1 **Abstract**

2 Flexible behavior requires switching between different task demands. It is known that such task-switching

3 is associated with costs in terms of slowed reaction time, reduced accuracy, or both. The neural correlates

4 of task-switching have usually been studied by requiring participants to switch between distinct tasks that

5 recruit different brain networks. Here, we investigated the transition of neural states underlying switching

6 between two memory-related processes with opposite task demands (i.e., memory retrieval and memory

7 suppression). We investigated 26 healthy participants who performed a Think/No-Think task while being

8 in the fMRI scanner. Behaviorally, we show that it was more difficult for participants to suppress

9 unwanted memories when a No-Think was preceded by a Think trial instead of another No-Think trial.

10 Neurally, we demonstrate that Think-to-No-Think switches were associated with an increase in control-

11 related and a decrease in memory-related brain activity. Neural representations of task demand, assessed

12 by decoding accuracy, were lower immediately after task switching compared to the non-switch

13 transitions, suggesting a switch-induced delay in the neural transition towards the required task demand.

14 This suggestion is corroborated by an association between demand-specific representational strength and

15 demand-specific performance in switch trials. Taken together, we propose that the brain's delayed

16 transition of neural states towards the task demand at hand is associated with a switch cost leading to less

17 successful memory suppression.

Significance statement

Our brain can switch between multiple tasks but at the cost of less optimal performance during transition. One possible neuroscientific explanation is that the representation of task demand is not easy to be updated immediately after switching. Thus, weak representations for the task at hand explain performance costs. To test this, we applied brain decoding approaches to human fMRI data when participants switched between successive trials of memory retrieval and suppression. We found that switching leads to a weaker representation of the current task. The remaining representation of the previous, opposite task is associated with inferior performance in the current task. Therefore, timely updating of task representations is critical for the task switching in the service of flexible behaviors.

1 **Introduction**

2 In everyday life, we are continuously switching between different tasks (Monsell, 2003). Transitions
3 between task demands have often been studied using task-switching paradigms in which participants are
4 required to switch between two or more distinct tasks (Meiran, 2010). Usually, participants perform less
5 accurately and/or more slowly immediately after switches (i.e., *switch costs*) (Jersild, 1927; Spector and
6 Biederman, 1976; Rogers and Monsell, 1995; Goschke, 2000). Results from univariate fMRI studies
7 suggested the involvement of prefrontal-parietal regions in task switching (Dove et al., 2000; Braver et al.,
8 2003; Gruber et al., 2006; Richter and Yeung, 2014). Two studies (Waskom et al., 2014; Loose et al.,
9 2017) used multivariate fMRI methods (Haynes, 2015; Cohen et al., 2017) to investigate how task
10 switching modulates task representations but reported mixed results. Waskom and colleagues reported
11 stronger task representations after a shift in task demands (Waskom et al., 2014), while Loose and
12 colleagues found no difference in task representations between the switch and the non-switch condition
13 (Loose et al., 2017).

14 Previous experiments that investigated task switching were typically designed to minimize the perceptual
15 differences between conditions, but not to maximize differences in underlying cognitive demands (Braver
16 et al., 2003; Kiesel et al., 2010; Waskom et al., 2014; Loose et al., 2017). Behavioral and neural correlates
17 of task-switching between two opposite tasks within one cognitive domain remain largely unexplored.
18 Switching between two opposite task demands should be cognitively more challenging than between
19 unrelated tasks, because they may be based on (partly) overlapping neural mechanisms. More importantly,
20 it provides us with the opportunity to examine the fast-adaptive transition between task demands
21 represented in the neural states of the same brain networks in response to switches. Here, we used a
22 modified Think/No-Think paradigm (Anderson and Green, 2001; Levy and Anderson, 2012) to probe
23 task-switching within the memory domain. Specifically, participants were instructed to switch between
24 memory retrieval and memory suppression according to trial-specific instructions. We asked whether we
25 can find behavioral *switch costs* when participants switch between two opposite memory tasks.

1 To detect the neural source of *switch costs*, we analyzed the dynamic transitions between neural states
2 during task switching using time-resolved multivariate decoding. Our analyses focused on frontoparietal
3 regions associated with control and a set of regions associated with memory retrieval. Cognitive and
4 neural models of memory retrieval and suppression suggest that successful retrieval could be the result of
5 cooperation between an inhibitory control network and an episodic retrieval network (Rugg and Vilberg,
6 2013), while effective suppression depends on top-down control of the inhibitory control network upon a
7 general episodic retrieval network (Anderson and Hanslmayr, 2014). Previous fMRI studies of memory
8 suppression supported this idea by showing that compared to Think trials, No-Think trials are associated
9 with stronger activation in control-related regions including the dorsolateral prefrontal cortex,
10 ventrolateral prefrontal cortex, inferior parietal lobule, and supplementary motor area (Anderson, 2004;
11 Guo et al., 2018; Liu et al., 2020b). At the same time, these activity increases are accompanied by reduced
12 activity in memory-related areas in the medial temporal lobe, including the hippocampus (Anderson and
13 Hanslmayr, 2014).

14 We hypothesized that a delayed transition between neural states that represent task demands could be the
15 neural underpinning of behavioral *switch costs* because failing to update neural states on time could result
16 in a neural state that is optimal for the opposite (e.g., retrieval), but not the current (e.g., suppression), task
17 demand. This assumption is built on the idea that the human brain can demonstrate diverse brain states
18 during different cognitive tasks or environmental demands (Hermans et al., 2011; Gonzalez-Castillo et al.,
19 2015; Sadaghiani et al., 2015; Shine et al., 2016; Westphal et al., 2017; Shine and Poldrack, 2018;
20 Cocuzza et al., 2019). The task-switching paradigm is suitable to study such a rapid neural reconfiguration
21 process because it allows us to compare directly how different task demands are represented in neural
22 states and how transitions of neural states are associated with switch costs.

23

24

1 **Results**

2 **Behavioral results**

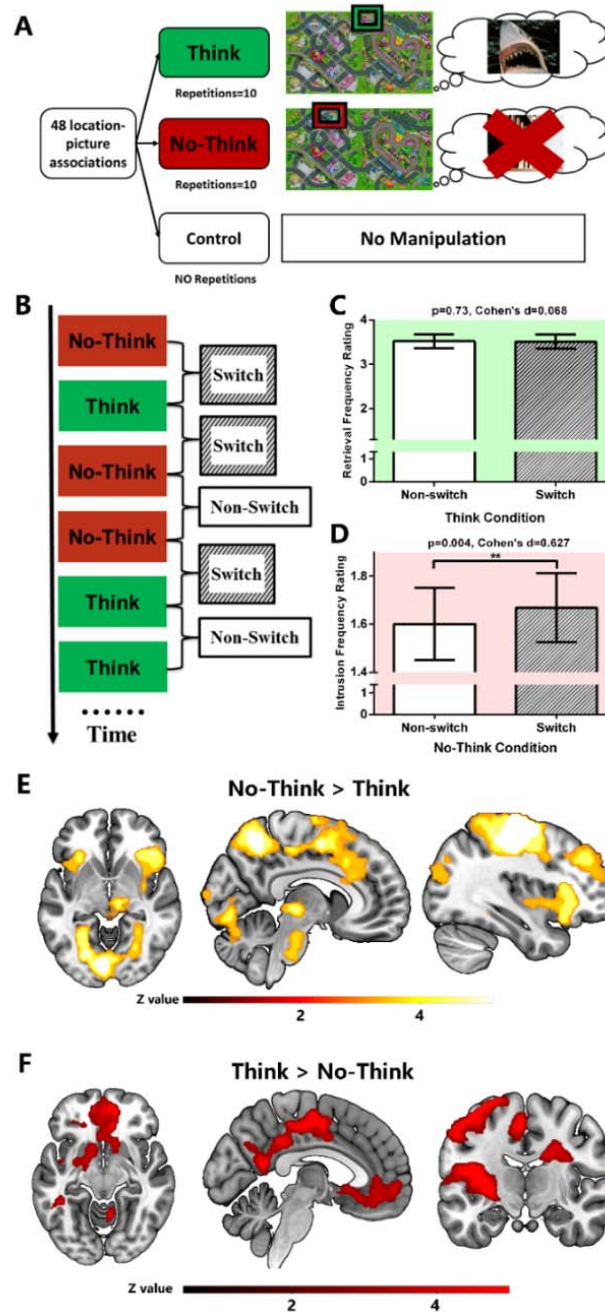

3 Our study used a modified think/no-think (TNT) paradigm (**Figure 1A**) with trial-by-trial reports of
4 (in)voluntary memory retrieval (i.e., retrieval/intrusion frequency rating) (Levy and Anderson, 2012). As
5 intended, most of the associations were successfully recalled in Think trials (1-mean $p_{(\text{Never})}$ =84.05%,
6 SD=11.79 %, range from 56.25% to 100%; **Figure S1A**), while participants suppressed memory retrieval
7 successfully in No-Think trials in about half of the trials (mean $p_{(\text{Never})}$ =50.62%, SD=25.35%, range from 4%
8 to 92.5%; **Figure S1B**).

9 Our central aim was to determine whether there were behavioral *switch costs* in the TNT task and to
10 reveal their neural underpinnings. We defined each trial as a “switch” or “non-switch” trial considering
11 both the task demand of the current trial and its predecessor (**Figure 1B**). Specifically, we identified
12 “switch” trials if a preceding trial had the *opposite* task demand (e.g., previous trial: Think; current trial:
13 No-Think). By contrast, if the current trial and the preceding trial had the *same* task demand, then the
14 current one was a “non-switch” trial. We compared the trial-by-trial performance between “switch” and
15 “non-switch” trials for the Think and the No-Think condition separately. Participants showed comparable
16 performance for “switch” and “non-switch” trials in the Think condition ($t(25)=0.348$, $p=0.731$, Cohen’s
17 $d=0.068$; **Figure 1C**), while they reported more memory intrusions for “switch” trials compared to “non-
18 switch” trials in the No-Think condition ($t(25)=3.19$, $p=0.004$, Cohen’s $d=0.627$; **Figure 1D**), suggesting
19 *switch costs* when the task demand switched from a previous Think trial to a current No-Think trial.

20 After the TNT task, participants performed a final memory test. Results from this task had been reported
21 in another publication in detail (Liu et al., 2020a) and *supplemental materials* (**Figure S2**) of this study.
22 Here, we focused on participants’ performance during the final memory test at the individual level. More
23 specifically, we quantified individual differences in both subjective and objective *suppression-induced*
24 *forgetting effects* and correlated them with fMRI measures (*see below*).

1 **fMRI results**

2 To replicate the univariate neural signature of memory suppression reported in prior studies (Anderson,
3 2004; Anderson and Hanslmayr, 2014), we first conducted a univariate analysis to contrast brain regions
4 engaged in memory suppression and memory retrieval (i.e., No-Think vs. Think). We found an increased
5 activity for No-Think trials in regions that are consistently involved in memory suppression, including the
6 bilateral dorsolateral prefrontal cortex (DLPFC), bilateral insula, bilateral inferior parietal lobule (IPL),
7 supplementary motor area (SMA), and middle cingulate gyrus (**Figure 1E; Table S1**). Additionally, we
8 found higher activity in ventral visual areas and the right thalamus during No-Think compared to Think
9 trials. Next, we contrasted the Think condition with the No-Think condition and found the increased
10 activity for Think condition in a set of regions including the medial prefrontal cortex (mPFC), posterior
11 cingulate cortex (PCC), hippocampus, inferior parietal lobule (IPL), precuneus, angular gyrus, and
12 cerebellum (**Figure 1F; Table S2**). Together with the behavioral results from the final memory test, these
13 results confirmed that participants in our experiment followed task instructions, leading to univariate
14 neural signatures of memory retrieval and suppression consistent with prior findings (Anderson, 2004;
15 Levy and Anderson, 2012; Hulbert et al., 2016), as well as recent meta-analyses of memory suppression
16 (Guo et al., 2018; Liu et al., 2020b).

1

2 **Figure 1** (A) After learning 48 location-picture associations, participants performed a Think/No-Think task while
 3 brain activity was measured by fMRI. During think trials, participants were instructed to retrieve associated pictures
 4 based on the highlighted locations as memory cues. By contrast, during no-think trials, participants were required to
 5 suppress the tendency to retrieve the associated pictures. (B) The sequence of trials was designed to probe task
 6 switching between two task demands (i.e., Think and No-Think). When the task demand of the current trial was the
 7 same as the previous trial, it was defined as the “Non-switch” trial. By contrast, while the task demand of the current
 8 differed from the previous trial, it was defined as the “switch” trial. (C) During Think trials, participants
 9 demonstrated comparable memory retrieval performance ($p=0.73$, Cohen's $d=0.068$) for both “switch” and “Non-
 10 switch” trials. (D) During No-Think trials, participants reported worse memory suppression performance, indexed by
 11 more memory intrusions for “switch” trials compared to “non-switch” trials ($p=0.004$, Cohen's $d=0.627$). (E) Brain
 12 regions showed increased activation during No-Think trials compared to Think trials. (F) Brain regions showed
 13 increased activation during Think trials compared to No-Think trials.

1 **The transition of large-scale neural states from memory retrieval to memory suppression**

2 Based on neurocognitive models of memory suppression (Anderson and Hanslmayr, 2014), we focused on
3 the neural dynamics within the inhibitory control network and the memory retrieval network. First, we
4 used *Neurosynth* (<https://neurosynth.org/>), an automatic meta-analysis tool of neuroimaging data (Yarkoni
5 et al., 2011), to identify the inhibitory control network and memory retrieval network independently from
6 our fMRI data. Using the term “*inhibitory control*” and “*memory retrieval*,” we performed term-based
7 meta-analyses to reveal two distinct brain networks of inhibitory control (**Figure S3A**) and memory
8 retrieval (**Figure S3B**) separately. The two meta-analytic maps have *overlapping* areas, including the IFG,
9 insular, SMA, inferior parietal lobule (**Figure S3C**). Interestingly, the latter areas are highly similar to a
10 “task switching” map generated by *Neurosynth* using the term “*task switching*” (**Figure S3D**).

11 In the next step, to enable a regions-of-interest analysis, we separated the identified *inhibitory control*,
12 *memory retrieval* and *overlapping* networks into regions-of-interest (ROIs) based on the combination of a
13 connectivity-based neocortical parcellation (number of parcels=300) (Schaefer et al., 2018) and
14 subcortical regions (number of regions=14) (*Details see Methods*). Using this approach, we identified 71
15 parcels as *memory-related regions*, 29 parcels were categorized as *control-related regions*, and 10 parcels
16 were labeled as *overlapping regions* (**Figure 2A**). Finally, BOLD time series were extracted from each
17 voxel, averaged within each ROI, and further processed.

18 Using these time series, we characterized the group-average transition of neural states when the task
19 demand changed from Think to No-Think trials (**Figure 2B**). Based on the task instruction, the time series
20 were firstly split for the Think and No-Think conditions separately and then concatenated across all runs
21 of all participants. For each task demand, all ROIs were ranked based on their state-specific averaged
22 neural activity across runs (the highest activity was ranked first) to represent their relative dominance
23 during that neural state (i.e., Think or No-Think). For control purposes, the same analysis was repeated for
24 raw signal intensities (**Figure S4B**) and their Z-values (**Figure S4C**) and yielded highly similar patterns.
25 A Kruskal-Wallis test showed that during Think trials, *memory-related regions*, *control-related regions*,

1 and *overlapping regions* differed in their ranks ($H(2) = 40.48, p < 0.001$). Post-hoc Mann-Whitney tests
2 using a Bonferroni-adjusted alpha level of 0.017 (0.05/3) were used to compare all group pairs. *Memory-*
3 *related regions* (mean_{memory}=40.22, SD_{memory}=27.39) ranked higher than *control-related regions* (mean
4 control=82.34, SD_{control}=22.28) and *overlapping regions* (mean_{overlap}=75.10, SD_{overlap}=19.08) (memory-
5 related vs. control-related: $U=263, p < 0.001$; memory-related vs. overlapping: $U=108, p < 0.001$). *Control-*
6 *related regions* and *overlapping regions* did not differ significantly in their ranks ($U=104, p=0.096$).
7 Three types of regions also differed in their ranks during No-Think trials ($H(2) = 36.60, p < 0.001$).
8 *Memory-related regions* (mean_{memory}=67.96, SD_{memory}=27.94) ranked lower than *control-related regions*
9 (mean_{control}=27.24, SD_{control}=23.13) and *overlapping regions* (mean_{overlap}=37.80, SD_{overlap}=21.10)
10 (memory-related vs. control-related: $U=238, p < 0.001$; memory-related vs. overlapping: $U=144, p=0.001$).
11 *Control-related regions* and *overlapping regions* did not differ significantly in their ranks ($U=101,$
12 $p=0.081$). All comparisons between *memory-related* and *control-related/overlapping regions* were
13 significant after Bonferroni-adjustment (all $p_s \leq 0.001$). Furthermore, we performed additional analyses of
14 neural state transition by dividing all ROIs into three groups (i.e., *increased group*, *stable group*, and
15 *decreased group*) based on their relative changes in rank (See *Supplemental Material*).

16

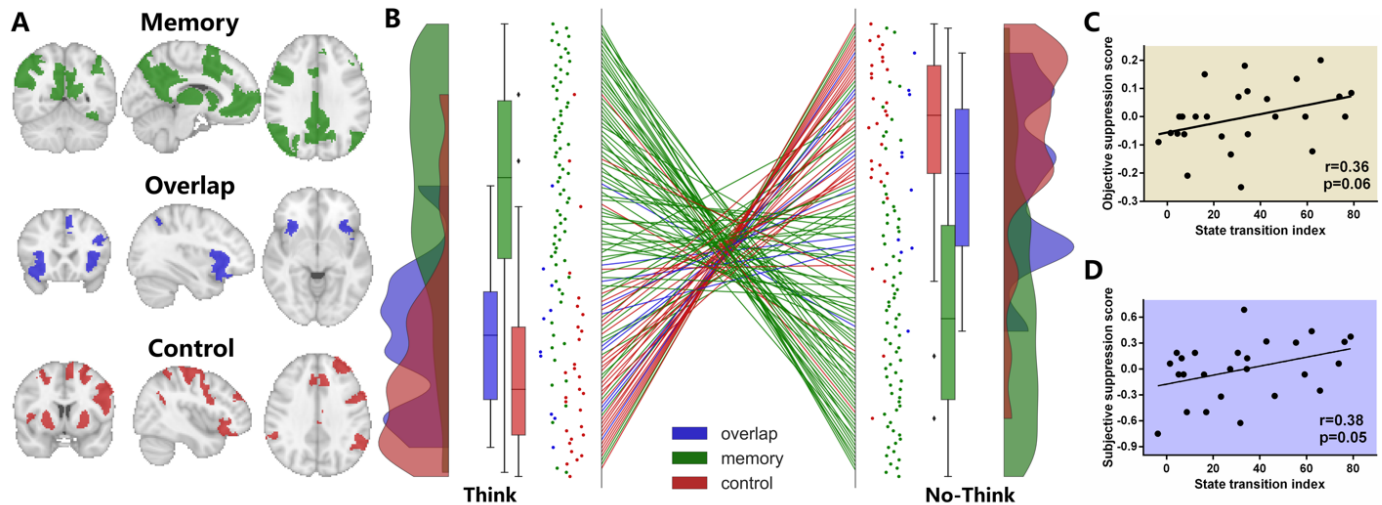

17 **The transition of neural states during the TNT task is associated with subsequent suppression-** 18 **induced forgetting**

19 We already demonstrated that activity of *control-related regions* increased, and the activity of *memory-*
20 *related regions* decreased when the task demands switched from Think to No-Think. To assess if these
21 regional brain activity changes are associated with the behavioral consequence of memory suppression
22 (i.e., suppression-induced forgetting effect), we quantified this neural state transition at the individual
23 level and examined whether individual differences in the transition predict individual subsequent
24 suppression-induced forgetting measures (i.e., *subjective and objective suppression score*). The subjective
25 and objective *suppression score* was calculated by subtracting the memory measure (i.e., confidence

1 rating or recall accuracy) of suppression associations (i.e., “No-Think” items) from the control association
2 separately.

3 Based on the group-level fMRI results, we calculated a *state transition index* to represent the degree of
4 neural transition during the TNT task for each participant. The state transition index was calculated by
5 adding up the averaged relative decreases in ranks of all *memory-related regions* and the averaged relative
6 increase in rank of all *control-related regions*. The *state transition index* tended to be positively correlated
7 with individual differences in *objective suppression scores* ($r=0.36$, $p=0.06$; **Figure 2C**), and *subjective*
8 *suppression scores* ($r=0.38$, $p=0.05$; **Figure 2D**). For validation purposes (not an independent analysis),
9 we used an alternative method (i.e., *state transition index Version2(V2)*) to measure neural state transitions
10 for each participant. This method was based on additional analyses of Think-to-No-Think neural state
11 transition (See *Supplemental Materials*): all ROIs were divided into three groups (i.e., *increased group*,
12 *stable group*, and *decreased group*) based on their relative changes in ranks. The state transition index V2
13 was calculated as the sum of the percentage of *memory-related nodes* within the *decreased group* and
14 percentage of *control-related nodes* within the *increased group*. We also found the same significant
15 correlations between *state transition index V2* and both *objective* and *subjective suppression scores*
16 (**Figure S5**). These results suggested that the transition of neural states during the TNT task is relevant for
17 the subsequent suppression-induced forgetting measured in the final memory test.

18

1

2 **Figure 2 (A)** Memory retrieval network (GREEN) and inhibitory control network (RED) was defined using the
3 *Neurosynth* independent of fMRI data analyzed in this study. The overlap between the two brain networks was
4 defined as the overlapping network (BLUE). **(B)** When the task demand switched from Think to No-Think, the
5 activity of brain regions within the inhibitory control network increased, while the activity of brain regions within the
6 memory retrieval network decreased. **(C)** Individual differences in the neural state transition (*state transition index*
7 *details see Methods*) tended to correlate with the objective suppression-induced forgetting effect during subsequent
8 memory retrieval task ($r=0.36$, $p=0.06$). **(D)** The same index also tended to correlate with the subjective suppression-
9 induced forgetting effect ($r=0.38$, $p=0.05$).

10

11 **Switch of task demand is accompanied by the delayed transition between neural states**

12 To reveal how neural representations of task demands change during task switching, we used a
13 multivariate decoding method to track the dynamics of neural state transitions on the volume-by-volume
14 basis (**Figure 3A**). Support Vector Classification (SVC) was used to classify the underlying neural states
15 (i.e., Think vs. No-Think) based on the fMRI activity intensity of all 110 ROIs at each given time point.
16 Participant-specific classifiers were fitted on neural and task demand data from N-1 runs (i.e., four runs)
17 and tested on the one remaining test run. Then the decoding accuracy was evaluated for each TNT run by
18 comparing the decoded task demands with the actual demands. Averaged across runs, we were able to
19 decode task demands based on ROIs' neural activity with the mean accuracy of 59.5% (SD=3.9% range
20 from 52.5% to 67.1%) (**Figure 3B**). This accuracy is significantly higher than the chance level (i.e., 50%)
21 ($t(25)=12.5$, $p<0.001$, Cohen's $d=2.453$). We generated the confusion matrix of our decoding analysis to
22 quantify all types of correct and incorrect classifications (**Figure 3C**). 57.9% (SD=4.1%, range from 50.6%

1 to 65.7%) of Think time points were correctly classified as Think. Among all No-Think time points, 61.1%
2 (SD=3.9%, range from 53.9% to 68.4%) of them were correctly classified as No-Think. To reveal the
3 relative contribution of each ROI to this decoding performance, we visualized the neural state-predictive
4 pattern (i.e., SVC discriminating weights) in **Figure 3D**, which revealed a frontoparietal network of strong
5 task demand representation, including the dorsal anterior cingulate cortex (dACC), DLPFC, IFG, superior,
6 and inferior parietal lobule (**Table S3**). These regions were largely similar to the *overlapping network*
7 (**Figure S6**).

8 To reveal how the switch of task demands affected underlying neural state transitions, we calculated the
9 decoding accuracy for “switch” and “non-switch” time points separately. Higher decoding accuracy
10 represented a timely update of neural states according to the current task demand, thus stronger neural
11 representation of task demand. Compared to “switch” time points, task demand of “non-switch” time
12 points can be decoded more accurately ($t(25)=3.93$, $p<0.001$, Cohen’s $d=0.77$; **Figure 3E**). That is to say,
13 time points within No-Think trials following a Think trial were more often misclassified as Think trials
14 compared to a No-Think trial following another No-Think trial. This pattern of results was also observed
15 for Think trials. These findings suggest a delayed neural state transition immediately after the task
16 switching.

17

18 **Mismatches between task demand and underlying neural state relate to switch costs**

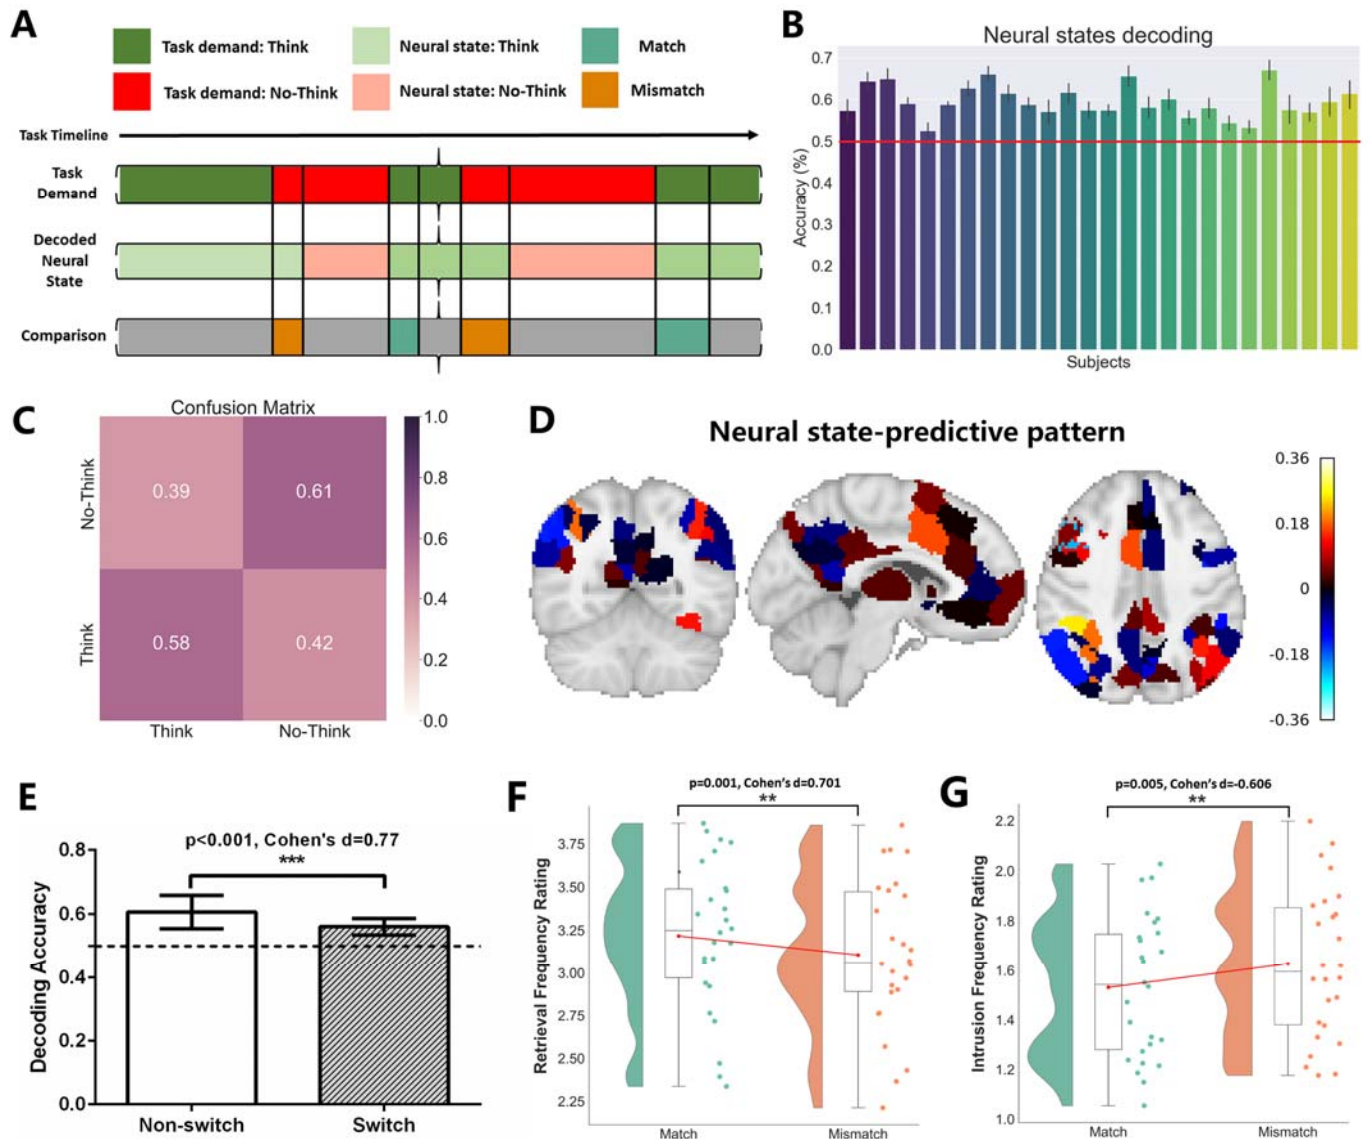

19 Unlike most of the decoding analyses, which usually focused on the accuracy of the classifier, here we
20 were particularly interested in the relationship between misclassified moments and *switch costs*. We
21 already demonstrated that these misclassifications were largely induced by task switching, and we
22 predicted that this mismatch could be the neural source of behavioral *switch costs*. To test this idea, we
23 averaged the trial-by-trial performance measures (i.e., retrieval frequency rating for Think trials and
24 intrusion frequency rating for No-Think trials) for four situations at issue (i.e., Think-Correct

1 classification, Think-Incorrect classification, No-Think- Correct classification and No-Think- Incorrect
2 classification) within switch trials.

3 We found that participants' behavioral performance was impaired during these mismatch moments (i.e.,
4 incorrect classifications (mean_{incorrect}=43.9%; SD_{incorrect}=2.6%; ranging from 38.5% to 49.8% of all
5 classifications)) immediately after task switches. Specifically, during the Think condition, when neural
6 states were mistakenly classified as No-Think, the retrieval frequency rating was lower ($t(25)=3.57$,
7 $p=0.001$, $d=0.701$; **Figure 3F**) compared to the situation in which task demands matched with the neural
8 state. During No-Think trials, if neural states were erroneously decoded as Think, participants reported
9 higher intrusion frequency rating ($t(25)=-3.08$, $p=0.005$, $d=-0.606$; **Figure 3G**) compared to the situation
10 in which classifications were correct.

11 In our exploratory analyses, we found that such mismatch moments not only occurred during the task-
12 switching but was also observed (but less frequently) during non-switch trials. Using the same decoding
13 method, but focusing on non-switch time points, we found a similar detrimental effect of mismatch on
14 behavioral performance (**Figure S7**). These findings suggested that spontaneous, uninstructed neural state
15 transitions that do not fit current task demands also have behavioral impacts.

16

1
2

3 **Figure 3** (A) Neural state decoding analysis. We trained the decoder based on large-scale brain network activity to
 4 classifier the task demand represented in the brain. We hypothesized that immediately after the switch of the task
 5 demand, the transition of the underlying neural state could be delayed. Therefore, the task demand could be
 6 misclassified as the opposite by the decoder. The real task demand was compared with the decoded neural state. The
 7 correctly decoded moments were labeled as “match” (e.g., Think as Think), while incorrectly decoded moments were
 8 defined as “mismatch” (e.g., Think as No-Think). (B) Decoding accuracies were presented for each participant and
 9 against the chance level of 50%. (C) Confusion matrix for four types of classification results. On average, 39% of the
 10 Think moments were labeled as No-Think, and 42% of the No-Think moments were regarded as Think moments by
 11 the decoder. These were the so-called “mismatch” moments depicted in Figure 3A. (D) The contribution of different
 12 brain regions during the decoding. This predictive pattern mainly includes the dACC, DLPFC, IFG, superior, and
 13 inferior parietal lobule. (E) More “mismatch” moments were found immediately after the task switching, indexed by
 14 the lower decoding accuracies during switch compared to non-switch moments ($p < 0.001$, Cohen's $d = 0.77$). (F) After
 15 the task switching, when the decoded neural state did not match with the task demand (i.e., Think decoded as No-
 16 Think), participants reported worse memory retrieval performance during Think trials ($p < 0.001$, Cohen's $d = 0.70$).
 17 (G) When the neural decoder misclassified No-Think moments as Think, participants reported more memory
 18 intrusions during No-Think trials ($p = 0.005$, Cohen's $d = 0.606$).

1 **Neural state transitions are not the results of differences in head motion**

2 We observed large-scale neural state transitions during the TNT task. Individual differences in these
3 transitions were associated with the subsequent suppression-induced forgetting effect. There is a
4 possibility that these neural state transitions are based on artifacts caused by different levels of participants'
5 head motion (Siegel et al., 2017; Huang et al., 2018) between Think and No-Think trials since more
6 inhibitory control resource was required for No-Think trials compared to Think trials (Anderson and
7 Green, 2001; Anderson and Hanslmayr, 2014). Therefore, we examined the relationship between head
8 motion, neural state transitions, and behaviors to rule out this alternative explanation.

9 We analyzed the time series of head motion (i.e., framewise displacement (FD) (Power et al., 2012))
10 during the TNT task. First, there is literally no difference in mean FD values between Think and No-Think
11 trials ($FD_{\text{Think}}=0.149$ (SD=0.047); $FD_{\text{No-Think}}=0.149$ (SD=0.046); $t(25)=0.30$, $p=0.76$, Cohen's $d=0.06$).
12 Second, for each participant, we calculated differences between the head motion of Think and No-Think
13 trials (i.e., $FD_{\text{Think}}-FD_{\text{No-Think}}$) and found no correlation between these differences and *state transition*
14 *indices* ($r=-0.3$, $p=0.12$), *objective suppression scores* ($r=-0.14$, $p=0.46$) or *subjective suppression scores*
15 ($r=-0.23$, $p=0.25$). Third, we asked whether head motion could affect our neural state decoding analysis.
16 The head motion level tended to be lower ($t(25)=-1.96$, $p=0.06$, $d=-0.38$) for correct decoding
17 ($FD_{\text{correct}}=0.147$; SD=0.045), compared to incorrect decoding ($FD_{\text{incorrect}}=0.151$; SD=0.048). This
18 difference raised the question of whether the lower decoding accuracy for switch compared to non-switch
19 condition resulted from higher head motion instead of differences in the neural representation related to
20 task demands. Therefore, we also compared head motions between the switch and the non-switch
21 conditions. In fact, we found that head motion is even lower in the switch condition ($FD_{\text{switch}}=0.145$
22 (SD=0.048); $FD_{\text{non-switch}}=0.150$ (SD=0.047); $t(25)=3.35$, $p=0.003$, $d=0.65$). This result ruled head motion
23 out as an alternative explanation for the lower decoding accuracy for the switch condition. If the lower
24 decoding accuracy during switching were driven by excessive head motion dominantly, we would observe

1 relatively higher instead of lower head motion. In sum, analyses of head motion suggest that our
2 neuroimaging results are not likely to a consequences of variations in head motions.

3

4 **Discussion**

5 Task switching is a crucial cognitive ability that has been intensively studied using behavioral and
6 neuroimaging methods (Meiran, 2010; Ruge et al., 2013; Richter and Yeung, 2014). Here, we investigated
7 the task switching process between memory retrieval and suppression and demonstrated that memory
8 suppression is more difficult when the task demand for the participants just switched from retrieval to
9 suppression. Applying multivariate decoding methods to human fMRI data, we revealed that immediately
10 after the switch, task demands were weakly represented by the inhibitory control and memory retrieval
11 networks, indexed by the lower decoding accuracy, compared to non-switch trials. Importantly, during the
12 switching, when the neural representation of task demand cannot be updated in time to match the current
13 demand, participants reported more memory intrusions in No-Think trials and less memory retrieval in
14 Think trials. Together, we propose a novel mechanism that explains behavioral *switch costs* during task
15 switching between retrieval and suppression: delayed transition of task-related neural states is associated
16 with behavioral switch costs. That is to say, if the neural state cannot be timely updated after the switch of
17 task demand, behavioral performance is compromised.

18 In the current study, participants were instructed to perform one of two opposite memory-related tasks (i.e.,
19 memory retrieval and memory suppression), with the task demand staying the same or switching between
20 consecutive trials. Similar to what reported in the classical task-switching paradigms (Jersild, 1927;
21 Spector and Biederman, 1976), we found *switch costs* that are specific to memory suppression.
22 Participants reported more memory intrusions when the current No-Think trial followed a Think trial,
23 suggesting a higher demand for cognitive control over the tendency to retrieve during switch trials
24 compared to non-switch trials. This lasting effect of memory retrieval on the subsequent memory

1 suppression has not been reported before, but Hulbert and colleagues reported a lasting effect of memory
2 suppression on the subsequent memory formation (Hulbert et al., 2016): when healthy participants
3 suppressed unwanted memories, they were more likely to fail to encode information that was presented
4 after a suppression trial. It was proposed that memory suppression created an amnesic time window,
5 preventing the experience within the window being transformed into long-term memory. Evidence from
6 fMRI supported this model by showing the reduction of hippocampal activity during memory suppression
7 trials, and the positive correlation between individual differences in decreased hippocampal activity and
8 the extent of memory impairment across participants (Hulbert et al., 2016).

9 Our finding of more memory intrusions during the No-Think trials that followed a Think trial could result
10 from a similar mechanism: the preceding Think trials creates a time window in which the hippocampus
11 remains active to support retrieval. However, if the transition of the neural state is delayed, the following
12 No-Think trials are still located within this window, and therefore more prefrontal control resources are
13 needed to down-regulate hippocampal activity. We tested this prediction beyond the hippocampus: large-
14 scale neural activity of the inhibitory control and memory retrieval networks were analyzed by
15 multivariate decoding methods to track the adaptive neural state transitions. We first characterized the
16 transitions in neural states of memory retrieval and inhibitory control networks between Think and No-
17 Think trials. Consistent with previous models of memory suppression (Anderson and Hanslmayr, 2014),
18 our results showed that when the task demand switched from retrieval to suppression, memory retrieval-
19 related regions, mainly including the hippocampus and regions of DMN, decreased their neural activity,
20 while inhibitory control-related regions, such as dACC and LPFC, increased their activity. We also
21 examined the relationship between individual differences in the efficiency of neural state transitions and
22 the *suppression-induced forgetting effect* measured in the subsequent final memory test and found a
23 positive correlation between them. There are two possible explanations for how neural state transitions are
24 related to the effect of memory suppression: either larger or smaller state transitions are associated with
25 stronger suppression effect. The more intuitive explanation is that larger transitions are beneficial for

1 suppression; however, our data suggested the opposite: participants who demonstrated less neural
2 reconfiguration showed stronger memory suppression effect in the following final memory test. This
3 finding is nevertheless consistent with a previous study, which demonstrated that higher intelligence is
4 associated with less task-related neural reconfiguration (Schultz and Cole, 2016). Our data, together with
5 this study, may suggest that less neural reconfigurations could reflect optimization for efficient (i.e., less)
6 state updates, reducing processing demands (Schultz and Cole, 2016). This optimal task-related neural
7 reconfiguration could then be beneficial for memory suppression.

8 Recent human fMRI studies revealed task representations using multivariate decoding methods. Brain
9 regions such as the parietal cortex, medial, and lateral PFC encode the current task demands (Bode and
10 Haynes, 2009; Cole et al., 2011; Gilbert, 2011; Woolgar et al., 2011; Momennejad and Haynes, 2013;
11 Waskom et al., 2014; Wisniewski et al., 2015; Etzel et al., 2016) and our study provided further support
12 for this idea by showing that neural activity patterns of these regions largely contributed to successful
13 discrimination between two kinds of visually highly similar trials with opposite task demands (i.e.,
14 memory retrieval and suppression). These identified regions have been previously associated with
15 cognitive processing such as retrieval, maintenance, the process of rules or demands during task switching
16 (Bunge et al., 2003; Sakai and Passingham, 2003; Gilbert, 2011; Woolgar et al., 2011; Reverberi et al.,
17 2012). Beyond that, memory-related areas such as the hippocampus and regions within the DMN also
18 contributed to the successful decoding in our study because the retrieval-demand and its associated neural
19 activity significantly differed between Think and No-Think trials. However, whether these task
20 representations can be modulated by external experimental manipulations and detected by fMRI signals is
21 an ongoing debate. Task representations are modulated by factors including rule complexity (Woolgar et
22 al., 2015), rewards (Etzel et al., 2016), and skill acquisition (Jimura et al., 2014), but not by variables such
23 as task novelty (Cole et al., 2011), difficulty (Wisniewski et al., 2015), or intention (Zhang et al., 2013;
24 Wisniewski et al., 2016). Two studies directly investigated whether and how cognitive control processes
25 during task switching modulate the neural representation of task demands. Waskom and colleagues found

1 that task representations are enhanced after switches, indexed by the higher decoding accuracy (Waskom
2 et al., 2014). However, they did not find evidence for behavioral switch costs in their sample; thus, the
3 relationship between higher decoding accuracy and task representation is unclear. Loose and colleagues
4 did find the behavioral switch costs, but no modulation effect in the task representations (i.e., comparable
5 decoding accuracy between the switch and non-switch trials) (Loose et al., 2017). They, therefore,
6 proposed the switch-independent neural representations of task demands. Compared to the mentioned two
7 studies mentioned here, our study found behavioral switch costs for memory suppression and lower
8 decoding accuracies for task representations in switch trials. Critically, our time-resolved decoding
9 approach revealed the relationship between task representation and behavioral performance on a trial-by-
10 trial basis. Specifically, we showed that in switch trials, if the underlying neural state matched the external
11 task demand, behavioral performance remained intact, while if the neural state was incorrectly represented,
12 task performance was compromised. This pattern of results may explain why higher decoding accuracy
13 was reported together with limited behavioral switch costs in Waskom's study (Waskom et al., 2014). As
14 the adaptive coding hypothesis suggests (Duncan, 2001, 2010; Waskom et al., 2014), our findings using
15 the time-resolved decoding approach demonstrated the dynamic adjustment of task-specific neural
16 representations and was able to associate delayed neural transitions with behavioral *switch costs*.

17 In summary, our results provide novel insights into the switch between memory retrieval and memory
18 suppression. We found evidence for *switch costs* in memory suppression: it is more difficult to suppress
19 unwanted memories immediately after memory retrieval. During switching between retrieval and
20 suppression, we observed delayed transitions of neural states that each of them separately represents
21 current task demand. Delayed neural transitions were associated with *switch costs* (i.e., unsuccessful
22 suppression and retrieval). These results provide insight into the critical role of dynamically adjusted
23 neural reconfigurations in supporting flexible memory suppression and the broader neural mechanisms by
24 which humans can flexibly adjust their behavior in ever-changing environments.

1

2 **Materials and Methods**

3 **Participants**

4 In total, thirty-two right-handed, healthy young participants recruited from the Radboud Research
5 Participation System finished all of the experimental procedures. All of them are native Dutch speakers.
6 Six participants were excluded from data analyses due to low memory performance (i.e., lower the chance
7 level) (n=2), or excessive head motion (n=4). We used the motion outlier detection program within the
8 FSL (i.e., FSLMotionOutliers) to detect timepoints with large motion (threshold=0.9). There are at least
9 20 spikes detected in these excluded participants with the largest displacement ranging from 2.6 to 4.3,
10 while participants included had less than ten spikes. Finally, 26 participants (15 females, age=19-30,
11 mean=23.51, SD=3.30) were included in the behavioral and neuroimaging analysis reported in this study.
12 Due to the reconstruction error during the data acquisition, one run of one participant is not complete (20-
13 30 images were missing). Therefore, that run was not included in our analysis of time series. But
14 unaffected acquired images of that run were used in our univariate activation analysis. No participants
15 reported any neurological and psychiatric disorders. We further used the Dutch-version of the Beck
16 Depression Inventory (BDI) (Roelofs et al., 2013) and State-Trait Anxiety Inventory (STAI) (van der Bij
17 et al., 2003) to measure the participants' depression and anxiety level during scanning days. No participant
18 showed a sign of emotional problems (i.e., their BDI and STAI scores are within the normal range). The
19 experiment was approved by and conducted in accordance with requirements of the local ethics committee
20 (Commissie Mensgebonden Onderzoek region Arnhem-Nijmegen, The Netherlands) and the declaration
21 of Helsinki, including the requirement of written informed consent from each participant before the
22 beginning of the experiment. Each participant got 10 euros/hour for their participating.

23 **Experiment design**

1 This experiment is a two-day fMRI study, with 24 hours delay between two sessions (**Figure S8**). fMRI
2 data of the day2 final memory test has been published in another publication (Liu et al., 2020a), and the
3 comprehensive reports of the experimental materials and design can be found there. Because all of the
4 behavioral and neuroimaging data included in this study came from the Day2 session, we just presented a
5 brief description of the Day1 session. On day1, we instructed participants to memorize a series of
6 sequentially presented location-picture associations, for which 48 distinct photographs were presented
7 together with 48 specific locations on two cartoon maps. All photographs can be assigned into one of the
8 four categories, including animal, human, scene (e.g., train station), and object (e.g., pen and notebooks).
9 Therefore, objective memory performance could be assessed within the scanner by instructing participants
10 to indicate the picture's category when cued by the map location. During this study phase, each location-
11 picture association was presented twice, and the learning was confirmed by two typing tests outside the
12 scanner. During the typing tests, participants were required to describe the photograph associated with the
13 memory cue in one or two sentences. Immediately after the study phase (Day1), 88.01% of the associated
14 pictures were described correctly (SD= 10.87%; range from 52% to 100%).

15 On Day2, participants first performed the second typing test, and still recalled 82.15% of all associations
16 (SD = 13.87%; range from 50% to 100%). Then, they performed the Think/No-Think (TNT) task, and
17 final memory test insider the scanner. We used the TNT task with trial-by-trial performance rating to
18 monitor the retrieval or suppression of each trial. Compared to the original TNT task (Anderson, 2004),
19 the additional self-report did not affect the underlying memory suppression process and also was used in a
20 neuroimaging experiment before (Levy and Anderson, 2012). Forty-eight picture-location associations
21 were divided into three conditions (i.e., “think or retrieval,” “no-think or suppression,” and “baseline or
22 control” condition) in a counterbalanced way, therefore, for each association, the possibility of belonging
23 to one of the three conditions is equal. During the retrieval condition, locations were highlighted with the
24 GREEN frame for 3s, and participants were instructed to recall the associated picture quickly and actively
25 and to keep it in mind until the map disappeared from the screen. By contrast, during the suppression

1 condition, locations were highlighted with the RED frame for 3s, and our instruction for participants was
2 to prevent the potential memory retrieval and try to keep an empty mind. We gave additional instructions
3 for the suppression condition: *“when you see a location, highlighted with a RED frame, you should NOT*
4 *think about the associated picture. Instead, you should try to keep an empty mind during this stage. It is a*
5 *difficult task, and it is totally fine that sometimes you still think about the associated picture. But please do*
6 *NOT close your eyes, focus on something outside the screen, or think about something else in your life.*
7 *These strategies, although useful, could negatively affect the brain activity that we are interested in”.*
8 After each trial, participants had a maximum 3s to press the button on the response box to indicate
9 whether and how often the associated picture entered their mind during Think or No-Think trials.
10 Specifically, they rated their experience from 1-4 representing from No Recall (i.e., Never) to Always
11 Recall. Responses during Think trials were used as retrieval frequency ratings, while responses during No-
12 Think trials were regarded as intrusion frequency ratings. Associations which belong to the control
13 condition were not presented during this phase. The TNT task included five functional runs, with 32
14 retrieval trials and 32 suppression trials per run. All “retrieval” or “suppression” associations were
15 presented twice within one run, but not next to each other. Therefore, they were presented ten times during
16 the entire TNT task. Between each trial, fixation was presented for 1-4s (mean=2s, exponential model) as
17 the inter-trial intervals (ITI).

18 To investigate the task switching within the TNT task, for each run of each participant, we predefined the
19 sequence of task demand to form “blocks” of memory retrieval or suppression with the length range from
20 1 trial to 4 trials (mean=1.9 trials, std=1.01 trials, $P_{\text{one-trial block}}=46.875\%$, $P_{\text{two-trials block}}=25\%$, $P_{\text{three-trials}}$
21 $_{\text{block}}=18.75\%$, $P_{\text{four-trials block}}=9.375\%$). In this sequence, the task demand of the current trial can be the same
22 as the previous trial (“non-switch” trial) or differ from the previous trial (“switch” trial). Within one run of
23 a total of 64 trials, 31 trials were “non-switch” trials, 32 trials were “switch” trials, and the first trial
24 cannot be labeled as “non-switch” trials or “switch” trials because it has no predecessor. The “non-switch”
25 trials and “switch” trials both accounted for around 50% of the “retrieval” and “suppression” trials. After

1 determining the sequence of task demand, specific location-picture associations from retrieval or
2 suppression condition were randomly selected for each trial.

3 After the TNT task, a final memory test was performed by participants within the scanner to evaluate the
4 effect of different modulations on memory. All 48 memory cues (i.e., locations) were presented again with
5 the duration of 4s by highlighting a certain part of the map with a BLUE frame. Participants were
6 instructed to recall the associated picture as vividly as possible during the presentation and then give the
7 responses on two multiple-choice questions within 7s (3.5s for each question). The first one is the measure
8 of subjective memory: “how confident are you about the retrieval?”. Participants had to rate from 1 to 4
9 representing “Cannot recall, low confident, middle confident and high confident” separately. The second
10 one is the measure of objective memory: “Please indicate the category of the picture you were recalling.”
11 They needed to choose from four categories (i.e., Animal, Human, Scene, and Object). It is notable that
12 we only analyzed the behavioral data from this within-scanner memory test; the neural activity during this
13 test is not the focus of this study.

14 **Behavioral data analysis**

15 Behavioral results of this project were comprehensively reported in another study of our lab with the focus
16 on the final memory test (Liu et al., 2020a). No results of tasks switching (i.e., *switch costs*) were reported
17 in that study, and task switching is the central scientific question of this study. First, we analyzed the
18 behavioral performance during the TNT task. Trial-by-trial performance reports from each participant
19 were used to calculate the percentage of successful recall chosen across 160 retrieval trials and successful
20 suppression across 160 suppression trials. Following previous studies (Levy and Anderson, 2012; Liu et
21 al., 2020a), performance reports from suppression trials were used to quantify individual differences in
22 memory suppression efficiency (“*intrusion slope score*”). To account for the individual differences in
23 memory performance before the TNT, we restricted the analysis of suppression into the associations for
24 which participants can still remember during the second typing test (“remembered associations”). We used
25 linear regression to model the relationship between intrusion frequency ratings of “remembered

1 associations” and the number of repetitions of suppression at the individual level. Participants with more
2 negative slope scores are better at downregulating memory intrusions than those with less negative slope
3 scores. Furthermore, we labeled each trial as the “non-switch” trial or “switch” trial based on whether the
4 task demand of the current trial is the same as the previous trial. Trial-by-trial performance between
5 “switch” and “non-switch” trials during retrieval or suppression was compared using paired t-tests.

6 We also quantified the individual differences in *suppression-induced forgetting effect* based on two types
7 of participants’ performance (i.e., recall accuracy and confidence rating) during the final memory test. For
8 each participant, recall accuracy (objective memory measure) and confidence rating (subjective memory
9 measure) were calculated for No-Think associations and control associations separately. Then objective
10 and subjective *suppression scores* were computed separately by subtracting the accuracy and confidence
11 of No-Think associations from the control associations. The more negative a *suppression score* is, the
12 stronger the *suppression-induced forgetting effect* is. The memory suppression score was used to correlate
13 with the “*intrusion slope score*” and transition of neural states during the TNT.

14 **MRI data acquisition and preprocessing**

15 We used a 3.0 T Siemens PrismaFit scanner (Siemens Medical, Erlangen, Germany) and a 32 channel
16 head coil system at the Donders Institute, Centre for Cognitive Neuroimaging in Nijmegen, the
17 Netherlands to acquire MRI data. For each participant, MRI data were acquired on two MRI sessions
18 (around 1 hour for each session) with 24 hours’ interval. In this study, we only used the data from the
19 day2 session. Specifically, we acquired a 3D magnetization-prepared rapid gradient echo (MPRAGE)
20 anatomical T1-weighted scan for the registration purpose with the following parameters: 1 mm isotropic,
21 TE = 3.03 ms, TR = 2300 ms, flip angle = 8 deg, FOV = 256 × 256 × 256 mm. All functional runs were
22 acquired with Echo-planar imaging (EPI)-based multi-band sequence (acceleration factor=4) with the
23 following parameters: 68 slices (multi-slice mode, interleaved), voxel size 2 mm isotropic, TR = 1500 ms,
24 TE = 39 ms, flip angle =75 deg, FOV = 210 × 210 × 210 mm. In addition, to correct for distortions,

1 magnitude and phase images were also collected (voxel size of $2 \times 2 \times 2$ mm, TR = 1,020 ms, TE = 12 ms,
2 flip angle = 90 deg).

3 We used the FEAT (FMRI Expert Analysis Tool) Version 6.00, part of FSL (FMRIB's Software Library,
4 www.fmrib.ox.ac.uk/fsl) (Jenkinson et al., 2012) together with Automatic Removal of Motion Artifacts
5 (ICA-AROMA) (Pruim et al., 2015) to perform our preprocessing. This pipeline was based on procedures
6 suggested by Mumford and colleagues (<http://mumfordbrainstats.tumblr.com>) and the article that
7 introduced the ICA-AROMA (Pruim et al., 2015). Specifically, we first removed the first four volumes of
8 each run from the 4D sequences for the stabilization of the scanner and then applied the following pre-
9 statistics processing: (1) motion correction using MCFLIRT (Jenkinson et al., 2002); (2) field
10 inhomogeneities were corrected using B0 Unwarping in FEAT; (3) non-brain removal using BET (Smith,
11 2002); (4) grand-mean intensity normalization of the entire 4D dataset by a single multiplicative factor; (5)
12 spatial smoothing (6mm kernel). ICA-AROMA was used to further remove motion-related spurious noise.
13 We chose to conduct “non-aggressive denoising” and applied highpass temporal filtering (Gaussian-
14 weighted least-squares straight-line fitting with sigma=50.0s) before the following analyses.

15 All of the mentioned preprocessing steps were performed in native space. We used the following steps to
16 perform the registration between native space, participant's high-resolution T1 space, and standard space.
17 Firstly, we used the Boundary Based Registration (BBR) (Greve and Fischl, 2009) to register functional
18 data to the participant's high-resolution structural image. Next, registration of high resolution structural to
19 standard space was carried out using FLIRT (Jenkinson and Smith, 2001; Jenkinson et al., 2002) and was
20 then further refined using FNIRT nonlinear registration (Andersson et al., 2007). Resulting parameters
21 were used to align processed functional images from native-space to standard space for the following
22 signal extraction.

23 **Univariate General Linear Model (GLM) analyses**

1 We ran the voxel-wise GLM analyses of the TNT task to identify brain regions that are more active during
2 memory suppression compared to memory retrieval (i.e., No-Think VS Think). All time-series statistical
3 analysis was carried out using FILM with local autocorrelation correction (Woolrich et al., 2001) using
4 FEAT. In total, three regressors were included in the model. We modeled the presentation of memory cues
5 (locations) as two kinds of regressors (duration=4s)(i.e., suppression trials and retrieval trials). To account
6 for the effect of unsuccessful memory retrieval, we separately modeled the location-picture associations,
7 which participants cannot recall before the TNT as a separate regressor. All the trials were convolved
8 double gamma hemodynamic response function (HRF) within the FSL.

9 We conducted the two contrasts-of-interest (i.e., No-Think VS Think and Think VS No-Think) first at the
10 native space and then aligned resulting statistical maps to MNI space using the parameters from the
11 registration. These aligned maps were first used for participant-level averaging across five TNT runs, and
12 then the group-level analyses. The group-level statistical map was corrected for multiple comparisons
13 using default cluster-level correction within FEAT (voxelwise $Z > 3.1$, cluster-level $p < .05$ FWER
14 corrected).

15 **Networks-of-interest identification**

16 To identify our networks-of-interest (i.e., inhibitory control network and memory retrieval network), we
17 performed several term-based meta-analyses using the *Neurosynth* (<https://neurosynth.org/>) (Yarkoni et al.,
18 2011). “Inhibitory control” and “memory retrieval” were used as terms separately to search for all studies
19 in the *Neurosynth* database whose abstracts include the input term at least once. Then, all identified
20 studies were combined separately for each term to generate the corresponding statistical map. We used
21 uniformity test maps in our study. This method tested whether the proportion of studies that report
22 activation at a given voxel differs from the rate that would be expected if activations were uniformly
23 distributed throughout the grey matter. Voxel-wise Z-score from the one-way ANOVA testing was saved
24 in a statistical map. Each map was thresholded to correct for multiple comparisons using a false discovery
25 rate (FDR)($p < 0.01$). It is notable that due to the continuous update of the *Neurosynth* database, the number

1 of studies included in the analyses could be slightly different for each search, the maps we used can be
2 found in our *NeuroVault* repository (<https://identifiers.org/neurovault.collection:7731>). Similar network
3 identification was also performed using *BrainMap* (Laird et al., 2005) as a confirmation. The two methods
4 of meta-analysis yielded highly similar maps of network-of-interests (**Figure S9**), and we used the maps
5 generated by the *Neurosynth* in our main text.

6 We used the thresholded ($p_{FDR} < 0.01$) spatial maps of “inhibitory control” and “memory retrieval” to
7 general three masks of networks-of-interest. The areas which belong to both the “inhibitory control” and
8 “memory retrieval” masks were labeled as *overlap regions*, the areas which only belong to the “inhibitory
9 control” mask were labeled as *control-related regions*, and the areas which only belong to the “memory
10 retrieval” masks were labeled as *memory-related regions*.

11 **Brain parcels for the extraction of time series**

12 We combined a parcellation of cerebral regions (N=300) (Schaefer et al., 2018) and all subcortical regions
13 (N=14) from the probabilistic Harvard-Oxford Subcortical Structural Atlas (Desikan et al., 2006) as a
14 whole-brain parcellation. The parcellation of cerebral regions was based on a gradient-weighted Markov
15 Random Field (gwMRF) model, which integrated local gradient and global similarity approaches
16 (Schaefer et al., 2018). Based on both task fMRI and resting-state fMRI acquired from 1489 participants,
17 parcels with functional and connectional homogeneity within the cerebral cortex were generated. Each
18 parcel is one of the seven large-scale functional brain networks, including *Visual, Somatomotor, Dorsal*
19 *Attention, Ventral Attention, Limbic, Frontoparietal, Default network* (Yeo et al., 2011). Subcortical
20 regions included bilateral thalamus, caudate, putamen, globus pallidus, hippocampus, amygdala, and
21 ventral striatum. Details of each parcel (e.g., name, coordinates, hemisphere) within the whole brain
22 parcellation can be found in our OSF folder (<https://osf.io/cq96h/>).

23 For each of the 314 parcels of the whole-brain parcellation, we compared it with the mask of *overlap*
24 *regions, control-related regions, and memory-related regions* and identified the mask in which the parcel

1 shared the highest percentage of common voxels. The parcel was assigned to that category if the highest
2 percentage is higher than 10%. If the highest percentage of common voxels is lower than 10%, the parcel
3 was not assigned to any category. After this procedure, 110 out of the 314 parcels were assigned to one of
4 the categories. Specifically, 71 parcels were considered as *memory-related regions*, 29 parcels were
5 categorized as *control-related regions*, and 10 parcels were labeled as *overlap regions* in our following
6 analysis.

7 **Extraction of time series from parcels**

8 We additionally removed nuisance time series (cerebrospinal fluid (CSF) signals, white matter signals,
9 motion, and event-related activity) using a method based on a projection on the orthogonal of the signal
10 space (Friston et al., 1994; Lindquist et al., 2019). We generated confounding time series (CSF, white
11 matter, the six rigid-body motion parameters (three translations and three rotations), and framewise
12 displacement (FD)) for each run of each participant. Event-related activity time series were estimated by a
13 finite impulse response (FIR) function. A recent study has shown that removal of event-related activity
14 based on FIR modeling is an important step for the preprocessing of time series during a task (Cole et al.,
15 2019). The signal from each parcel was extracted and z-scored, and all nuisance time series were removed
16 simultaneously using the *nilearn.signal.clean* function. All cleaned time series were shifted 3 TRs (4.5 s)
17 to account for the HRF delay and then aligned with the task demand (i.e., retrieval or suppression) at that
18 moment.

19 **The transition of neural states analysis**

20 First, we characterized the transition of neural states at the group level. Extracted time series from each
21 run of each participant were split according to the task instruction (i.e., memory retrieval or memory
22 suppression) and concatenated. Second, two kinds of time series were further concatenated across five
23 TNT runs within that participant (*except for one participant, only four complete TNT runs were included*).

1 Third, time series were concatenated across all participants. Fourth, two time-series were averaged across
2 all time points to represent mean activity intensity for that parcel during retrieval or suppression.

3 To estimate the relative dominance of each parcel during two neural states (i.e., Think and No-Think), we
4 ranked the mean activity intensity of each parcel (the highest activity was ranked first). We then calculated
5 the changes in ranks when the task switched from Think to No-Think by subtracting the rank during Think
6 from the rank during No-Think. The same analyses were conducted with raw signal intensity and Z-values.
7 Related results can be found in the *Supplemental Materials*. The negative change suggested an increase in
8 relative dominance, while the positive change represented the opposite. We calculated two neural indexes
9 (“state transition index” and “state transition index Version 2 (V2)”) to quantify the transition of neural
10 states at the individual level and associate this individual difference with the subsequent suppression-
11 induced forgetting effect. The state transition index was calculated by adding up the averaged relative
12 decreases in rank values all *memory-related regions*, and the averaged relative increase in rank values of
13 all *control-related regions*. The calculation and results of “state transition index Version 2 (V2)” can be
14 found in the *Supplemental Material*. It is notable that although transition index and transition index V2
15 were calculated using different methods, they were based on the same set of data. Therefore, the data
16 analyses of index V2 should not be regarded as independent analysis. These two state transition indices
17 were used to correlated with the *objective suppression score* and *subjective suppression score* calculated
18 based on behavioral performance during the final memory test after TNT.

19 **Neural states decoding analysis**

20 Before the decoding analysis, we generated the labels of task demand for each time point within the trial
21 based on its instruction (i.e., Think or No-Think). For example, if the trial is a Think trial, time points
22 started from the presentation of memory cues of this trial to the presentation of memory cues of the next
23 trial were labeled as “Think.” We performed the time-resolved multivariate decoding analysis based on
24 the brain activity of all 114 ROIs and corresponding labels of task demand during each time point. This
25 decoding analysis allowed us to generate the predicted label of task demand for each time point, thus

1 revealing the fast dynamics of the neural state transition induced by the switch of task demand.
2 Specifically, decoding analysis via the Support Vector Classification (SVC), the C-Support Vector
3 Machine within the scikit-learn package (<https://scikit-learn.org/stable/>). We used default parameters of
4 the function (regularization (C)=1, radial basis function kernel with degree=3). The classification of neural
5 states was performed separately for each time point using a leave-one-run-out cross-validation approach
6 within each participant. This procedure resulted in a decoded task demand for each time point of each
7 participant. These predictions were evaluated by comparing these decoded task demands with actual task
8 demand. To separate all types of correct and incorrect classification for the following analyses, we
9 generated the confusion matrix for each participant. This confusion matrix contained the percentage of all
10 four situations based on the task demand and if the prediction matches the task instruction (i.e., Think-
11 Correct classification, Think- Incorrect classification, No-Think- Correct classification, and No-Think-
12 Incorrect classification). We extracted all SVC discriminating weights assigned to the features during the
13 participant-specific decoding and averaged them across all participants to generate the neural state-
14 predictive pattern. The brain parcels with higher absolute values contributed more to decoding models.
15 To test for possible differences in neural representations of task demand induced by the task-switching, we
16 performed the described decoding analyses for switch time points and non-switch time points separately.
17 The switch time points were defined as the presentation time (3TRs; 4.5s) of first memory cue after the
18 switch of task demand. The two decoding analyses yielded decoding accuracies for switch time points and
19 for non-switch time points for each participant. We compared these two types of decoding accuracies
20 using the paired t-test. Less accurate decoding was described as the evidence for the weaker representation
21 of the current task demand in the literature (Waskom et al., 2014; Loose et al., 2017). Also, because we
22 only have two task demands, less accurate decoding reflects the unsuccessful transition from the previous
23 demand to the current demand according to the instruction.
24 Next, we aimed to investigate the behavioral relevance of the mismatch (i.e., incorrect classification)
25 between task demand and the underlying neural state. Because we were mainly interested in the switch-

1 induced mismatch, we first restricted our analyses to these switch time points and then extended to the
2 non-switch time points as an exploratory analysis. For each participant, we averaged the trial-by-trial
3 behavioral performance during the TNT task based on whether the actual task demand matches with
4 decoded task demands. This yielded retrieval performance and suppression performance for match and
5 mismatch conditions. Paired t-tests were performed to examine the effect of mismatch on the performance
6 of memory retrieval and memory suppression separately. The performance calculations and comparisons
7 described above were repeated for non-switch time points as well.

8 **Relationship between head motion, neural state transitions, and behaviors**

9 To explicitly assess how head motion could potentially affect our results, we derived a volume-by-volume
10 measure of head motion, framewise displacement (FD) (Power et al., 2012), during the TNT task. FD is
11 defined as the sum (in mm) of rotational and translational displacements from the current volume to the
12 next volume. We aligned the time-series of FD with task structure and behaviors in a way similar to the
13 analyses of time series of fMRI signals but did not consider the HRF. The following contrasts were
14 performed to compare head motion between conditions: (1) difference in FD between Think trials and No-
15 Think trials; (2) difference in FD between correct neural state decoding and incorrect neural state
16 decoding; (3) difference in FD between the switch and non-switch condition. Correlations analyses were
17 performed between individual differences in head motion between Think and No-Think trials (i.e.,
18 $FD_{\text{Think}} - FD_{\text{No-Think}}$), *state transition index*, *objective/subjective suppression score*.

19 **Data and code availability**

20 All research data were uploaded to the Donders Repository and will be publicly available after manuscript
21 acceptance, in which case the persistent identifier that is currently reserved for this collection will become
22 effective. The reviewable data can be found here: ([https://data.donders.ru.nl/login/reviewer-
23 32038430/OhATso8yhvEv05RvdkvJQmGfuxTA7T6SinYgBAADafM](https://data.donders.ru.nl/login/reviewer-32038430/OhATso8yhvEv05RvdkvJQmGfuxTA7T6SinYgBAADafM)). Some data, such as statistical
24 maps and brain parcels of interest were shared via the Neurovault Repository

1 (<https://identifiers.org/neurovault.collection:7731>). Supplemental Material can be found in OSF
2 (<https://osf.io/cq96h/>).

3 Behavioral data were analyzed by *JASP* (<https://jasp-stats.org/>). For the term-based meta-analysis of
4 neuroimaging studies, we used the *Neurosynth* (<https://neurosynth.org/>), and *BrainMap*
5 (<http://www.brainmap.org/>). Preprocessing of neuroimaging data was performed by *FSL*
6 (<https://fsl.fmrib.ox.ac.uk/fsl/fslwiki>), *ICA-AROMA* (<https://github.com/maartenmennes/ICA-AROMA>),
7 and *fMRIPrep* (<https://fmriprep.readthedocs.io/en/stable/>). Python packages, including *Nilearn*
8 (<https://nilearn.github.io/>), *Nistats* (<https://nistats.github.io/>), *Pandas* (<https://pandas.pydata.org/>), and
9 *Numpy* (<https://numpy.org/>) were used for the analyses of time series. Machine learning algorithms were
10 based on *scikit-learn* (<https://scikit-learn.org/>) and implemented via *Nilearn* (<https://nilearn.github.io/>).
11 *Anaconda* (<https://www.anaconda.com/>) Python 3.6 was used as the platform for all the programming and
12 statistical analyses. Custom Python scripts were written to perform all analyses described based on the
13 mentioned Python packages; all code is available from the authors upon request and will be released via
14 our OSF repository (<https://osf.io/cq96h/>) upon publication.
