23 **Abstract**

24 The high mutation rate in retroviruses is one of the leading causes of rampant drug
25 resistance and the emergence of novel infectious diseases. In human
26 immunodeficiency virus type-1 (HIV-1), synergistic mutations in its protease and the
27 protease substrate – the Group-specific antigen (Gag) polyprotein – work together to
28 confer drug resistance against protease inhibitors and compensate the effects of the
29 mutations on viral fitness. Some Gag mutations have been reported to restore Gag-
30 protease binding, yet most Gag-protease correlated mutations occur outside of the
31 Gag cleavage site. To rationalize this, we report multiscale modelling approaches to
32 investigate various sequentially cleaved Gag products in the context of clinically
33 relevant mutations that occur outside of the cleavage sites. Simulations of the
34 complete oligomeric structure of the largest Gag proteolytic product in its viral
35 membrane-bound state revealed how non-cleavage site mutations can directly interact
36 with cleavage site residues to affect their local environment, facilitated by
37 conformational changes upon lipid interaction. Mutations in the matrix domain led to
38 the enrichment of phosphatidylinositol bisphosphate (PIP2) lipids – whose association
39 is essential for Gag targeting and assembly on the plasma membrane – facilitated by
40 creation of novel PIP2 binding sites. Additional studies of the mature CA hexamer
41 suggest that some mutations can modulate recruitment of cyclophilin A (CypA) into
42 the mature virion, as well as stabilise the oligomerisation of the viral core. Collectively,
43 our results reveal that non-cleavage site mutations have far-reaching implications
44 outside of Gag proteolysis, with important consequences for drugging Gag maturation
45 intermediates and tackling protease inhibitor resistance.

46

47

48 **Introduction**

49 RNA viruses are among the most adaptable pathogens threatening human health.
50 With their high mutation rates¹, they are orders of magnitude more adaptable than
51 most DNA-based organisms², resulting in their ability not only to escape the immune
52 system and become drug resistant, but jump across host species boundaries causing
53 emerging infectious diseases that could turn into global pandemics³⁻⁶. HIV-1
54 represents one of the most extensively characterized RNA viruses, with mathematical
55 modelling showing that many clinically established drug resistance mutations could
56 occur within the first replication cycle⁷, and every single possible point mutation could
57 occur thousands of times within a single day, leading to rapid drug resistance⁸, hence
58 leading to the need to treat HIV patients with a cocktail of multiple antiviral drugs with
59 different mechanism. Understanding the role of these mutations is thus an imperative
60 aspect in novel antiviral drug development.

61 Most clinically approved HIV treatments target various key enzymes that are
62 critical to the life cycle of the virus, most prominently the HIV-1 protease. HIV-1
63 protease cleaves the structural polyproteins Gag and Gag-Pol into their mature
64 components to create the infectious virion. To inhibit this, protease inhibitors (PIs) bind
65 competitively to the viral protease to prevent Gag substrate proteolysis and virion
66 maturation. PIs form a major component of the highly active antiretroviral therapy
67 (HAART) in the management of HIV; however, emerging mutations in HIV-1 protease
68 often render PIs ineffective, with some mutations even leading to cross-drug
69 resistance⁹. This is further aggravated by synergistic mutations on the Gag polyprotein
70 itself^{10,11}, making Gag an attractive drug target in addition to the protease¹⁰. Gag
71 mutations around the protease cleavage site have been shown to restore Gag-
72 protease binding by introducing new chemical interactions and inducing subtle
73 conformational changes that compensate for the loss of affinity due to the mutations
74 on HIV-1 protease¹². Apart from mutations around the protease cleavage sites, Gag
75 also harbours mutations away from these regions, many of which have been shown
76 to directly contribute towards PI resistance^{13,14}. To date, the role of these non-cleavage
77 site mutations is largely unknown, with some analysis pointing to allosteric
78 communication¹⁵. In this study, we aim to use structural modelling and simulations to
79 decipher how Gag non-cleavage site mutations contribute towards the overall fitness
80 of the HIV-1 virus.

81 The HIV-1 Gag polyprotein is a 500 amino acid precursor protein containing the
82 matrix (MA), capsid (CA), nucleocapsid (NC) and P6 domains, as well as two spacer
83 peptides, SP1 and SP2. During the late phase of the HIV-1 replication cycle, Gag is
84 sequentially cleaved by the protease enzyme into these domains (Figure S1), which
85 subsequently form an infectious mature virion¹⁶. Each domain plays a specific role
86 during maturation; for example, the MA domain drives full-length Gag to assemble at
87 the plasma membrane of the host cell, while the CA and NC domains encapsulate the
88 viral RNA genome. The CA domain also interacts with CypA, which is a host cell
89 protein that is incorporated into the virion and is essential for capsid uncoating^{17,18}.
90 Due to its functional significance in the HIV-1 life cycle, Gag is an attractive target for
91 therapeutic agents and to date, several drugs that target the CA domain have been
92 identified¹⁹. Nevertheless, a Gag inhibitor is yet to be clinically approved. For example,
93 Bevirimat is a drug candidate that stabilises the immature Gag lattice by preventing
94 proteolysis between the CA and SP1 domains²⁰. A clinical trial, however, showed a
95 reduced response amongst certain patients due to a high prevalence of Gag
96 polymorphisms and resistant mutations^{21,22}, which highlights the importance of
97 understanding the role of Gag non-cleavage site mutations.

98 Over the past few years, integrative modelling and molecular dynamics (MD)
99 simulations, in tandem with advances in structural biology, have provided valuable
100 insights into the molecular mechanism underlying viral function and dynamics²³. In the
101 study of HIV-1, this ranges from multiscale simulations of the entire viral capsid shell
102 and its assembly pathways^{24–29}, to simulations of individual Gag proteins with host cell
103 components, such as the CA domain with CypA³⁰, kinesin-1 adaptor protein FEZ1³¹
104 and inositol hexakisphosphate (IP6)³², as well as the MA domain with a model plasma
105 membrane³³. A previous structural model of full-length monomeric HIV-1 Gag revealed
106 allosteric communications between non-cleavage site mutations and the first Gag
107 cleavage site¹⁵, providing a glimpse into how residues far away from the protease
108 cleavage site could affect proteolysis. However, this model did not take into account
109 *in vivo* Gag oligomerisation, which is instrumental during virus particle maturation.
110 Crystal structures show that the MA domain exists as a trimer³⁴, whilst the CA domain
111 forms a hexamer³⁵. An electron microscopy (EM) study of the MA protein in a PIP2
112 containing membrane showed that under higher order conditions, it organizes into
113 hexamers-of-trimers³⁶.

114 Structural models of sequentially cleaved Gag are imperative for understanding
115 the conformational changes involved upon proteolysis, which may improve our overall
116 knowledge of Gag mutations and potential drugging of these intermediates. Using
117 available structures of HIV-1 Gag domains, we built an integrative model of the
118 complete oligomeric Gag polyprotein cleavage product (Figure 1) bound to a viral
119 membrane model (Figure 2). Based on coarse grained (CG) MD simulations using the
120 Martini forcefield of the wild-type (WT) and mutant Gag variants, supported by careful
121 calibration against atomic-resolution sampling, we found that non-cleavage site
122 mutations can interact with cleavage site residues and potentially alter their local
123 environment, while mutations on the MA domain confer stronger binding to the plasma
124 membrane. Subsequent all-atom MD simulations of the CA domain revealed how
125 mutations in this region modulate CypA recruitment as well as stabilise oligomer
126 formation. Overall, our study uncovers how these distant mutations can affect various
127 processes during HIV-1 viral maturation and contribute towards its overall fitness.

135 of the MA trimers are connected to the CA domains and coloured as in (B), whereas the peripheral MA
136 subunits are coloured grey.
137

138 **Results**

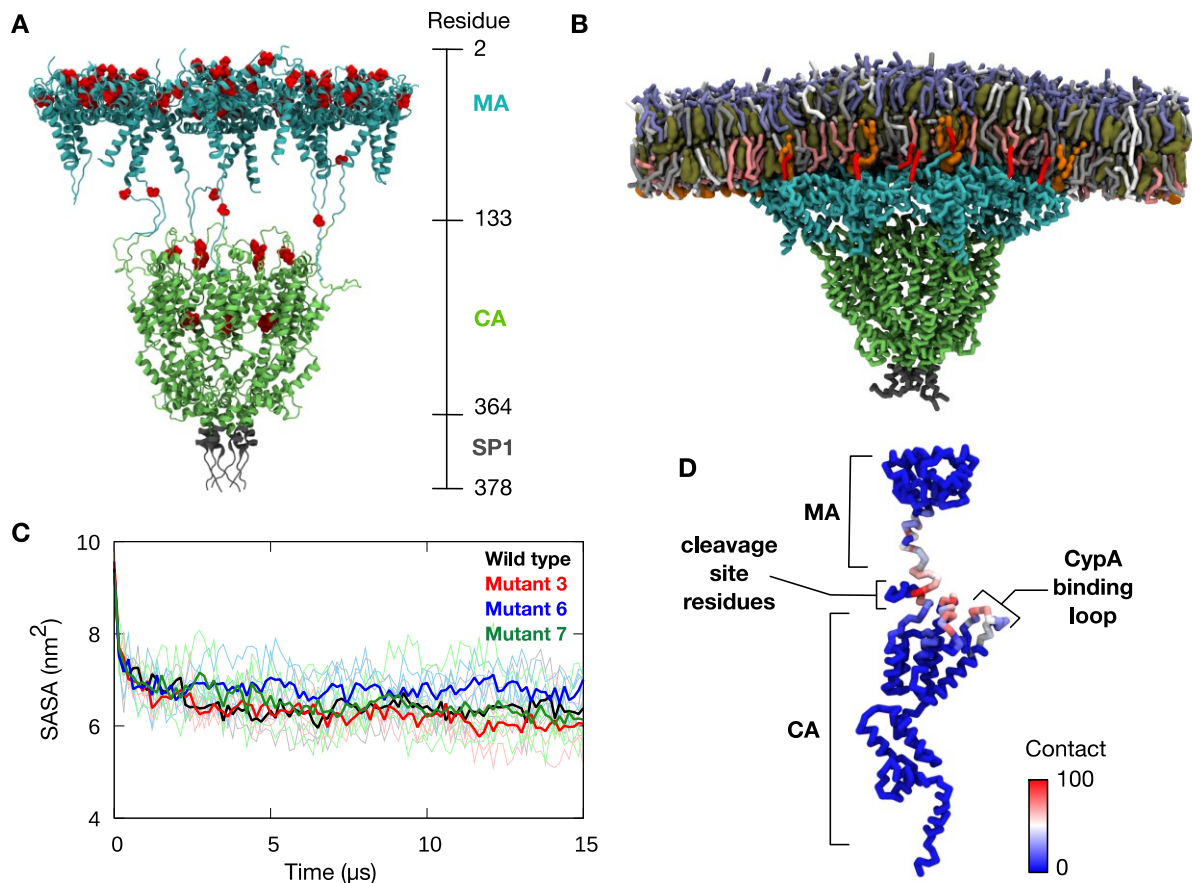

139 ***Membrane dynamics of the HIV-1 Gag MA-CA-SP1 polyprotein***

140 The Gag polyprotein is sequentially cleaved by HIV-1 protease during viral maturation
141 (Figure S1). The first cleavage occurs between the SP1 and NC domains to produce
142 the MA-CA-SP1 polyprotein, which represents the largest Gag cleavage product. A
143 hexameric model of the HIV-1 Gag MA-CA-SP1 polyprotein was built using the crystal
144 structures of the MA trimer³⁴ and CA hexamer³⁵, with the intervening linker between
145 the MA and CA domains constructed *ab initio* (see Methods section for further details)
146 (Figure 1). The crystal structure of the immature CA hexamer was aligned with six
147 copies of MA trimers (hexamers-of-trimers) following the arrangement observed in
148 membrane bilayers³⁶. Gatanaga et al. discovered PI-resistant Gag variants with non-
149 cleavage site mutations mapped to the MA-CA-SP1 complex (Table S1, Figure S1)¹⁴.
150 These include seven unique mutations, with five located in the MA domain and two in
151 the CA domain. We generated models for three variants (specifically variant numbers
152 3, 6, and 7, as outlined in Tables S1-S2) that cover all of these seven unique mutations
153 (Figure 2A). To understand the conformational dynamics of the polyprotein and the
154 potential roles of these non-cleavage site mutations, we performed four independent
155 15 μ s CG MD simulations of the MA-CA-SP1 model bound to a realistic HIV-1
156 membrane model (Table S2). The membrane model contained phosphatidylcholine
157 (PC), phosphatidyl ethanolamine (PE) and phosphatidylserine (PS) lipids, as well as
158 PIP2, sphingomyelin and cholesterol, as determined by a previous lipidomics study³⁷
159 (see Methods section for further details), whilst the MA domain N-terminus was
160 myristoylated (Figure 2B).

161 As previously predicted³³, the myristate group on the N-terminal glycine residue
162 of MA domain effectively anchored the protein to the membrane. Within the first few
163 nanoseconds, the linker connecting the MA and CA domains contracted, effectively
164 pulling the CA-SP1 domain towards the membrane (Figure 2B). To verify these
165 domain-domain dynamics observed during CG sampling, we also performed four
166 independent 500 ns atomistic simulations of the MA-CA-SP1 monomer with positional
167 restraints applied to the backbone atoms of lipid binding residues to mimic membrane
168 association. Additionally, we also conducted CG simulations of the same monomeric
169 system. Both of these additional sets of simulations showed a contraction of the MA-
170 CA linker, resulting in a similar distribution of distances between the MA and CA
171 domains compared to the CG hexamer simulations (Figure S2). While the atomistic

172 simulations initially sampled a wider spread of distances, after around 300 ns this
173 converged to 4-6 nm, reproducing the CG distributions. This validates our CG hexamer
174 model and shows that the linker region does not maintain an extended conformation,
175 but rather contracts to allow direct contact between the MA and CA domains.

176

177

178 **Figure 2: HIV-1 Gag MA-CA-SP1 model.** (A) An atomic model of MA-CA-SP1 hexamer built using the
179 crystal structures of MA trimer³⁴ and immature CA hexamer³⁵, shown in cartoon representation. The
180 MA domain (cyan), CA domain (green), and SP1 domain (dark grey) are shown in different colours.
181 The positions of seven unique non-cleavage site mutations¹⁴ are shown in red. Residue numbering for
182 each domain and their approximate positions are shown on the right. (B) The final snapshot from one
183 of the 15 μs CG simulations of a membrane-bound WT MA-CA-SP1 hexamer showing contraction of
184 the linker connecting MA and CA domains. Protein backbone and lipids are shown in licorice
185 representation. N-terminal myristate (red), PC (white), PE (light grey), PS (pink), PIP2 (orange),
186 sphingomyelin (purple) and cholesterol (dark green) are shown in different colours. (C) Solvent
187 accessible surface area (SASA) of the MA-CA cleavage site region (residue 128-137) over the course
188 of 15 μs CG simulations. Thin lines represent the six individual subunits and thick lines show the running
189 average. Data were averaged over four independent simulations. (D) Average percentage of contact
190 made by the cleavage site residues with the rest of the protein, mapped onto the backbone of a single

191 subunit of MA-CA-SP1 from the WT simulations. Data were averaged over six subunits and four
192 independent simulations.

193

194 ***Interaction between cleavage site residues and non-cleavage site mutations***

195 The linker contraction described above resulted in a decrease in solvent accessibility
196 of the cleavage site residues between the MA and CA domains from $\sim 10 \text{ nm}^2$ to ~ 6
197 nm^2 (Figure 2C). After the first round of Gag proteolysis, the MA domain is cleaved off
198 from the MA-CA-SP1 polyprotein, and the P6 domain is cleaved from the NC-SP2-P6
199 polyprotein (Figure S1). However, the rate at which the former occurs is noticeably
200 slower than that of the latter³⁸. Our simulations suggest that this may be caused by
201 the reduction in exposure of the cleavage site, due to the contraction of the linker
202 region between MA and CA domains. This linker contraction also led to the cleavage
203 site residues interacting with neighbouring subdomains, predominantly with the C-
204 terminal helix of the MA domain and several inter-helical loops on the CA domain,
205 including the CypA binding loop (Figure 2D).

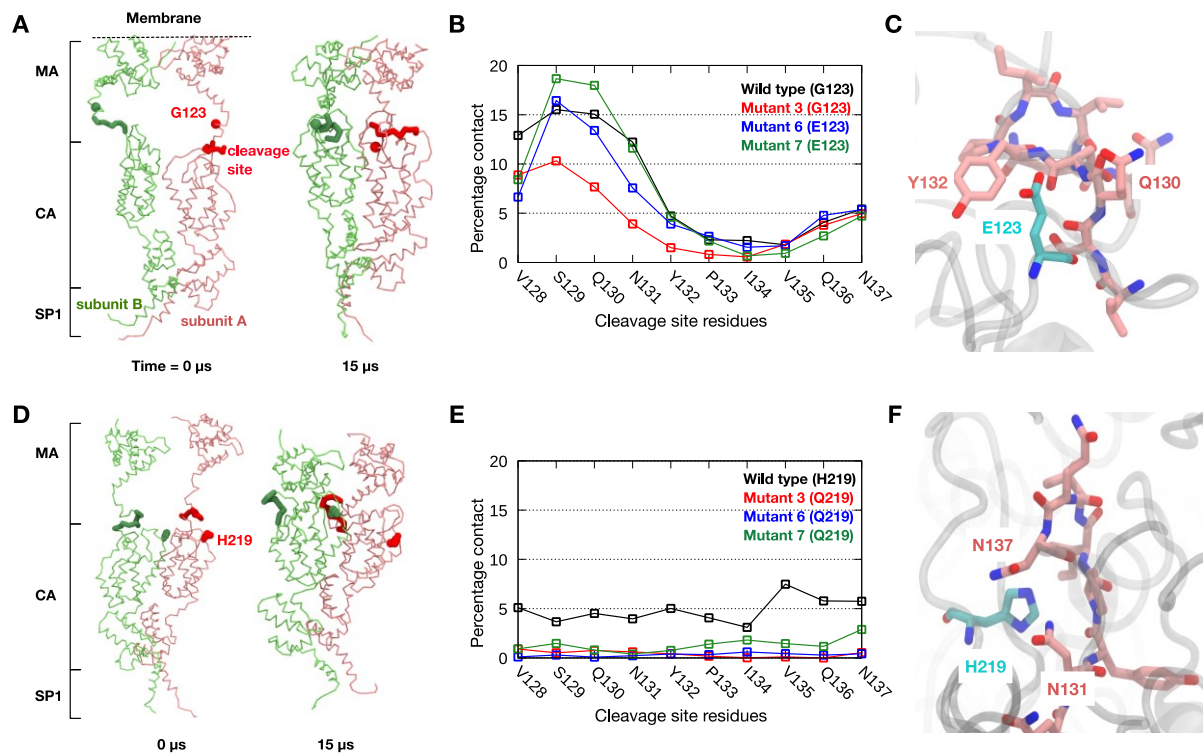

206 Two PI-resistant mutations were identified at the interaction sites – G123E and
207 H219Q. To understand how these mutations may affect the cleavage site residues,
208 contact analysis was performed between the cleavage site residues and these two
209 specific positions in the WT and mutant proteins, particularly focusing on potential
210 inter- and intra-subunit interactions. Due to their close proximity, we found that the
211 residue at position 123 made contact primarily with the N-terminal portion of the
212 cleavage site from the same Gag subunit (Figure 3A and 3B). Both WT (glycine) and
213 mutant (glutamate) residues showed a similar percentage of contact over the course
214 of the simulations. “Back-mapping” of CG simulation snapshots to transform them into
215 atomic resolution suggested that a glutamate residue at this position may interact with
216 polar residues on the cleavage site, such as Q130 and Y132 (Figure 3C). We
217 performed three independent 200 ns atomistic simulations of a single MA-CA-SP1
218 subunit to refine the back-mapped structure, and indeed found that the glutamate
219 residue interacted primarily with Y132 (Figure S3). Additionally, the residue also
220 contacted residues N131 and Q130. In contrast, a glycine residue at this position
221 interacted primarily with V128 and S129. Given the change in the overall size and
222 charge of the residue in the WT and mutants (from small and neutral to large and
223 acidic), the G123E mutation alters the accessibility and electrostatic properties in the

224 vicinity of the cleavage site and would therefore be expected to directly interfere with
225 proteolysis.

226 While the interactions of G123E with the cleavage site residues occur within
227 the same subunit of the MA-CA-SP1 polyprotein, inter-subunit interactions were
228 observed for H219, whereby this residue contacted the cleavage site of an adjacent
229 subunit (Figure 3D). The frequency of such interactions, however, was notably lower
230 than that displayed by G123E, and interestingly, mutation to glutamine resulted in a
231 reduced contact with the cleavage site (Figure 3E). Back-mapping to atomistic
232 representation suggested potential for interactions with polar residues such as N131
233 and N137 (Figure 3F). Atomistic simulations of two adjacent MA-CA-SP1 subunits
234 using the back-mapped structure showed that histidine at this position made
235 intermittent contacts with I134, V135, Q136 and N137, whilst glutamine interacted
236 primarily with Y132 (Figure S3). Given that the WT histidine may potentially become
237 protonated, it may affect local electrostatic surface properties of the Gag cleavage site
238 to modulate the catalytic efficiency of the protease enzyme.

239 Overall, our data suggest that even though these mutations occur far from the
240 protease binding site, they can physically interact with the cleavage site residues,
241 either within the same Gag subunit or with a neighbouring subunit, as the linker region
242 between MA and CA domain contracts following the first proteolytic cleavage.

243

244
 245 **Figure 3: Interactions between non-cleavage site mutations and cleavage site residues.** (A)
 246 Snapshot at the beginning and end of the CG simulations of WT MA-CA-SP1 showing the interaction
 247 of residue G123 (sphere representation) and cleavage site residues (thick licorice representation). Two
 248 subunits are shown in red and green. (B) Percentage of contacts across the entire CG simulation
 249 sampling made between G123/E123 with each of the residues of the MA-CA cleavage site. This is
 250 averaged over the six subunits of MA-CA-SP1 and the four independent trajectories. (C) Atomistic
 251 model, derived from the final snapshot of one of the CG simulations, highlighting E123 in mutant Gag
 252 (cyan) and nearby cleavage site residues (pink). (D) Snapshot at the beginning and end of the CG
 253 simulations showing the interaction between H219 from one subunit to cleavage site residues on an
 254 adjacent subunit. (E) Contact analysis similar to (B) for H219/Q219. (F) Atomistic model derived from
 255 the CG simulations of WT Gag highlighting H219 in WT Gag (cyan) and surrounding cleavage site
 256 residues (pink).

257

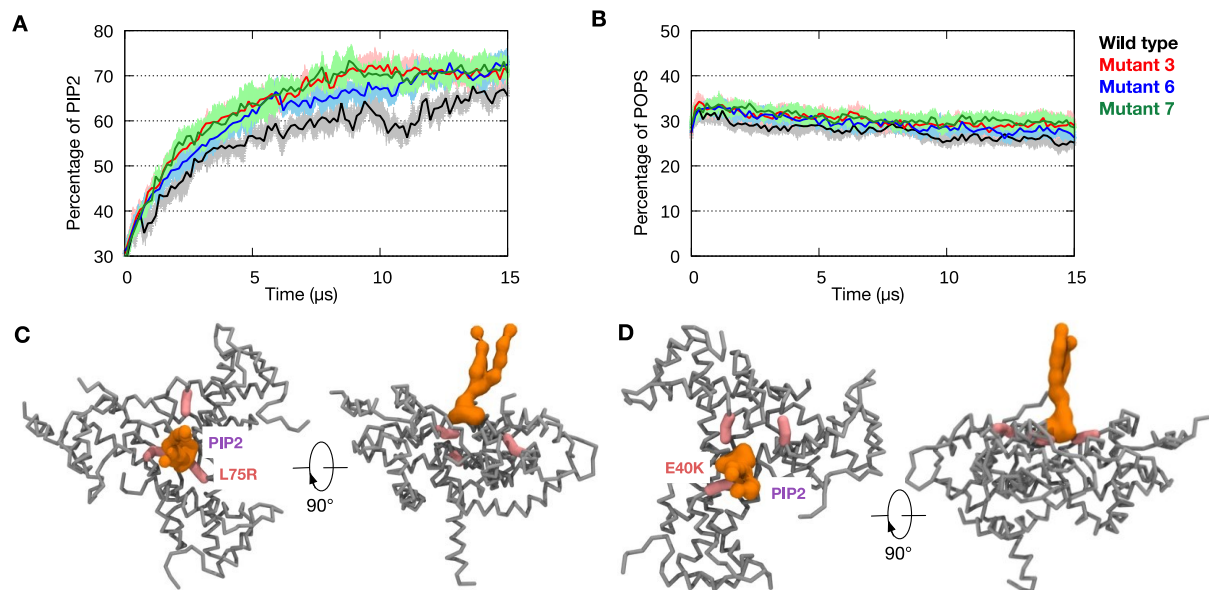

258 ***Mutations in the MA domain modulate membrane binding***

259 Four of the mutations in the MA domain map onto the plasma membrane associating
 260 surface of our model, and three mutations – E12K, E40K and L75R – involve a switch
 261 to basic amino acids. We hypothesized that these mutations may therefore alter key
 262 electrostatic interactions with lipids. Indeed, in the three mutant variants, there is a
 263 notable increase in positive electrostatic charge on the membrane binding region
 264 compared to WT (Figure S4). In the WT Gag MA domain, the positive charge is
 265 concentrated on the peripheral region of the membrane binding surface of the MA
 266 trimer. In the mutant variants, in particular mutants 6 and 7, the positive charge covers

267 almost the entire membrane binding surface including the central region at the
268 interface of the MA trimer subunits.

269 Previous biochemical and structural studies showed that PIP2 is instrumental
270 in targeting Gag to the plasma membrane of the host cell, and that it binds directly to
271 the MA domain^{39,40}. To understand how the changes in electrostatic surface properties
272 caused by the PI-resistant mutations affect membrane binding, we determined the
273 number of PIP2 lipids interacting with the MA domains throughout our CG simulations.
274 Over the course of the 15 μ s simulations, there was a significant enrichment of PIP2
275 lipids around the MA domain, consistently observed across all trajectories, from
276 around 30% at the beginning of the simulations to 60-80% by the end (Figure 4A).
277 This was due to electrostatic attraction between the anionic PIP2 headgroups and the
278 positively charged membrane-peripheral surface of the MA domain. Interestingly, we
279 did not observe any increment in the amount of anionic PS lipids despite its higher
280 concentration compared to PIP2 in the membrane (Figure 4B). This may be due to the
281 higher negative charge on the headgroups of PIP2 compared to PS lipids. PIP2
282 enrichment around the MA domain is in agreement with previous experimental studies
283 showing that PIP2 is responsible for anchoring HIV-1 Gag to the plasma membrane⁴¹.
284 While both WT and mutant variants displayed PIP2 enrichment, all three mutants
285 showed a larger degree of accumulation of PIP2 around MA. More importantly, the
286 E40K and L75R mutations, which map around the interface of the MA trimer subunits,
287 formed novel binding sites for PIP2 lipids (Figure 4C, 4D). Our simulations therefore
288 suggest that these non-cleavage site mutations enhance interactions between the MA
289 domain and PIP2 lipids, and may consequently improve membrane targeting of HIV-
290 1 Gag during viral assembly.

291

292

293 **Figure 4: PIP2 is enriched around MA domain.** (A) The percentage of PIP2 found within 0.6 nm of
294 the MA domain during CG simulations of WT and mutant MA-CA-SP1 models. Error bars indicate
295 standard deviation from four independent simulations. (B) The same analysis as in (A) performed for
296 PS lipids. (C) Representative snapshots from one of the simulations of mutant 3 showing PIP2 binding
297 at the interface of the MA trimer. The position of mutant residue, L75R, is shown in pink stick
298 representation, whereas PIP2 is shown in orange surface representation. The rest of the MA domain is
299 shown in grey. (D) Representative snapshot from simulations of mutant 7 showing PIP2 binding
300 facilitated by E40K mutation, displayed in similar colours and representation as in (C).

301

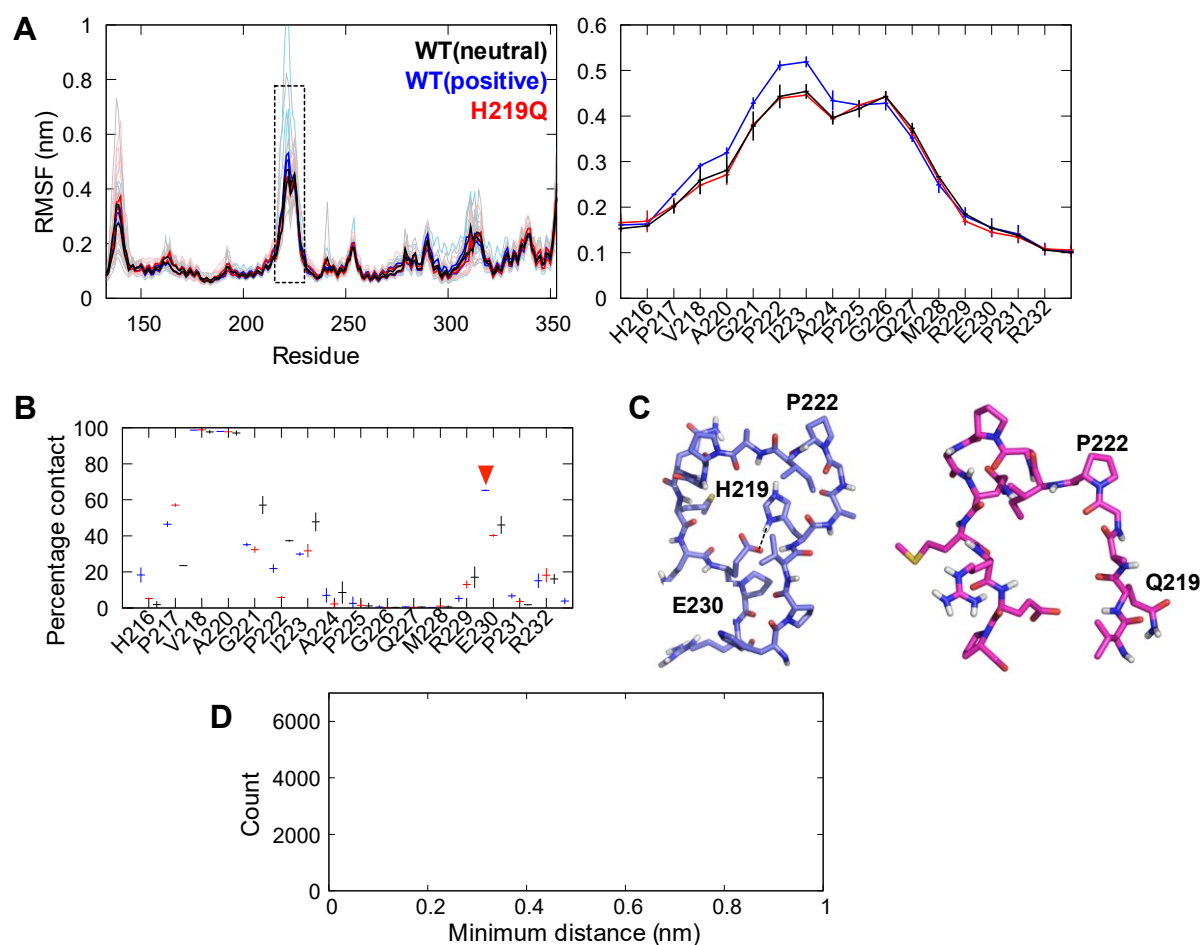

302 ***Mutations in CypA-binding loop optimize CypA recruitment***

303 Cyclophilin A (CypA) is a host protein that is recruited by HIV-1 Gag into mature virion
304 particles. While the exact role of CypA in HIV-1 replication remains unclear, it is
305 thought that the prolyl isomerase activity destabilises interactions between the
306 subunits of the CA hexamer and therefore promotes viral core disassembly during the
307 early stage of the replication cycle^{18,42,43}. Recruiting an optimal concentration of CypA
308 is critical to viral fitness. At a very low CypA concentration, the HIV-1 replication rate
309 is severely reduced as the CA subunits are tightly bound to one another, which hinders
310 virion uncoating. On the other hand, at a very high CypA concentration, interactions
311 between CA subunits are greatly destabilised, resulting in an unstable virion core and
312 thereby delayed virion maturation⁴⁴. CypA binds to CA via an exposed proline-rich
313 unstructured loop region in the N-terminal domain of the latter⁴³. Interestingly, this loop
314 houses one of the most prevalent PI-resistant non-cleavage site mutations, H219Q.
315 This mutation is found in all seven variants from Gatanaga et al (Table S1). To
316 investigate the potential role of this mutation *vis-à-vis* CA-CypA interactions, we

317 performed two independent 500 ns atomistic MD simulations of the WT and H219Q
318 mutant of the mature CA hexamer either in its CypA-free (apo) or CypA-bound state.
319 As the imidazole ring of a histidine side chain has a pKa value that is close to
320 physiological pH, it is possible that H219 may exist in either protonated or
321 unprotonated form. As such, the simulations of WT CA were performed with H219 in
322 both protonation states. IP6 has been shown to be an important assembly co-factor
323 for HIV-1³². Crystal structures show that IP6 binds to the centre of the Gag CA
324 hexamer and promotes the formation of the mature capsid lattice. As such, we
325 included the IP6 molecule in all of our atomistic simulations of mature CA hexamer
326 (see Methods section for further details).

327 Our apo simulations revealed that the CypA binding loop was the most dynamic
328 region of the entire CA molecules (Figure 5A). No noticeable difference was found
329 between the flexibility of this loop in simulations with the neutral H219 *versus* the
330 H219Q mutant. Interestingly, when this histidine residue was protonated, we saw a
331 slight increase in the RMSF values of the loop, especially around G221-P222, which
332 is the putative substrate for the CypA rotamase activity. An increased association was
333 observed between protonated H219 and E230, found on the opposite side of the loop
334 (Figure 5B), as a result of salt bridge formation (Figure 5C). However, this salt bridge
335 was intermittent (Figure 5D), such that the CypA-binding loop may adopt alternative
336 conformational states when H219 is protonated. This means that under low pH
337 conditions, the transition between these two states increases the overall flexibility of
338 the loop, which consequently may make it more difficult for CypA to bind. Mutation of
339 H219 to glutamine would therefore abolish the ability of the loop to adopt these two
340 conformational states, reducing the loop flexibility, and facilitate initial CypA binding.
341 This would be advantageous inside the endosome which is associated with a lower
342 local pH, to ensure sufficient CypA binding and incorporation into the mature virion for
343 subsequent core disassembly⁴⁵.

344

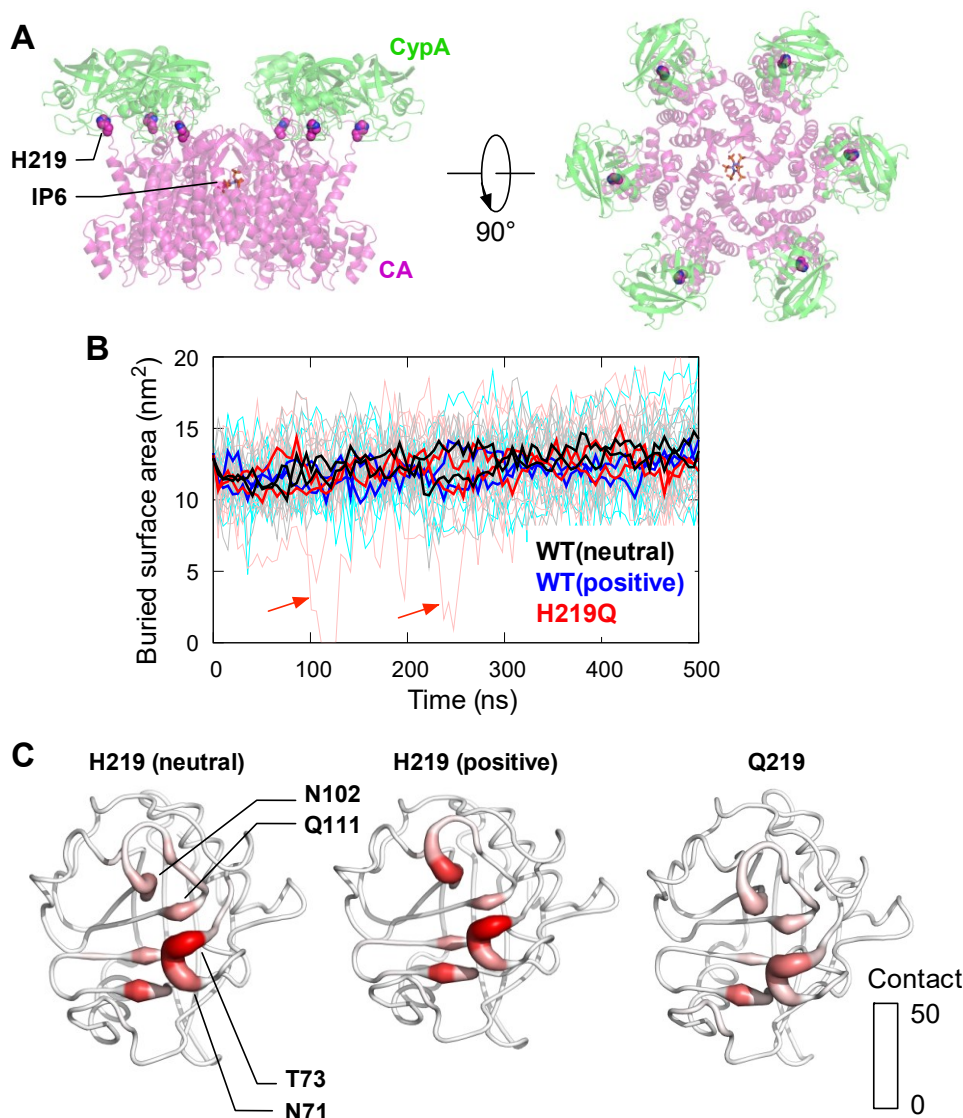

345
 346 **Figure 5: The dynamics of CypA-binding loop.** (A) (Left) Per-residue root mean square fluctuations
 347 (RMSF) of the CA from two independent 500 ns apo simulations. Thin lines show the RMSF of each
 348 individual CA subunit, whilst the thick lines show the average from each simulation. Simulation with
 349 neutral H219 is shown in black, positively charged H219 in blue, and mutant H219Q in red. Dotted box
 350 indicates the loop region where CypA binds. (Right) Enlarged RMSF plot for CypA-binding loop.
 351 Average from the two simulations is shown and error bars indicate standard deviations between repeat
 352 simulations. (B) Atomic contact analysis performed between residues at position 219 and the rest of
 353 the CypA-binding loop, including E230 (indicated by red arrowhead). Average values from two
 354 simulations are shown and error bars indicate standard deviations between repeat simulations. Cut-off
 355 distance for contact analysis is 0.4 nm. (C) Representative structures of the CypA-binding loop from
 356 the simulations with positively charged H219 (left) and mutant H219Q (right) calculated using cluster
 357 analysis (representative structures of the top clusters are shown). In the former, H219 can form a salt
 358 bridge interaction with residue E230 found on the opposite side of the loop, represented as dotted line.
 359 (D) The distribution of minimum distance between the hydrogen atoms bonded to the two nitrogen
 360 atoms on the side chain of the protonated H219 and the two oxygen atoms on the side chain of E230.
 361 Data taken from all six CA subunits and both repeat simulations.

362
 363 Since the interactions between H219 and CypA form a part of the binding
 364 interface⁴³, this raises the question of whether a mutation to glutamine would

365 undermine the strength of binding. To investigate the potential effects of the H219Q
366 mutation upon CypA binding affinity, we performed two independent 500 ns atomistic
367 MD simulations of a mature CA hexamer with each of the subunits bound to a CypA
368 molecule (Figure 6A). While the average buried surface area between CA and CypA
369 in the WT and mutant CA systems were comparable throughout the simulations, we
370 observed transient detachment of CypA molecules in two of the CA subunits from the
371 H219Q variant (Figure 6B). Based on the crystal structure⁴³, H219 forms hydrogen
372 bonds with residues in the CypA active site, including N71. Our simulations revealed
373 that this histidine residue also interacts with other polar residues such as T73, N102,
374 and Q111 on CypA. In the H219Q mutant, the contacts made by the glutamine residue
375 followed a largely similar pattern, although the frequency of interactions was
376 noticeably lower compared to both neutral and protonated histidine (Figure 6C). Both
377 of these analyses of CypA-bound CA simulations suggest that the H219Q mutation
378 may potentially weaken CypA binding to the CA domain. This mutation is therefore
379 likely beneficial in a CypA-rich environment whereby over-recruitment of CypA may
380 destabilise the viral core. Taken together, the H219Q mutation on the CypA-binding
381 loop may play a crucial role in fine-tuning the packaging of CypA into virions, especially
382 in low endosomal pH and CypA-enriched host environments. It is worth noting that a
383 cryo-EM study showed CypA could simultaneously bind two CA subunits from
384 adjacent pairs of hexamers through a second, non-canonical binding site³⁰. However,
385 previous MD simulations have revealed that the interaction at this second site is
386 weaker than the canonical binding site; we therefore did not focus on this second
387 binding site. Nevertheless, as the binding is facilitated primarily by residues A220 and
388 P222, both of which became more mobile upon H219 protonation in on our apo
389 simulations (Figure 5A), it is conceivable that CypA binding at this second site may
390 also be regulated by the H219Q mutation.

391

392
 393 **Figure 6: Atomistic simulations of mature CA with CypA.** (A) Side and top views of mature CA
 394 hexamer (PDB: 6BHT) with each subunit bound to CypA (aligned using PDB: 1AK4). Residue H219 is
 395 shown in van der Waals representation, while IP6 bound in the center of the hexamer is shown in stick
 396 representation. (B) Buried surface area between CA and CypA throughout 500 ns simulations. Data
 397 taken from two independent simulations of CA with neutral H219 (black), protonated H219 (blue) and
 398 H219Q mutant (red). Thin lines indicate values from each of the six subunits, whilst the thick lines show
 399 the running averages. Red arrows show transient dissociation of CypA from CA in H219Q mutant
 400 simulations. (C) Residues on CypA that made contacts specifically with the side chains of neutral and
 401 protonated H219 (left and centre, respectively) from the WT CA simulations and Q219 (right) from the
 402 mutant CA simulations. CypA is shown in ribbon representation, the colour and thickness of which
 403 represent the percentage of contact made with CA during the simulations.

404

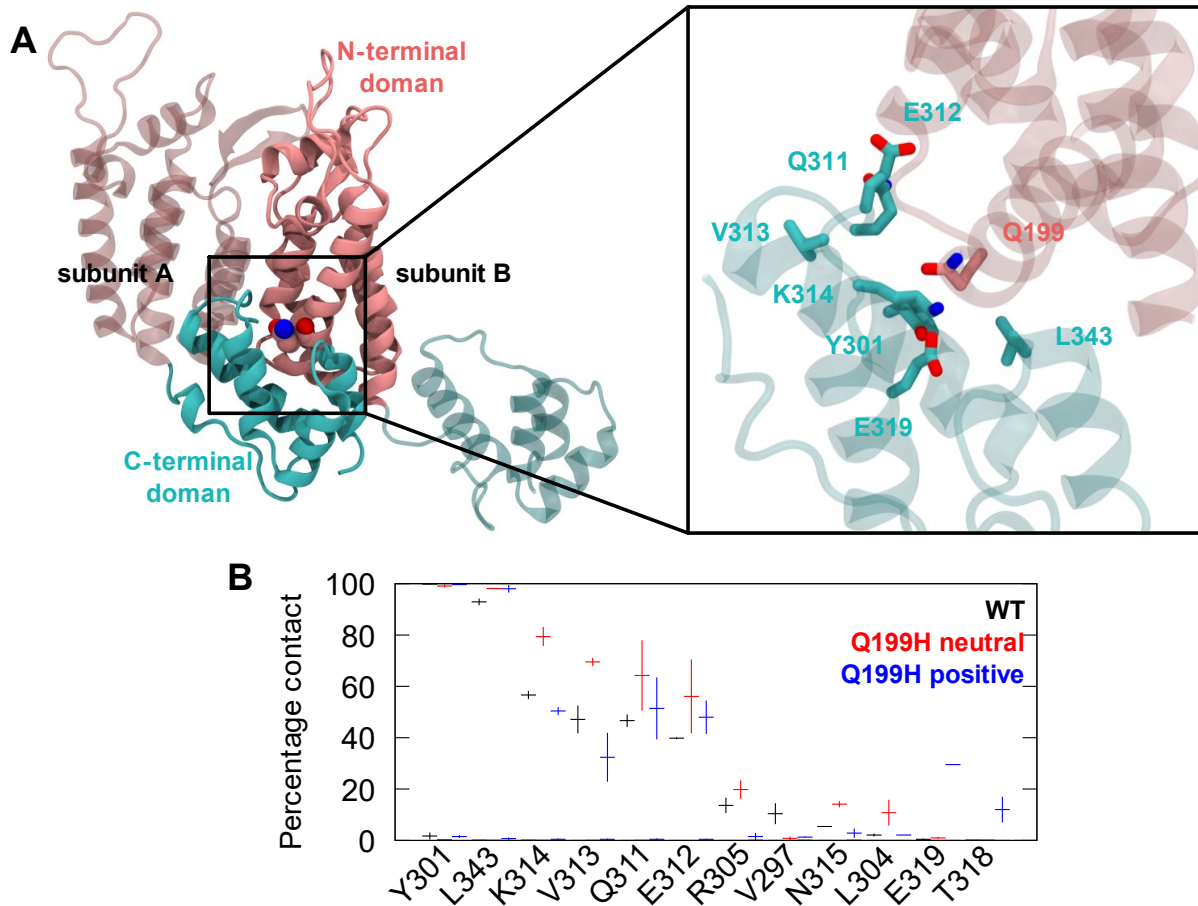

405 ***Mutation in the CA hexameric interface stabilizes oligomerisation***

406 Finally, another non-cleavage site mutation in the CA domain occurs at position 199,
 407 in which a glutamine residue is mutated to a histidine¹⁴. In immature Gag, this residue

408 is located inside the CA domain pointing towards the internal cavity. Our CG
409 simulations show that this residue did not form any major interactions with other CA
410 residues as it was fully exposed to the solvent within the cavity of the CA. However,
411 as CA undergoes large conformational changes during maturation, the Q199 residue
412 forms a part of the hexameric interface of a mature CA domain (Figure 7A). This
413 residue bridges the N-terminal domain of one CA subunit and the C-terminal domain
414 of an adjacent subunit via polar interactions with residues such as Y301, K314 and
415 Q311. We hypothesized that a mutation to histidine may alter the interactions between
416 the two CA subdomains and therefore affect oligomerisation.

417 To test this hypothesis, we performed two repeat 500 ns atomistic simulations
418 of mature CA for the WT and Q199H variants, the latter in either protonated or
419 unprotonated states (Figure 7B). We found that both neutral and charged histidine
420 retained all major interactions as observed for glutamine in the WT protein; for
421 example, the two most prevalent interacting partners from the neighbouring subunit
422 were Y301 and L343, via polar and van der Waals interactions, respectively. Similar
423 to the WT simulations, these residues were found to interact with H199 throughout
424 most of the trajectories. However, the mutant simulations also showed additional
425 contacts with some residues compared to WT. Thus, neutral H199 made significantly
426 more frequent interactions with K314 and V313, whilst protonated H199 could form a
427 salt bridge with E319. Our simulations therefore suggest that a histidine residue at
428 position 199 has the capability to interact with more residues in neighbouring subunits
429 compared to WT, and thus potentially strengthen the binding interface between CA
430 subunits to enhance the stability of the hexameric complex.

431

432

433 **Figure 7: The role of the Q199H mutation in CA oligomerisation.** (A) (Left) A representative
434 snapshot of two subunits of the mature WT CA hexamer in cartoon representation. The Q199 residue
435 bridging the N-terminal domain (pink) of one subunit and the C-terminal domain (cyan) of an adjacent
436 subunit is shown in van der Waals representation. (Right) Enlarged image of the hexameric interface
437 showing residues found within 0.4 nm of the Q199 residue. (B) Percentage contact made by residue
438 Q199 (WT), neutral or positively charged H199 (mutants) with residues from adjacent CA subunits.
439 Contacts are averaged over all six subunits and two independent simulations. Error bars indicate
440 standard deviations between repeat simulations.

441

442 Discussion

443 Given the possible benefits of drugging Gag together with the protease, we set out to
444 study cleaved Gag structures using multiscale modelling and simulations of the HIV-1
445 Gag protein to understand the effect of clinically relevant mutations that occur outside
446 of the cleavage sites. We built a model of the MA-CA-SP1 polyprotein complex in its
447 multimeric state, which constitutes the largest cleavage product of the immature Gag
448 protein. Our simulations of the membrane-bound complex suggest that the long linker
449 connecting the MA and CA domains is flexible and may contract, enabling interactions
450 between protease cleavage site residues and the C-terminal region of the MA domain,

451 as well as several regions on the CA domain including the CypA binding loop. Two
452 clinical mutations, G123E and H219Q, are found in these regions and alter the
453 accessibility and electrostatic properties of the protease binding site. Mutations in the
454 MA domain are concentrated on the predicted membrane binding surface and at least
455 three of them – E12K, E40K and L75R – render the surface more positively charged
456 compared to wild type Gag. Our CG simulations of these mutant variants show more
457 pronounced interactions with PIP2 lipids, leading to the hypothesis that these
458 mutations improve Gag targeting and anchoring to the plasma membrane during viral
459 assembly. Atomic-resolution simulations of the mature Gag CA domain showed that
460 the H219Q mutation may play a role in optimizing CypA recruitment by controlling the
461 conformational flexibility of the CypA binding loop and fine-tuning the CypA binding
462 affinity. We also found that a mutation in the CA domain, Q199H, likely enhances
463 oligomerisation by providing more stabilising interactions between adjacent subunits.

464 In the field of HIV and other related retroviruses, multiscale modelling and
465 simulations have been utilised to study CA in different maturation states, providing
466 important insights into their structural dynamics and interactions with drugs and host
467 cell proteins^{30,46–48}. For example, landmark microsecond-timescale atomic simulations
468 of the entire HIV-1 capsid revealed important physicochemical properties, such as its
469 electrostatics, dynamics, and water/ion permeability, as well as pointing towards long-
470 range allosteric motions in the shell²⁷. Simulations of the monomeric MA domain shed
471 light on the molecular mechanism underlying membrane anchoring by the myristoyl
472 group and PIP2 lipids³³. Our study reports the first complete oligomeric model of the
473 proteolytic product of HIV-1 Gag polyprotein, allowing the investigation of interactions
474 between residues on the protease binding site and distant residues on the MA and CA
475 domains, especially those from different subunits. Such inter-subunit “crosstalk” would
476 be difficult to identify using individual crystal structures of mature Gag domains or a
477 monomeric Gag model. Understanding structural changes that occur upon proteolysis
478 could provide important clues on HIV-1 protease activity. For example, the MA-CA
479 linker contraction observed in our simulations resulted in a significant decrease in
480 solvent accessibility of the protease binding site, which helps to explain the lower
481 cleavage rate of the MA-CA domain compared to the SP2-P6 domain³⁸. From the
482 perspective of anti-HIV drug development, targeting Gag proteolytic products in
483 addition to the mature form, by virtue of identifying intermediate structural models, may
484 allow for the discovery of Gag inhibitors that can inhibit multiple stages of maturation¹⁰.

485 Since accumulation of deleterious mutations could negatively impact virion
486 survival, Gag polyprotein and protease co-compensate to outcompete protease
487 inhibitors and restore viral fitness^{10,11,49}. While HIV-1 protease acquires drug resistant
488 mutations to evade PI activity, its ability to bind and subsequently cleave the Gag
489 protein is impaired. Thus, Gag gains additional mutations to compensate for fitness
490 defects to recover protease function. Structural studies show that associated
491 mutations on cleavage sites do not restore interactions lost due to mutations on the
492 protease, but rather establish novel interactions surrounding the site of protease
493 mutations as well as induce conformational changes to drive better binding¹². Apart
494 from cleavage site mutations, mutations in more distant regions have been shown to
495 contribute towards recovery from the reduced viral fitness caused by protease
496 mutations^{13,14}. Our study shows that these non-cleavage site mutations have far
497 reaching implications outside of Gag proteolysis, from improving membrane binding
498 to fine-tuning CypA recruitment and stabilising the CA hexamer. A recent single
499 genome sequencing study revealed that, indeed, most Gag-protease correlated
500 mutations occur outside of the Gag cleavage site with the viral MA and CA domains
501 representing the largest subsets of the mutations⁴⁹. Interestingly, a high concentration
502 of compensatory mutations was uncovered within the globular domain of the MA,
503 which binds to the plasma membrane, and the CypA binding loop of the CA, further
504 corroborating our simulation results. Our results also highlight that the residues on the
505 CypA binding loop can interact directly with MA-CA cleavage site residues, thus
506 potentially influencing their local electrostatics and surface accessibility, although
507 determining the exact interactions made between these residues and subsequent
508 molecular effects would require further studies. For example, PS lipids are known to
509 be exposed on the outer leaflet of HIV-1 membrane and may facilitate HIV-1 entry into
510 the host cells^{50,51}, and it is possible that the highly basic surface generated by the non-
511 cleavage site mutations could attract anionic PS lipids, similarly to the PIP2 enrichment
512 around the MA domain observed here. It is worth noting that compensatory non-
513 cleavage site mutations also occur in the NC and P6 domains. Gatanaga et al.
514 discovered five such mutations with clinical importance¹⁴, and many clinical drug
515 resistant mutations can occur within the first replication cycle⁷. While modelling these
516 domains is beyond the scope of the current study, it is certainly worth exploring in the
517 future, specifically regarding how these mutations affect interactions with the viral RNA
518 genome. Overall, our data have revealed new insights into the role of Gag non-

519 cleavage site mutations on HIV-1 viral fitness. Given that HIV-1 is one of the fastest
520 mutating RNA viruses, an in-depth comprehension of emerging mutations will aid in
521 the general understanding of viral drug resistance, as well as the emergence of novel
522 viruses that are able to cross species during zoonotic infections.

523

524

525 **Methods**

526 ***Model building and system setup***

527 The model of HIV-1 Gag MA-CA-SP1 was built using two structural templates: MA
528 trimers (PDB: 1HIW)³⁴ and the immature CA hexamer (PDB: 5L93)³⁵. Six copies of
529 MA trimers were arranged based on EM images showing that they organize as
530 hexamer-of-trimers on a model membrane bilayer³⁶. The CA hexamer was placed
531 such that the N-termini of its subunits align with the C-termini of the central subunits
532 of the MA trimers. Modeller version 9.21⁵² was used to build the loops connecting the
533 MA trimers and CA hexamer (Figure S1) using the discreet optimized protein energy
534 (DOPE)-based loop modelling protocol, and the model with the lowest DOPE score
535 was chosen⁵³. Stereochemical assessment using Ramachandran analysis⁵⁴ showed
536 only one outlier residue, confirming that the model was structurally reasonable. The
537 atomistic MA-CA-SP1 structure was subsequently converted to CG representation
538 using the MARTINI 2.2 force field⁵⁵ and the elastic network model, EINEDyn⁵⁶, was
539 imposed to maintain the integrity of the secondary and tertiary structure. The N-
540 terminal glycine residue on each MA subunit was myristoylated based on parameters
541 from Charlier et al³³. Three mutant variants were generated using PyMOL⁵⁷ based on
542 non-cleavage site mutations published by Gatanaga et al¹⁴.

543 A 30 x 30 nm² patch representing the HIV-1 membrane model was built using
544 the CHARMM-GUI Martini Maker Bilayer Builder^{58,59} and the lipid composition was
545 based on a previous HIV-1 lipidomic study³⁷. This membrane was asymmetric: the
546 upper leaflet was made of 10% phosphatidyl choline (PC), 10% phosphatidyl ethanol
547 amine (PE), 30% sphingomyelin, and 50% cholesterol, whereas the lower leaflet was
548 made of 10% PC, 20% PE, 15% phosphatidyl serine (PS), 5% phosphatidylinositol-
549 4,5-bisphosphate (PIP2), and 50% cholesterol. The HIV-1 membrane is enriched in
550 saturated lipid species especially for PC; we therefore modelled the lipid tails of PC as
551 1,2-dipalmitoyl (DP), whereas the rest of the lipids were modelled with 1-palmitoyl-2-
552 oleoyl (PO) lipid tails. Following minimization and equilibration procedures according
553 to the CHARMM-GUI, the model membrane was further simulated for 1 μ s to allow
554 better mixing of the lipid components prior to simulations in the presence of protein.

555

556 ***Molecular dynamics simulations***

557 The HIV-1 Gag MA-CA-SP1 CG model was placed underneath the membrane
558 such that the myristoylated N-termini were inserted into lower leaflet of the membrane.

559 Energy minimization was then performed using the steepest descent method to
560 remove any overlapping beads. The system was solvated with standard MARTINI
561 water molecules and neutralized with 0.15 M NaCl ions. Further energy minimization
562 was performed. The system was then equilibrated for 10 ns whereby positional
563 restraints with a force constant of 1000 kJ mol⁻¹ nm⁻² were imposed on all of the
564 backbone atoms of the protein. Temperature coupling using the V-rescale thermostat
565 with a time constant of 1 ps⁶⁰ was applied to maintain the temperature at 310 K. Semi-
566 isotropic pressure coupling using the Berendsen barostat with a time constant of 5 ps
567 was utilized to maintain the pressure of the system at 1 atm. Electrostatics were
568 calculated using the reaction field method. The der Waals interactions were computed
569 using a potential shift Verlet scheme. The short-range cut-offs for both of these were
570 set to 1.1 nm. After the equilibration simulations, four independent production runs of
571 15 μ s were performed using different distributions of initial velocities. The same
572 protocols used for the equilibration simulation were used for the production runs in the
573 absence of position restraints, except for the pressure coupling in which the Parrinello-
574 Rahman barostat was used with a coupling constant of 12.0 ps⁶¹.

575 Atomistic MD simulations were performed to understand the role of the H219Q
576 mutations on CypA binding and Q199H on CA oligomerisation. The structure of the
577 mature HIV-1 CA hexamer in complex with inositol IP6 (PDB: 6BHT)³² was aligned to
578 that of the CA N-terminal domain bound to CypA (PDB: 1AK4)⁴³. This alignment
579 generated a structure of the CA hexamer bound to six copies of CypA (Figure 6A).
580 Mutations in the CA were performed using PyMOL. The proteins were parameterized
581 using the CHARMM36 force field⁶², whereas the CHARMM-GUI Ligand Reader &
582 Modeller⁶³ was used to generate the parameters for the IP6 molecule. The complex
583 was solvated with TIP3P water molecules and 0.15 M NaCl was added to neutralize
584 the system. The steepest descent minimization protocol was used to remove
585 overlapping atoms. A short 100 ps equilibration simulation with position restraints
586 (force constant of 1000 kJ mol⁻¹ nm⁻²) applied to all heavy atoms of the protein was
587 conducted. The temperature of the system was maintained at 310 K using the Nosé-
588 Hoover thermostat with a time constant of 1.0 ps^{64,65}. The pressure was kept at 1 atm
589 using an isotropic coupling to the Parrinello-Rahman barostat with a time constant of
590 5.0 ps⁶¹. Electrostatic interactions were measured using the smooth particle mesh
591 Ewald (PME) method with a real-space cut off of 1.2 nm⁶⁶. The van der Waals
592 interactions were calculated using the force switch smoothing function applied

593 between 1.0 and 1.2 nm, and truncated at 1.2 nm. An integration time step of 2 fs was
594 used with all covalent bonds involving hydrogens constrained using the LINCS
595 algorithm⁶⁷. After equilibration, the positional restraints were removed and two
596 independent 500 ns production runs were conducted using the same setup for each
597 of the WT and mutant variants starting with different initial velocities.

598 Additional atomistic and CG simulations were performed to verify the
599 conformation of the MA-CA linker. A single subunit of the HIV-1 Gag MA-CA-SP1
600 model was placed in solution with 0.15 M NaCl ions. Positional restraints with a force
601 constant of 1000 kJ mol⁻¹ nm⁻² were applied to the backbone atoms of membrane
602 binding residues (residue 2-53 and 72-90) to mimic membrane binding. Four
603 independent 500 ns simulations were performed for both atomistic and CG systems
604 using the same protocols described above.

605 To refine interactions between the linker region and mutant residues observed
606 in the CG simulations of the MA-CA-SP1 hexamer, we converted the structure of the
607 hexamer from the final frame of one of the simulations to atomistic representation
608 using the CHARMM-GUI All-Atom Converter⁶⁸. A single subunit of the MA-CA-SP1
609 was subsequently used to refine interactions with the G123E mutant, whereas two
610 adjacent subunits were used for interactions with the H219Q mutant. The protein was
611 inserted into a box of water with 0.15 M NaCl ions. Positional restraints with a force
612 constant of 1000 kJ mol⁻¹ nm⁻² were imposed on the backbone atoms of residues
613 outside of the MA-CA linker and CypA binding loop (residue 2-117, 147-215 and 233-
614 376). For each system, three independent 200 ns simulations were performed using
615 the parameters described above.

616 All simulations were performed using GROMACS 2018⁶⁹. The list of simulations
617 performed is provided in Table S2. Analysis of the electrostatic surface charge of the
618 MA domain was performed in PyMOL using the APBS plugin⁷⁰.

619
620

621 **Acknowledgments**

622 This work was supported by BII and EDDC of A*STAR. Simulations were performed
623 on the petascale computer cluster ASPIRE-1 at the National Supercomputing Centre
624 of Singapore (NSCC) and the A*STAR Computational Resource Centre (A*CRC).
