de novo* mutations

231 We characterized the type of *de novo* mutations and found that transition from a strong base to weak base (G > A and C > T) were most common (311/624), with 43 % of those mutations located in CpG sites (Fig. 232 233 3a). In total, 22.9 % (143/624) of the *de novo* mutations were located in CpG sites. This is slightly higher 234 than what has been found in humans, for which 19 % of the *de novo* mutations are in CpG sites (Besenbacher et al. 2015), but not significantly (human:  $X^2 = 2.318$ , df = 1, P = 0.128). Moreover, 32.0 % 235 236 (136/424) of the transition mutations (A > G and C > T) were in CpG sites, higher than what has been found in chimpanzee, with 24 % of the transition *de novo* mutations in CpG sites (Venn et al. 2014). The 237 transition to transversion ratio (ti/ty) was 2.12, which is similar to the ratio observed in other species 238 239 (human: ti/tv ~ 2.16 (Yuen et al. 2016); human ti/tv ~ 2.2 (Wang and Zhu 2014); chimpanzee: ti/tv ~ 1.98 240 (Tatsumoto et al. 2017). The 624 de novo mutations showed some clustering in the genome (Fig. 3b and 241 Supplementary Fig. 6). Across all trios, we observed 8 clusters, defined as windows of 20,000 bp where more than one mutation occurred in any individual, involving 17 mutations. Two clusters were made of 242 mutations from a single individual, accounting for four mutations (Fig. 3b). Overall, 2.72 % of the de 243 244 novo mutations were located in clusters, and 0.64 % were mutations within the same individual located in a cluster, which is significantly lower than the 3.1 % reported in humans (Besenbacher et al. 2016) ( $X^2 =$ 245 11.84, DF = 1, P = 0.001; Supplementary Fig. 7, Supplementary Table 3). We observed 12 mutations 246 occurring recurrently in more than one related individual (Tab. 1), which accounted for 1.9 % of the total 247

number of *de novo* mutations (12/624) and 1.0 % of sites (6/618 unique sites). Four *de novo* mutations (2

249 sites) were shared between half-siblings on the maternal side, and 10 (5 sites) were shared between half-250 siblings on the paternal side. However, there was no significant difference between the proportion of 251 mutations shared between pairs of individuals related on the maternal side (9 pairs, 0.73 % shared), and 252 pairs related on their paternal side (53 pairs, 0.23 % shared; Fisher's exact test P = 0.07). In 4 sites, the 253 phasing to the parent of origin confirmed that the mutation was coming from the common parent for at 254 least one individual (Tab. 1). Moreover, the phasing was never inconsistent by attributing a shared de 255 *novo* mutation to the other parent than the parent in common. However, these shared sites did not appear 256 mosaic in the parents as no alternative allele was observed in the parents except for one site where the 257 common father had only one read supporting the alternative allele (out of 53 reads). Eight of the *de novo* 258 mutations (1.1% of the total *de novo* mutations) were located in coding sequences (CDS regions), which 259 is close to the overall proportion of coding sequences region (1.2%) in the whole macaque genome. Seven 260 out of those eight mutations were non-synonymous.

261

#### 262 Molecular dating with trio-based mutation rate

Based on our inferred mutation rate and the genetic diversity of Indian rhesus macaques ( $\pi = 0.00247$ ) 263 estimated using whole genomic sequencing data from more than 120 unrelated wild individuals (Xue et 264 al. 2016), we calculated the effective population size ( $N_e$ ) of rhesus macaques to be 84,336. This is higher 265 than the N<sub>e</sub> = 80,000 estimated previously using  $\mu = 0.59 \times 10^{-8}$  from hippocampal transcriptome and 266 267 H3K4me3-marked DNA regions from 14 individuals (Yuan et al. 2012), and  $N_e = 61,800$  estimated using  $\mu = 1 \times 10^{-8}$  with 120 individual full genome data (Xue et al. 2016). Assuming a generation time of 11 268 269 years and an average reproduction age of 10 years for females and 12 years for males, the yearly mutation 270 rate of rhesus macaques was calculated based on our regression model of the number of mutations given 271 by males and females independently, and the average callability (see equation 2 in the Methods section). 272 As captive animals usually reproduce later than in the wild, which could impact the average mutation rate 273 per generation, we used the regression instead of the mutation rate per generation to correct for this possible bias. The yearly mutation rate of rhesus macaques in our calculation was  $0.60 \times 10^{-9}$  per site per 274 275 year, almost 1.5 times that of humans (Jónsson et al. 2017).

276 Given a precise evolutionary mutation rate is essential for accurate calibration of molecular divergence

277 events between species, we used the mutation rate we inferred for rhesus macaques to re-date the 278 phylogeny of closely-related primate species with full genome alignment available (Moorjani et al. 2016) (Fig. 4a). The molecular divergence time  $(T_D)$  is the time since an ancestral lineage started to split into 279 280 two descendant lineages, and can be inferred from the genetic divergence between the two descendant 281 lineages and the mutation rate. The speciation time  $(T_s)$  is a younger event that implies no more gene 282 flow between lineages (Steiper and Young 2008). On the backward direction, the alleles of two 283 descendant lineages are randomly sampled from their parents until going back to the most recent common 284 ancestor (Rosenberg and Nordborg 2002). This stochastic event, known as the coalescent, depends on the 285 population sizes, being slower in a large population (Kingman, 1982). Thus, from the divergence time, 286 the speciation time can be inferred given the rate of coalescence (see equation 3 in the Method section). 287 We also compared our results to those of previous dating attempts based on molecular phylogenetic trees 288 calibrated with fossils records (Fig. 4b). We found that the two methods concur for the most recent events. 289 Specifically, we estimated that the Macaca mulatta and Macaca fascicularis genomes had already 290 diverged around 4.02 million years ago (Mya) (95 % CI: 3.55 - 4.61), which is slightly older than 291 previous estimates using the molecular clock calibrated with fossils, as the molecular divergence of the 292 two species has been estimated at 3.44 Mya with mitochondrial data (Pozzi et al. 2014) and 3.53 Mya 293 from nuclear data (Perelman et al. 2011). We estimated a speciation event between the two species 2.16 294 Mya after the coalescent time, also consistent with previous findings of a most common recent ancestor to 295 the two populations of the rhesus macaque, the Chinese and the Indian population, around 1.94 Mya 296 based on coalescent simulations (Hernandez et al. 2007). For the next node, the molecular clock seems to 297 differ between mitochondrial and nuclear data, as the divergence time for the Papionini group into the 298 Papio and Macaca genera has been estimated to 8.13 Mya using nuclear data (Perelman et al. 2011), and 299 12.17 Mya with mitochondrial data (Pozzi et al. 2014). We estimated a divergence time between these 300 two genera of 13.57 Mya (95 % CI: 12.01 – 15.59). For earlier divergence events, our estimated 301 divergence times are more ancient than previous reports. For instance, we estimated that the 302 Cercopithecini and Papionini diverged 20.46 Mya (95 % CI: 18.11 - 23.51), while other studies had 303 calculated 11.55 Mya using nuclear data (Perelman et al. 2011), and 14.09 Mya using mitochondrial data 304 (Pozzi et al. 2014). Finally, the divergence between Cercopithecidae and Hominoidea has been reported 305 between 25 and 30 Mya (Stewart and Disotell 1998; Moorjani et al. 2016), with an estimation of 31.6 306 Mya using the nuclear molecular clock (Perelman et al. 2011) and 32.12 Mya using the mitochondrial one 307 (Pozzi et al. 2014). Our dating of the divergence time between the Cercopithecidae and Hominoidea of 308 53.89 Mya (95 % CI: 47.70 - 61.93) is substantially older than previous estimates. However, the

estimated speciation time inferred based on the ancestral population size, suggested a speciation of theCatarrhini group into two lineages 46.08 Mya (Fig. 4b).

311

### 312 **Discussion**

313

314 Despite many efforts to accurately estimate direct *de novo* mutation rates, it is still a challenging task 315 due to the rare occurrence of *de novo* mutations, and the small sample size that is often available. Sequencing coverage is known to be a significant factor in affecting false-positive (FP), and false-316 317 negative (FN) calls when detecting *de novo* mutation (Acuna-Hidalgo et al. 2016; Tatsumoto et al. 2017). A minimal sequencing coverage at 15X was recommended for SNPs calling (Song et al. 2016). 318 319 However, such coverage cannot provide sufficient power to reduce FPs because the lower depth 320 threshold cannot preclude Mendelian violations due to sequencing errors. Moreover, a larger portion of 321 the genome would be removed in the denominator at low depth in order to reduce the FN. While most studies on direct estimation of mutation rate use 35-40X coverage (Jónsson et al. 2017; Thomas et al. 322 323 2018; Besenbacher et al. 2019), their methods to reduce FP and FN differ. Some studies use the 324 deviation from 50 % of the *de novo* mutation pass to the next generation to infer the false-positive rate 325 (Jónsson et al. 2017; Thomas et al. 2018). Others use probabilistic methods to access the callability 326 (Besenbacher et al. 2019), or simulation of known mutation to control the pipeline quality (Pfeifer 2017). Differences in methods likely impact the calculated rate. Here, we produced sequences at 76X 327 328 coverage, which allows us to apply conservative filtering processes, while still obtaining high coverage 329 (89%) of the autosomal genome region when inferring *de novo* mutations. To our knowledge, only one 330 other study has used very high coverage (120X per individuals), on a single trio of chimpanzees 331 (Tatsumoto et al. 2017). Such high coverage allowed us to achieve a false-positive rate below 8.91 % 332 and within the regions we deemed callable, we calculated a low false-negative rate of 4.28 %. Our estimated rate is higher than the  $0.58 \times 10^{-8}$  de novo mutations per site per generation estimated in 333 a preprint report (Wang et al.2019). The difference should be mainly attributed to the fact that they 334 335 sequenced the offspring of younger parents (average parental age of 7.1 years for females and 7.8 years 336 for males compared to 8.4 years for females and 12.4 years for males in this study). Using our regression from the phased mutation, we estimated a mutation rate of  $0.45 \times 10^{-8}$  per site per 337 generation, when males reproduce at 7.8 years and females reproduce at 7.1 years old. Moreover, using 338 339 their regression based on the age of puberty and the increase of paternal mutation per year, Wang and collaborators estimated a per generation rate of  $0.71 \times 10^{-8}$  mutations when males reproduce at 11 340

years, and a yearly rate of  $0.65 \times 10^{-9}$  mutations per site per year, which is approx 8% higher than our 341 342 estimate of  $0.60 \times 10^{-9}$  (2019). This difference may be due to any combination of stochasticity. differences in *de novo* mutation rate pipelines (callability estimate, false-negative rate, and false-343 344 positive rate estimate) and different models for converting pedigree estimates to yearly rates. However, 345 the close correspondence between these independently derived estimates serves to validate that the pipelines are largely consistent with one another. Our combination of high coverage data and a large 346 347 number of trios allowed us to gain high confidence estimates of the germline mutation rate of rhesus macaques at around  $0.73 \times 10^{-8}$  de novo mutation per site per generation, ranging from  $0.43 \times 10^{-8}$  to 348  $1.13 \times 10^{-8}$ . This is similar to the mutation rate estimated for other non-Hominidae primates;  $0.81 \times 10^{-8}$ . 349  $10^{-8}$  for the owl monkey (*Aotus nancymaae*) (Thomas et al. 2018) and  $0.94 \times 10^{-8}$  for the African green 350 monkey (Chlorocebus sabaeus) (Pfeifer 2017), while all Hominidae seem to have a mutation rate that is 351 higher than  $1 \times 10^{-8}$  de novo mutation per site per generation (Jónsson et al. 2017; Besenbacher et al. 352 2019). However, if we count for the *de novo* mutation per site per year, the rate of rhesus macaque (0.60 353  $\times 10^{-9}$ ) is almost 1.5-fold the human one of  $0.43 \times 10^{-9}$  mutation per sites per year (Jónsson et al. 2017). 354 One of the main factors affecting the mutation rate within the species is the paternal age at the time of 355 356 reproduction, which was attributed to the accumulation of replication-driven mutations during 357 spermatogenesis (Drost and Lee 1995; Li et al. 1996; Crow 2000), and has been observed in many other 358 primates (Venn et al. 2014; Jónsson et al. 2017; Maretty et al. 2017; Thomas et al. 2018; Besenbacher et 359 al. 2019). In rhesus macaques, the rate at which germline mutation increases with paternal age seems faster than in humans; we inferred 2.26 mutations more per year for the rhesus macaque father (95% CI 360 0.97 - 3.54 for an average callable genome of 2.24 Mb), compared to 1.51 in humans (95% CI 1.45-361 1.57 for an average callable genome of 2.72 Mb) (Jónsson et al. 2017). For females, there is less 362 difference, with 0.48 more mutations per year for the mother in rhesus macaque (95% CI -0.10 - 1.07), 363 and 0.37 more per year in human mothers (95% CI 0.32-0.43) (Jónsson et al. 2017). In rhesus 364 macaques, males produce a larger number of sperm cells per unit of time  $(23 \times 10^6 \text{ sperm cells per gram})$ 365 of testis per day (Amann et al. 1976)) than humans  $(4.4 \times 10^6$  sperm cells per gram of testis per day 366 367 (Amann and Howards 1980)). This could imply a higher number of cell division per unit of time in 368 rhesus macaques and thus more replication error during spermatogenesis. This is also consistent with 369 the generation time effect which stipulates that an increase in generation time would decrease the 370 number of cell division per unit of time as well as the yearly mutation rate assuming that most 371 mutations arise from replication errors (Wu and Lit 1985; Goodman et al. 1993; Ohta 1993; Li et al. 372 1996; Ségurel et al. 2014; Scally 2016). Indeed, humans have a generation time of 29 years, while it is

373 11 years for rhesus macaques. Another explanation for a higher increase of mutation rate with paternal 374 age could be differences in the replication machinery itself. Due to higher sperm competition in rhesus 375 macaque, the replication might be under selective pressure for fast production at the expense of 376 replication fidelity, leading to less DNA repair mechanisms. As in other primates, we found a male bias 377 in the contribution of *de novo* mutations, as the paternal to maternal ratio is 3.9:1. However, this ratio is 378 between the 2.7:1 ratio observed in mice (Lindsay et al. 2019) and the 4:1 ratio observed in humans 379 (Goldmann et al. 2016; Jónsson et al. 2018; Lindsay et al. 2019). Similarly to the wild, the males of our 380 dataset reproduced from 10 years old, which did not allow us to examine if the contribution bias was 381 also present just after maturation. Moreover, the promiscuous behavior of rhesus macaque leads to 382 father reproducing with younger females. Using our model to compare the contribution of each parent 383 reproducing at the similar age, it seems that the male bias increases with the parental age, with a similar 384 contribution at the time of sexual maturation (1.7:1 for parents of 5 years old) and an increase in male to 385 female contribution with older parents (3.1:1 for parents of 15 years old). This result differs from 386 humans, where the male bias seems constant over time (Gao et al. 2019), but more time points in 387 macaque would be needed to interpret the contribution over time. In rhesus macaques, the ratio of 388 paternal to maternal contribution to the shared mutations between related individuals is 1:1, similarly to 389 what has been shown in mice (Lindsay et al. 2019), highlighting that those mutations probably occur 390 during primordial germ cell divisions in postzygotic stages. Our study shows many shared patterns in 391 the *de novo* mutations among non-Hominid primates. More estimation of mammals could help 392 understanding if these features are conserved across a broad phylogenetic scale. Moreover, further work 393 would be needed to understand if some gamete production stages are more mutagenic in some species 394 than others. 395 An accurate estimation of the mutation rate is essential for the precise dating of species divergence events. 396 We used the rhesus macaque mutation rate to estimate its divergence time with related species for which

397 whole-genome alignments are already available and their molecular divergence times have been

investigated before with other methods (Moorjani et al. 2016). The results of our direct dating method,

399 based on molecular distances between species and *de novo* mutation rate, matched those of traditional

400 molecular clock approaches for speciation events within 10 to 15 million years. However, it often produced

- 401 earlier divergence times for more ancient nodes than the molecular clock method. This incongruence might
- 402 be attributed to the fossils that were used for calibration with the clock method, which has many
- 403 limitations (Heads 2005; Pulquério and Nichols 2007; Steiper and Young 2008). A fossil used for
- 404 calibrating a node is usually selected to represent the oldest known specimen of a lineage. Still, it

405 cannot be known if real even older specimens existed (Heads 2005). Thus, a fossil is usually assumed to

- 406 be younger than the real divergence time of the species (Benton et al. 2015). Moreover, despite the error
- 407 associated with the dating of a fossil itself, determining its position on a tree can be challenging and
- 408 have effects on the inferred ages across the whole tree (Pulquério and Nichols 2007; Steiper and Young
- 409 2008). For instance, the Catarrhini node, marking the divergence between the Cercopithecidae and the
- 410 Hominoidea, is often calibrated in primate phylogenies (Heads 2005). This node has been calibrated to
- 411 approx. 25 Mya using the oldest known Cercopithecidae fossil (*Victoriapithecus*), and the oldest known
- 412 Hominoidea fossil (*Proconsul*), both around 22 My old (Goodman et al. 1998). However, if the oldest
- 413 Catarrhini fossil (*Aegyptopithecus*) of 33 to 34 My age is used, this node could also be calibrated to 35
- 414 Mya (Stewart and Disotell 1998). Finally, instead of being an ancestral specimen of the Catarrhini,
- 415 Aegyptopithecus has been suggested as a sister taxon to Catarrhini, which would lead to an even older
- 416 calibration time for this node (Stewart and Disotell 1998).
- 417 On the other hand, the direct mutation rate estimation could have produced overestimated divergence
- 418 times for the Catarrhini node age compared to previous estimates (Perelman et al. 2011; Pozzi et al.
- 419 2014), because the mutation rate and generation time might change cross-species and over time. It is
- 420 possible that the Catarrhini ancestor would have had a faster yearly mutation rate, and/or a shorter
- 421 generation time than the recent macaques. Since fossil calibration could underestimate real divergence
- 422 times, molecular-based methods could overestimate it, especially by assuming a unique mutation rate to
- 423 an entire clade (Steiper and Young 2008).
- 424 To obtain more confidence in the estimation of divergence time, it would be necessary to have an accurate
- 425 estimation of the mutation rate for various species. The estimates available today for primates vary from
- 426  $0.81 \times 10^{-8}$  per site per generation for the Owl monkey (*Aotus nancymaae*) to  $1.66 \times 10^{-8}$  per site per
- 427 generation for Orangutan (*Pongo abelii*). However, the different methods and sequencing depth make it
- 428 difficult to compare between species and attribute differences to biological causes or methodological
- 429 ones. Therefore, more standardized methods in further studies would be needed to allow for cross-
- 430 species comparison.
- 431

## 432 Methods

- 433
- 434 **Samples.** Whole blood samples (2 mL) in EDTA (Ethylenediaminetetraacetic acid) were collected from
- 435 53 Indian rhesus macaques (Macaca mulatta) during routine health checks at the Biomedical Primate
- 436 Research Centre (BPRC, Rijswijk, Netherlands). Individuals originated from two groups, with one or two

437 reproductive males per group. After ensuring the relatedness with a test based on individual genotypes

- (Manichaikul et al. 2010), we ended up with 19 trios formed by 33 individuals and two extended trios (for 438
- which a second generation was available). In our dataset males reproduced from 10 years old to 14.5 439
- years old ( $\bigcirc$  reproductive range: 4.5 years), and females from 3.5 years old to 15.7 years old ( $\bigcirc$ 440
- 441 reproductive range: 12.2 years). Genomic DNA was extracted using DNeasy Blood and Tissue Kit
- 442 (Qiagen, Valencia-CA, USA) following the manufacturer's instructions. BGIseq libraries were built in
- 443 China National GeneBank (CNGB), Shenzhen, China. The average insert size of the samples was 230
- 444 base pairs. Whole-genome pair-ended sequencing was performed on BGISEQ500 platform, with a read
- 445 length of 2x100 bp. The average coverage of the raw sequences before trimming was 81X per sample (SE
- 446 = 1.35). Whole-genome sequences have been deposited in NCBI (National Center for Biotechnology)
- 447 Information) with BioProject number PRJNA588178 and SRA submission SUB6522592.
- 448

449 **Reads mapping, SNPs calling, and filtering pipeline.** Adaptors, low-quality reads, and N-reads were 450 removed with SOAPnuke filter (Chen et al. 2017). Trimmed reads were mapped to the reference genome of rhesus macaque Mmul 8.0.1 using BWA-MEM version 0.7.15 with the estimated insert size option. 451 452 Only reads mapping uniquely were kept and duplicates were removed using Picard MarkDuplicates. The average coverage after mapping was 76X per individuals (SE = 1.16). Variants were called using GATK 453 454 4.0.7.0 (Poplin et al. 2018); calling variants for each individual with HaplotypeCaller in BP-RESOLUTION mode; all gVCF files per sample were combined into a single one using CombineGVCFs

- 455
- 456 per autosomal chromosomes; finally joint genotyping was applied with GenotypeGVCF. Because *de novo*
- mutations are rare events, variant quality score recalibration (VQSR) is not a suitable tool to filter the sites 457
- 458 as *de novo* mutations are more likely to be filtered out as low-quality variants. Instead we used a site
- 459 filtering with the following parameters: QD < 2.0, FS > 20.0, MQ < 40.0, MQRankSum < -2.0,
- MQRankSum >4.0, ReadPosRankSum <- 3.0, ReadPosRankSum > 3.0 and SOR > 3.0. These 460
- 461 filters were chosen by first, running the pipeline with the site filters recommended by GATK (QD <
- 462 2.0; FS > 60.0; MQ < 40.0; MQRankSum < -12.5; ReadPosRankSum < -8.0; SOR > 3.0), then,
- 463 doing a manual curation of the candidates *de novo* mutations on the Integrative Genome Viewer
- 464 (IGV). Finally, we identified the common parameters within the apparent false-positive calls and decided
- 465 to adjust the site filter to remove as many false-positives without losing much true positive calls (see the
- pipeline Supplementary Fig. 8). 466
- 467
- Detection of *de novo* mutations. The combination of high coverage (76X) and stringent filters reduced 468

false-positive - calling a *de novo* mutation while it is not there. Thus, for each trio, we applied thefollowing filters:

- 471 (a) Mendelian violations were selected using GATK SelectVariant and refined to only keep sites
  472 where both parents were homozygote reference (HomRef), and their offspring was heterozygote
  473 (Het).
- (b) In the case of a *de novo* mutation, the number of alternative alleles seen in the offspring should
  account for ~ 50 % of the reads. Our allelic balance filter allowed the alternative allele to be
  present in 30 % to 70 % of the total number of reads (applying the same 30% cutoff as in other
  studies (Kong et al. 2012; Besenbacher et al. 2015; Francioli et al. 2015; Supplementary Fig. 9).
- (c) The depth of the three individuals was filtered to be between 0.5×m<sub>depth</sub> and 2×m<sub>depth</sub>, with m<sub>depth</sub>
  being the average depth of the trio. Most of the Mendelian violations are due to sequencing
  errors in regions of low sequencing depth; therefore, we applied a stricter threshold on the
  minimum depth to avoid the peak of Mendelian violations around 20X (Supplementary Fig. 10).
  (d) Finally, after analyzing each trio with different genotype quality GQ cutoff (from 10 to 90), we
  set up a filter on the genotype quality of 60 to ensure the genotypes of the HomRef parents and

485 the Het offspring (Supplementary Fig. 11).

From 21,246,733 autosomal SNPs, 372,549 were potential Mendelian violations found by GATK, 486 487 208,447 were filtered Mendelian violations with parents HomRef and offspring Het (a), 65,731 passed 488 the allelic balance filter (b), 13,197 passed the depth filter (c) and 690 the genotype quality filter (d) 489 (see Supplementary Table 4 for details on each individual). We also remove sites where a *de novo* 490 mutation was shared among non-related individuals (1 site shared between 5 unrelated individuals). 491 This allowed us to detect the number of *de novo* mutations observed per trio called m. We manually 492 checked the reads mapping quality for all *de novo* mutations sites in the Integrative Genome Viewer 493 (IGV). And we found possible false-positive calls in 8.9 % of the sites for which the variant was absent 494 from the offspring or also present in a parent (see Supplementary Fig. 1). We kept those sites for the

495 estimation of the mutation rate, and corrected for false-positive ( $\beta = 0.0891$ ), but removed them for 496 downstream pattern analysis. We experimentally validated the *de novo* candidates from the trio Noot 497 (father), Platina (mother), and Lithium (offspring). Primers were designed for the 39 candidates 498 (Supplementary Table 5). PCR amplification and Sanger sequencing were conducted on each individual 499 (protocol in Supplementary materials). On 24 sites the PCR amplification and sequencing returned 500 high-quality results for all three individuals. A candidate was considered validated when both parents 501 showed homozygosity for the reference allele and the offspring showed heterozygosity (Supplementary 502 Fig. 2). All sequences generated for the PCR validation have been deposited in Genbank with accession 503 numbers MT426016 - MT426087 (Supplementary Table 4).

Estimation of the mutation rate per site per generation. From the number of de novo mutations to an 504 505 estimate of the mutation rate per site per generation, it is necessary to also correct for false-negatives - not 506 calling a true *de novo* mutation as such. To do so, we estimated two parameters: the false-negative rate 507 and the number of callable sites, C, ie. the number of sites in the genome where we would be able to 508 call a de novo mutation if it was there. We used the BP\_RESOLUTION option in GATK to call variants 509 for each position and thus get the exact genotype quality for each site in each individual - also sites that 510 are not polymorphic. So unlike other studies, we do not have to rely on sequencing depth as a proxy for 511 genotype quality at those sites. Instead, we can apply the same genotype quality threshold to the non-512 polymorphic sites as we do for *de novo* mutation candidate sites. This should lead to a more accurate 513 estimate of the number of callable sites. For each trio, C is the sum of all sites where: both parents are 514 HomRef, and the three individuals passed the depth filter (b) and the genotype quality filter (d). To 515 correct for our last filter, the allelic balance (c), we estimated the false-negative rate  $\alpha$ , defined as the 516 proportion of true heterozygotes sites (one parent HomRef, the other parent HomAlt and their offspring 517 Het) outside the allelic balance threshold (Supplementary Fig. 9). We also implemented in this 518 parameter the false-negative rate of the site filters following a normal distribution (FS, MQRankSum, 519 and ReadPosRankSum). For all trios combined, the rate of false-negatives caused by the allele balance 520 filter and the site filters was 0.0428. To validate this false-negative rate estimation we also used a 521 simulation method, used in other studies (Keightley et al. 2015; Pfeifer 2017). With BAMSurgeon 522 (Ewing et al. 2015), 552 mutations were simulated across the 19 trios at random callable sites. The

523 false-negative rate was calculated as 1 – (number of detected mutations/number of simulated

524 mutations), after running the pipeline from variant calling. The mutation rate per sites per generation

525 can then be estimated per trio with the following equation:

$$\mu = \frac{m \times (1 - \beta)}{(1 - \alpha) \times 2 \times C} \tag{1}$$

528 529

530 Sex bias, ages, and relatedness. *De novo* mutations were phased to their parental origin using the read531 backed phasing method described in Maretty et al. 2017 (script available on GitHub:

532 <u>https://github.com/besenbacher/POOHA</u>). The method uses read-pairs that contain both a *de novo* 

533 mutation and another heterozygous variant, the latter of which was used to determine the parental origin

of the mutation if it is present in both offspring and one of the parents. The phasing allowed us to identify

535 any parental bias in the contribution of the *de novo* mutations. Pearson's correlation test was performed

between the mutation rate and ages of each parent, as well as a linear regression model for father and mother

537 independently. A multiple linear regression model was performed to predict the mutation rate from both

538 parental ages as predictor variables. The phased mutations were used to dissociate the effect of the

parental age from one another. Because the total number of SNPs phased to the mother or the father may

540 differ, we divided the phased *de novo* mutations found in a parent by the total SNPs phased to this parent.

541 Only a subset of the *de novo* mutations in an offspring was phased. Thus, we applied the paternal to

542 maternal ratio to the total number of mutations in a trio, referred to as 'upscaled' number of mutations, to

543 predict the number of total mutations given by each parent at different ages. The two extended trios,

analyzed as independent trios, also allowed us to determine if ~ 50 % of the *de novo* mutations observed

545 in the first trio were passed on to the next generation.

546

547 **Characterization of** *de novo* **mutations.** From all the *de novo* mutations found, the type of mutations 548 and their frequencies were estimated. For the mutations from a C to any base we determined if they were 549 followed by a G to detect the CpG sites (similarly if G mutations were preceded by a C. We defined a 550 cluster as a window of 20,000 bp to qualify how many mutations were clustered together; over all 551 individuals, looking at related individuals, and within individuals. We simulated 624 mutations following

552 a uniform distribution to compare with our dataset. We investigated the mutations that are shared between related individuals. Finally, we looked at the location of mutations in the coding region using the 553 554

555

annotation of the reference genome.

Molecular dating using the new mutation rate. We calculated the effective population size using 556 557 Watterson's estimator  $\theta = 4N_e\mu$  (Watterson 1975). We estimated  $\theta$  with the nucleotide diversity  $\pi =$ 558 0.00247 according to a recent population study (Xue et al. 2016). Thus, we calculated the effective population size as  $N_e = \frac{\pi}{4\mu}$  with  $\mu$  the mutation rate per site per generation estimated in our study. To 559 calculate divergence time, we converted the mutation rate to a yearly rate based on the regression model of 560 the number of mutations given by each parent regarding their ages and the average callability C =561 2,342,539,326. Given the maturation time and the high mortality due to predation, we assumed an average 562 age of reproduction in the wild at 10 years old for females and 12 years old for males and a generation 563 564 time of 11 years, also reported in another study (Xue et al. 2016). Thus, the yearly mutation rate was:  $\mu = \frac{2.8835 + 0.4827 \times agematernal - 2.2036 + 2.2588 \times agepaternal \times (1 - \beta)}{(1 - \alpha) \times 2 \times C}$ 565 (2)The divergence time between species was then calculated using  $T_{divergence} = \frac{d}{2u}$  with d the genetic 566 distance between species which were calculated from the whole-genome comparison (Moorjani et al. 567 568 2016) and  $\mu$  the yearly mutation rate of rhesus macaques. We also used the confidence interval at 95% of

569 our mutation rate regression to compute the confidence interval on divergence time. Based on the

570 coalescent theory (Kingman, 1982), the time to coalescence is 2NeG with G the generation time and Ne

571 the ancestral effective population size, assumed constant over time, as shown in a previous study (Xue et

572 al. 2016). Thus, we dated the speciation event as previously done by Besenbacher et al. 2019 with:

573

 $T_{speciation} = T_{divergence} - 2 \times N_{e ancestor} \times G$ (3)

574

#### Acknowledgments 575

- 576 This project was supported by a Carlsberg Foundation Grant to GZ (CF16-0663), Strategic Priority
- 577 Research Program of the Chinese Academy of Sciences (XDB13000000), and ERC Consolidator grant

- 578 681396 Extinction Genomics. LB was supported by Carlsberg Foundation. We would like to thank
- 579 GenomeDK at Aarhus University for providing computational resources and supports to this study. We
- also thank Josefin Stiller for helpful comments on the manuscript. Whole-genome sequences have been
- 581 deposited in NCBI (National Center for Biotechnology Information) with BioProject number
- 582 PRJNA588178.
- 583

### 584 Authors contributions

- 585 G.Z., M.H.S., S.B. and L.B. conceived this work. J.B. provided the samples. L.B., J. Z., P.L., G.A.P.,
- 586 M.H.S.S, and M.T.P.G. participated in extraction, library preparation, and sequencing. MK planned and
- 587 executed the experimental validation. L.B. and S.B. built the analyses pipelines and conducted all the
- analyses. L.B, G.Z, S.B, and M.H.S wrote this manuscript with the input of all co-authors. G.Z.
- supervised this project. The authors declare no competing interests.
- 590

# **Figures and Tables**

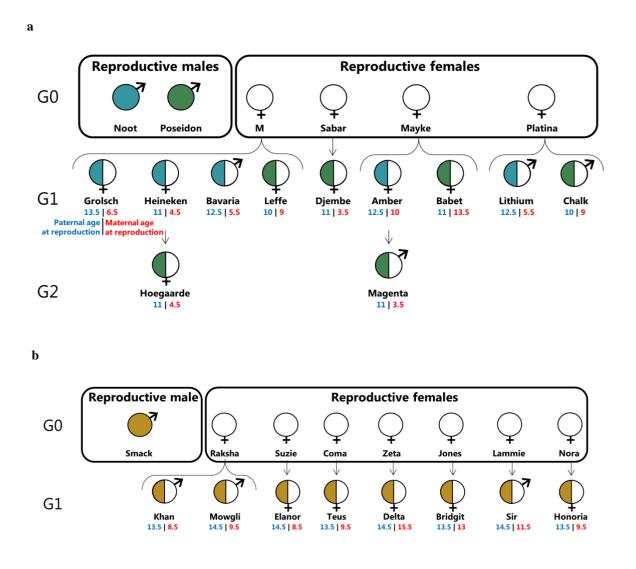

Fig 1 - Pedigree of the 19 trios used for the direct estimation of mutation rate. a, The first group is composed of two reproductive males and four reproductive females. b, The second group contained one reproductive male and seven reproductive females. In each offspring, the color on the left corresponds to the paternal lineage and under the name are the age of the father (in blue) and mother (in red) at the time of reproduction. The reproductive ranges are 4.5 years for males and 12.2 years for females.

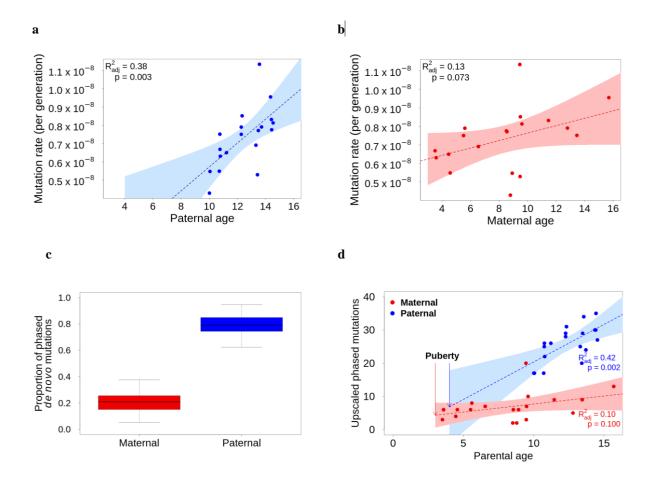

Fig. 2 - Parental contribution and age effect to the *de novo* mutation rate. a, There is a positive correlation between the mutation rate and the paternal age. b, The correlation between maternal age and mutation rate is not significant. c, Males contribute to 79.7 % of the *de novo* mutations while females contribute to 23.3 % of them. d, Upscaled number of *de novo* mutations given by each parent shows a similar contribution at the age of sexual maturation and a substantial increase with male age.

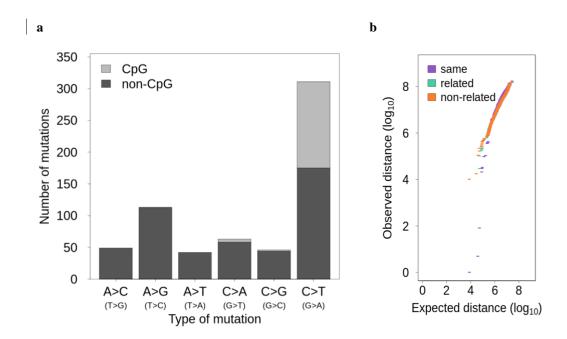

Fig. 3 - Characterizations of the *de novo* mutations. a, The type of *de novo* mutations in CpG and non-CpG sites. b, QQ-plot of the distance between *de novo* mutations compared to a uniform distribution within individuals (purple), between related individuals (green), and between non-related individuals (orange).

a

b

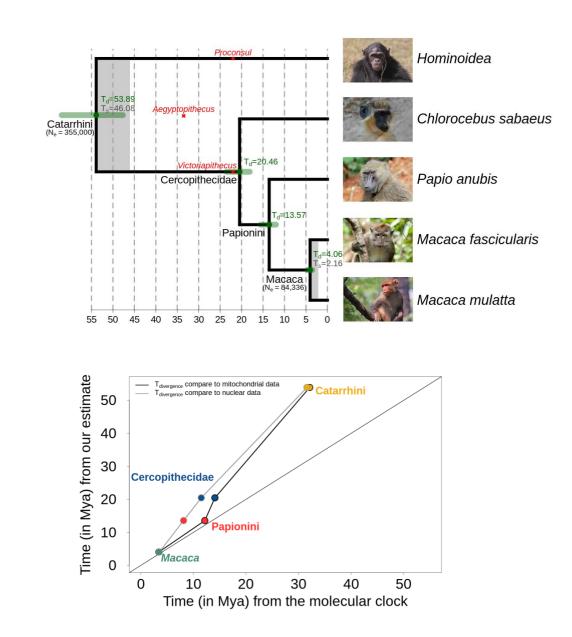

Fig. 4 - Molecular dating with pedigree-based mutation rate. a, Primates phylogeny based on the yearly mutation rate  $(0.60 \times 10^{-9} \text{ per site per year})$ . In green are the confidence interval of our divergence time estimates (Td) and grey shades represent the time of speciation (Ts). The effective population sizes are indicated under the nodes (N<sub>e</sub> Macaca ancestor is our estimate of N<sub>e</sub> *Macaca mulatta* and N<sub>e</sub> Catarrhini from the literature (Schrago 2014)). b, Comparison of our divergence time and speciation time with the previous estimation using the molecular clock from mitochondrial (Pozzi et al. 2014) and nuclear data (Perelman et al. 2011) calibrated with fossils records.
