Dendrite growth rule

A developmental stretch-and-fill process that optimises dendritic wiring

Dendrite growth rule

In brief

We derive a detailed mathematical model that describes long-term time-lapse data of growing dendrites; it optimises total wiring and space-filling.

Highlights

- Dendrite growth iterations guarantee optimal wiring at each iteration.
- Optimal wiring guarantees optimal space filling.
- The growth rule from fly predicts dendrites of other cell types and species.
- Fly neurons stretch-and-fill target area with precise scaling relations.
- Phase transition of growth process between fly embryo and larval stages.

Abstract

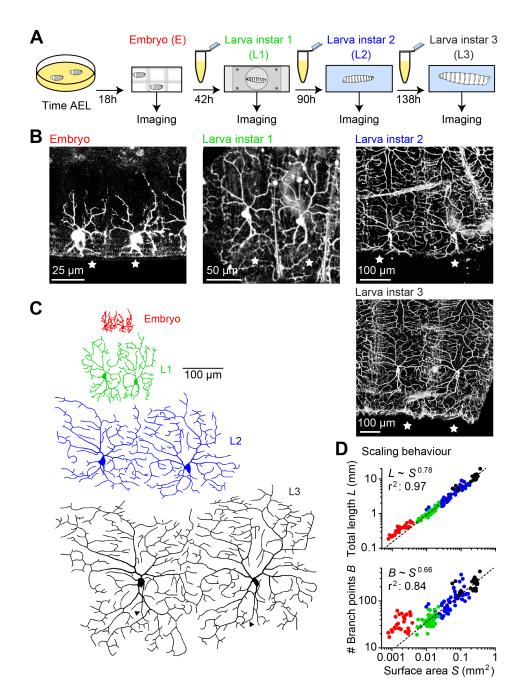

The way in which dendrites spread within neural tissue determines the resulting circuit 2 connectivity and computation. However, a general theory describing the dynamics of this 3 growth process does not exist. Here we obtain the first time-lapse reconstructions of neurons 4 in living fly larvae over the entirety of their developmental stages. We show that these neurons 5 expand in a remarkably regular stretching process that conserves their shape. Newly available 6 space is filled optimally, a direct consequence of constraining the total amount of dendritic 7 cable. We derive a mathematical model that predicts one time point from the previous and use 8 this model to predict dendrite morphology of other cell types and species. In summary, we 9 formulate a novel theory of dendrite growth based on detailed developmental experimental 10 data that optimises wiring and space filling and serves as a basis to better understand aspects 11 of coverage and connectivity for neural circuit formation. 12

Introduction

No one has to date proposed a theory of dendritic development that predicts the actual details 14 of the biological growth process. Existing models describe the branching structures of mature 15 dendrites using statistical growth rules (Koene et al., 2009), their spatial embedding (Luczak, 16 2006) or optimal wiring constraints (Cuntz et al., 2007, 2010). Only recently, time-lapse analysis 17 has become more quantitative (Chalmers et al., 2016; Lee et al., 2013) enabling to link the 18 developmental dendritic growth process with actual computational models. Understanding 19 dendrite growth is essential to relate dendrite structure and the self-organisational process 20 of neural circuit formation with respect to the set of all connections, i.e. the connectome 21 (Denk et al., 2012). Also, only through simulations of dendritic development can the mature 22 morphology be understood with respect to its underlying biology. We analyse in this work 23 the maturation of the sensory dendritic arborisation (da) neurons of Drosophila larvae, a model 24 system to study dendrite growth using genetics and molecular techniques (Jan and Jan, 2010). 25 Among the da neurons, class IV ddaC (CIVda) cells tile (Grueber et al., 2002) and efficiently 26 fill the available two-dimensional space (Shimono et al., 2010; Sugimura et al., 2007) via local 27 interactions between neighbouring branches (Matthews et al., 2007; Soba et al., 2007). 28

Dendrite growth rule

A, Sketch illustrating the imaging procedure throughout *Drosophila* larva developmental stages: embryo (E), larval instar (L) 1, 2 and 3. The larvae were kept in culture medium between the imaging steps. Times shown are AEL (after egg laying). **B**, Maximum intensity projections of image stacks from the same two neighbouring da dendrites (stars) for all four developmental stages. **C**, Digital reconstructions of the two neighbouring dendrites from **B** with small diameters clamped at $2\mu m$. Triangular markers in L3 show axons, which are ignored in the rest of the study. **D**, Scaling behaviour of total length *L* and number of branch points *B* against the total surface that the dendritic trees span *S*. Dashed lines show the best fit for data points L1—L3 with respective power and r^2 values. In all panels, the colours for the developmental stages are E (red), L1 (green), L2 (blue), L3 (black).

Dendrite growth rule

Using live imaging, we obtained time-lapse reconstructions (Lee et al., 2013) of developing 29 dendrites of the same CIVda neurons throughout larval development (E-L3), over the 30 course of several days (Figure 1A). Remarkably, large parts of the dendritic architecture were 31 conserved over all developmental stages while the overall shape was stretched, increasing the 32 size homogeneously in all directions (Peng et al., 2015) (Figures 1B and C). Most importantly, 33 individual dendritic branches from previous stages were easily identifiable and new branches 34 grew in the space that became available through the extensive epidermal stretching. In the 35 following, we dissect the stretch-and-fill process that underlies the development of CIVda 36 dendrites, thereby formalising their maturation in a general theory of dendritic growth. 37

Results

38

39

Scaling behaviour of CIVda neuron throughout larval development.

In order to confine our model quantitatively, we first studied the scaling behaviour of dendritic 40 morphological parameters during development, i.e. in which relation to one another their 41 values increased (Cuntz et al., 2012; Iyer et al., 2013). The surface area S covered by the 42 dendritic trees increased by a factor of $62 \times$ between embryo (E) and third instar larva (L3) 43 stages, consistent with previous observations (Parrish et al., 2009). After a phase of filling 44 the dendrite's available spanning area in the embryo stage reflected in a different scaling 45 behaviour (Parrish et al., 2009), S scaled regularly with total dendrite cable length L in the 46 range of L1—L3 stages with a strict power relation of exponent 0.78 ($L \sim S^{0.78}$; $R^2 = 0.97$). 47 Branches appeared to fill up newly available space beyond a stretching process ($L \sim S^{1/2}$, 48 increasing the size without adding branches), however without conserving cable density 49 $(L \sim S)$ throughout development (Figure 1D, top panel). Similarly, the number of branch 50 points B scaled with S with an exponent of 0.66 ($B \sim S^{0.66}$; $R^2 = 0.84$) lingering between 51 a pure stretching process with no new branches ($B \sim S^0$, i.e. B does not change with S) 52 and a conservation of branch point density ($B \sim S$, a linear relation with an exponent of 53 1; Figure 1D, bottom panel). In line with a general growth process conserving dendritic 54 features, all branching statistics that we studied scaled extensively with developmental stages 55 (Figure 2A) but were essentially invariant of the developmental stage once the differences in 56 overall sizes were normalised out (Figure 2B). 57

Dendrite growth rule

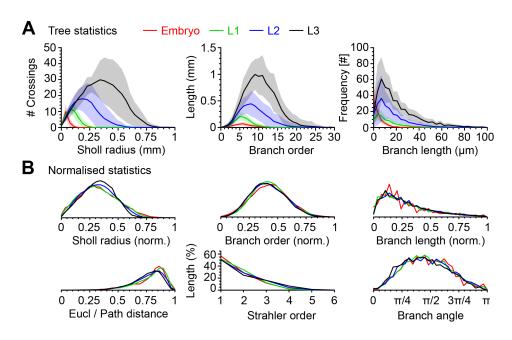

Fig 2. Branching statistics are similar throughout developmental scaling

A–B, Average branching statistics of reconstructions at the four developmental stages in absolute (**A**) and normalised (**B**) values. Panels in **A** indicate standard deviations in shaded areas. In all panels, the colours for the developmental stages are E (red), L1 (green), L2 (blue), L3 (black).

Minimal wiring and optimal space filling.

Since CIVda neurons possess space-filling dendrites we consider here an efficient coverage 59 of available surface area S with short dendritic cable length L. Such an efficient coverage 60 could be achieved by spreading out branches to regularly distributed target locations. As 61 a reference, we used targets on a closed hexagonal lattice arrangement that are well spread 62 (**Figure 3A**) (Hales, 2000). Tightly packed circles with radius θ around these targets are known 63 to cover $\frac{\pi}{2\sqrt{3}} \approx 90.69\%$ of total available S. This simple geometrical framework yields direct 64 relationships for all morphological variables of interest when connecting N such targets to a 65 tree: 66

$$\theta = (h^{-1/2}/2) \cdot S^{1/2} \cdot N^{-1/2} \approx \frac{S}{(2 \cdot h \cdot L)} \qquad L \approx h^{-1/2} \cdot S^{1/2} \cdot N^{1/2}$$
(1)

where $h = \frac{\sqrt{3}}{2}$ (see Methods). In order to later compare these relations with random target distributions (Figure 3B) and real trees (Figure 3C), we also calculated their corresponding 69

58

Dendrite growth rule

equivalent θ values as the distance one has to move away from all points on the tree to cover $\sim 90.69\%$ of S.

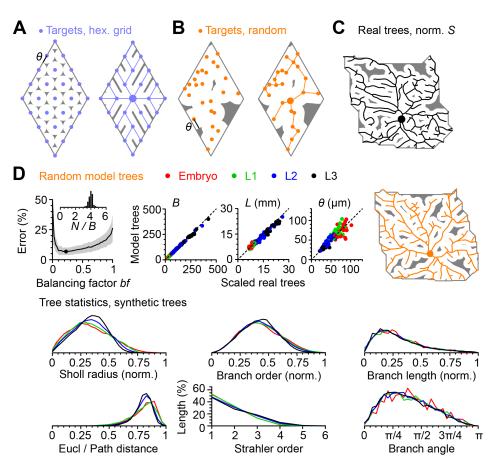

Fig 3. CIVda neuron minimal wiring and optimal space filling.

A, Targets (blue dots) distributed on a closed regular hexagonal grid optimise space coverage (left) and form a minimum spanning tree (blue straight lines) when connected to minimise total cable and path lengths toward the root (large blue dot, right). Grey shaded area indicates 10% (> θ ; θ shown as black line for one sample target) furthest away from targets (left) or from the tree (right). **B**, Similar arrangement as **A** but with random uniformly distributed targets (orange colours) as a comparison. **C**, Similar arrangement as **A** for real da dendrite normalised to the same *S* as in **A** (targets are not shown since they are unknown). **D**, Model trees based on random homogeneously distributed targets in the dendrite spanning area (see Methods). Upper row (left to right): Model parameter bf vs. error (comparing total length, branch order, compression and path length with corresponding real tree values; straight black line), optimal bf (0.225, black dot), standard deviation of the error (shaded area), and distribution of ratio values between numbers of targets and branch points (inset, 4.07 ± 0.29) for the optimal bf; Validation of number of branch points *B*, total cable length *L* and space coverage θ between scaled real trees and model trees with dashed line indicating unity for comparisor; sample random tree grown in the spanning area of the dendrite depicted in **C**. Lower part: similar panels as in **Figure 2B** but for synthetic trees.

However, for a concrete comparison between real and synthetic trees, it was essential to 72

Dendrite growth rule

estimate N — the number of targets — an unknown measure in real trees. Fortunately, CIVda 73 branching structures were well predicted by minimum spanning trees based on optimal 74 wiring constraints (Nanda et al., 2018), which were best matched in our case with a trade-off 75 parameter bf = 0.225 between minimising total cable L and path lengths PL along the tree 76 from any target toward the root ($Cost = L + bf \cdot PL$; Figure 3D, upper left panel) (Cuntz et 77 al., 2007, 2008, 2010; Wen and Chklovskii, 2008). Such synthetic trees grown on a number 78 N of randomly distributed targets within the spanning area of real dendrites to minimise 79 this effective cost matched all remaining branching statistics of their real counterparts after 80 simply matching the total number of branch points B (Figure 3D). A tight ratio of 4.07 ± 0.29 81 between number of targets N and number of branch points B was observed in such synthetic 82 dendrites (Figure 3D, left panel inset) (c.f. Cuntz et al., 2012) enabling us to estimate N in real 83 dendrites directly from B ($N = 4.07 \times B$). 84

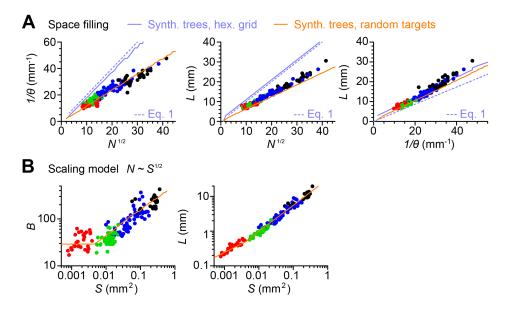

Fig 4. Modelling scaling relations in CIVda neuron development.

A, Comparison of the scaling behaviour of the variables in the space filling equations between real neurons (dots, same colours as in **Figure 1D**) and the two models shown in **Figure 3A** (Hexagonal arrangement, blue; dashed line **Equation 1** for targets only, straight lines for connected trees) and **Figure 3B** (Random, orange lines). Number of branch points in real dendrites were converted to target number *N* by the factor 4.07 obtained in **Figure 3D**. **B**, Scaling behaviour of the random model from **Figure 3B** (orange) assuming that target number *N* grows with the side length of the surface area between L1–L3 compared with data from **Figure 1D**.

Equipped with **Equation 1** and after normalising *S* in all cases we were able to isolate entirely ⁸⁵ linear relationships between the square root of the number of target points $N^{1/2}$, *L* and $\frac{1}{\theta}$, the ⁸⁶

Dendrite growth rule

Baltruschat, Tavosanis & Cuntz

inverse of θ quantifying the amount of space filling (Stepanyants et al., 2002). Interestingly, the 87 corresponding scaling relationships indicated that real dendrites were shorter but less space 88 filling (smaller $\frac{1}{4}$) for one given N than synthetic trees from well-spread targets on a hexagonal 89 grid (Figure 4A, Equation 1). Real dendrites almost perfectly matched a configuration with 90 randomly distributed targets (compare orange lines and data in Figure 4A). However, when 91 comparing $\frac{1}{4}$ and L all configurations reached similar space filling for a given total length 92 of dendrite (Figure 4A, Equation 1). Optimal wiring criteria seemed to, therefore, optimise 93 space filling with respect to dendritic cable length regardless of target distributions, which 94 seemed to be a general feature of minimum spanning trees. Optimally wired dendrites with 95 uniformly distributed random targets were overall an excellent match for all measured CIVda 96 neuron morphologies at all developmental stages and explained their specific space filling 97 character. This could be qualitatively consistent with a random branching process of the 98 Galton Watson type (Watson and Galton, 1875) that includes self-avoidance (Ganguly et al., 99 2016; Memelli et al., 2013). In fact, assuming that the number of targets N is proportional to 100 the side length (or square root) of the total surface area S (Figure 4B) such a model was also 101 an excellent match for the precise scaling behaviour observed previously in **Figure 1D**. Thus, 102 we can accurately model CIVda dendrites at each developmental stage. We therefore next 103 addressed the developmental process leading to such optimally wired trees from one stage to 104 the following. 105

Dendritic developmental stretch-and-fill.

In order to unravel the developmental growth process using the time-lapse data, we identified ¹⁰⁷ branch and termination points that were conserved in consecutive reconstructions using a ¹⁰⁸ newly developed semi-automated registration procedure (**Figure 5A**). The analysis unveiled ¹⁰⁹ a surprisingly linear and isometric stretching (**Figure 5B**) with a tight slope between the ¹¹⁰ stretching vector and the distance of points from the dendrite root (**Figure 5C**). Interestingly, ¹¹¹ the overall origin of stretching did not lay precisely in the dendritic root location (**Figure 5B**) ¹¹² consistent with a possible impact of superficial epithelium extension on dendritic scaling ¹¹³ during development (Jiang et al., 2014).

Dendrite growth rule

Baltruschat, Tavosanis & Cuntz

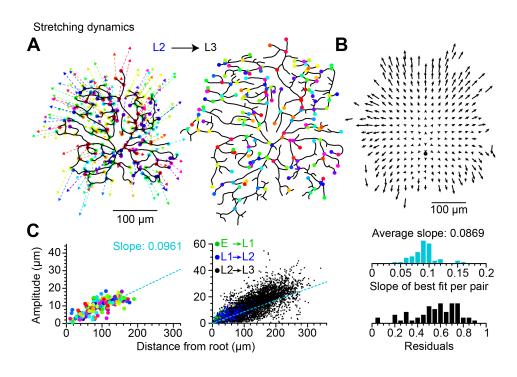

Fig 5. CIVda neuron developmental stretching.

A, Time-lapse data analysis: Branch and termination points (coloured dots) in time 1 (left, here L2) are registered to corresponding points in time 2 (right, here L3, same colour). The arrows on the left depict the movement of the respective topological points and illustrate the stretching of the entire structure between two acquisitions. **B**, Overall analysis for all pairs (N = 47). Arrows (every $25\mu m$) are averages only shown where data for at least 5 pairs were available. Dendrites were centred on their root (black dot). **C**, Analysis of stretching by comparing the arrow lengths (left, one dot per topological point with same colours as in **A**; right, topological points collected from all pairs with colours indicating larval instar at time 2 and their distance to the root. Linear fits (dashed cyan lines) determine the slope for all pairs (far right: histograms of slope values and residuals).

Our time-lapse registration method enabled us then to identify the new branches filling 115 the empty space after the dendrite's linear stretching and the way they affected the scaling 116 relationships (Figure 6A). Analogously to Figure 3 and 4, we simulated the filling process by iteratively either connecting random targets within S or targets that were selected to be 118 maximally far away from the existing tree (Figure 6B, orange and blue respectively; compare 119 with pink new branches in the experimental dataset). Whereas random targets had efficiently 120 connected to realistic synthetic trees in one go, the iterative — developmental -- filling of real dendrites yielded slightly inferior space filling $\frac{1}{\theta}$ compared to the maximal filling model and 122 fewer branch points *B* than the random filling model. A mixed model, however, predicted 123 both values appropriately (Figure 6B, green) and enabled the growth process to remain on the 124 realistic trajectories within the scaling behaviour plots (Figure 6B, bottom panels; compare 125

with **Figure 6A**). The results of the time-lapse analysis, therefore, put precise quantitative ¹²⁶ bounds to our growth model and indicated that a mixed model between maximal and random ¹²⁷ filling would best match the biological developmental iterations of dendrite growth. ¹²⁸

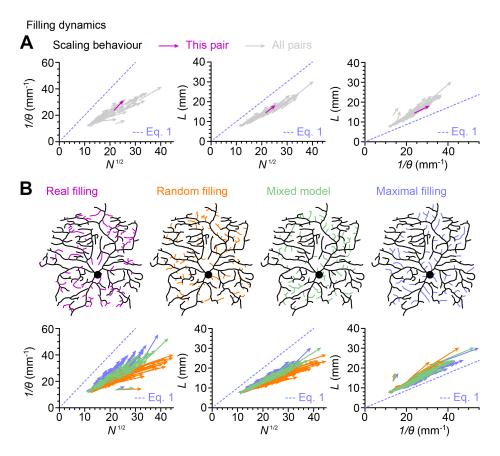

Fig 6. CIVda neuron developmental space-filling.

A, Scaling trajectories of variables defined in **Figure 4** for all pairs in real cells (grey arrows) and the one example shown from **Figure 5A** (pink arrow). **B**, Filling characterised by new branches in time 2 (real cell from **Figure 5A**, pink branches; black branches are conserved from time 1). Models filling randomly (orange), mixed (green), and maximally (blue) away from the existing dendrite (black tree with dots indicating the root). Panels show the trajectories obtained from model filling (orange dots – random, green dots – mixed model, blue dots – maximal, compare with **A**).

Morphological model of dendrite development.

Having formalised the growth process from one time point to the following we simulated the developmental steps to grow entire synthetic dendrites *de novo* in the three different models (**Figure 7**). The mixed model reproduced the scaling behaviour that real dendrites underwent while optimising wiring and space filling throughout development. The resulting synthetic 133

Dendrite growth rule

dendrites reproduced the shape of L1–L3 morphologies but failed to match the distinct aspect ¹³⁴ of embryo stage dendrites indicating once again that at the phase transition between E and L1 135 the mode of branching changed dramatically. Our synthetic developmental growth process 136 was able to reproduce morphologies of other planar dendrites (cerebellar Purkinje cells 137 and fly lobula plate tangential cells) and 3D dendrites (dentate granule cells, hippocampus 138 pyramidal cells and cortical layer 5 pyramidal cells) as well as their space filling character 139 (Figures 8A and B). Our new iterative model represents a substantial improvement over our 140 previous optimal wiring based models and will be useful at dissecting the developmental 141 growth process leading to the mature dendritic morphology. 142

Discussion

In summary, we have shown how the iterations of dendrite growth lead to optimally wired 144 morphologies throughout development, in other words how nature implements minimum 145 spanning dendritic trees sequentially. We further have shown that optimally wired minimum 146 spanning trees necessarily lead to optimal space filling regardless whether targets are dis-147 tributed randomly or spread out maximally, meaning that minimising dendritic cable length 148 guarantees optimal space filling in all cases. Our synthetic growth algorithm completely 149 describes CIVda neurons showing that the dendrites of these cells are optimally built to 150 constrain wire and explaining the scaling behaviour that most likely conserves connectivity 151 (Gerhard et al., 2017) and function (Cuntz et al., 2013). The scaling behaviour exhibits a phase 152 transition between embryo and L1—L3 (Parrish et al., 2009) that is similar to observations 153 that have been made in *C. elegans* (Nicosia et al., 2013). Our models open up the possibility in 154 the future to associate mutant phenotypes or elements of structural plasticity to parameter 155 alterations in our model to better understand the underlying mechanisms of dendrite growth 156 (Tavosanis, 2012; Yalgin et al., 2015). In our model, new targets that are chosen to be far from 157 the existing tree are connected to a close node on the existing tree while also considering short 158 paths in the dendrite. Elucidating the precise dynamics of elongation and retraction due to 159 repulsion from other branches and molecules that establish the dendritic territory (Hattori 160 et al., 2009; Matthews et al., 2007; Parrish et al., 2007) will require time-lapse analysis with 161 much higher temporal resolution (Chalmers et al., 2016; He and Cline, 2011). However, with 162 the current model in hand, quantitative predictions for such studies are given. Ultimately, 163 our model will link neurite outgrowth and space filling with circuit formation (Schröter et 164

Dendrite growth rule

al., 2017) in neural networks of arbitrary complexity basing simulations on well-understood ¹⁶⁵ principles instead of vast collections of neuronal reconstructions (Markram et al., 2015). ¹⁶⁶

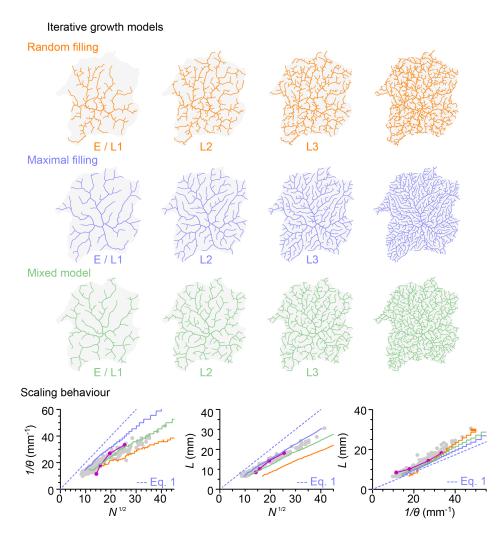

Fig 7. Morphological model of CIVda dendrite development.

Synthetic dendrites generated from scratch using the growth rules derived in **Figure 6**. Iterations shown correspond to total lengths of 9, 14, 20 and 30mm approximating mean values for E/L1, L2, L3 and maximal length in L3 respectively after normalising *S* from left to right with models that fill randomly (orange, top row), maximally (blue, middle row) and a mixed model (green, bottom row). Scaling behaviour (Bottom panels) is compared to the real cells (grey dots, otherwise similar to **Figure 4**). Straight lines (orange, green and blue) indicate the scaling behaviour during the growth iterations of the respective examples (random, maximal, mixed model filling) shown in Top panels. Pink line with dots shows the four (E, L1–L3) developmental stages of the same real cell from **Figure 6**.

Materials and methods

Fly handling

To label Class IV da (CIVda) neurons specifically, we used a fly strain that carried a fusion 178 of a fraction of the enhancer of the *ppk* gene and eGFP (w^{1118} ; ; *ppk* – *eGFP*) (Grueber et al., 179 2003). This strain expresses eGFP in CIVda neurons from embryonic stage 16 throughout 180 larval stages. We concentrated on the dorsal ddaC neuron (Grueber et al., 2002). For embryo 181 collection, young fertilised females were placed in population cages, supplemented with 182 apple agar plates maintained in an incubator at $25^{\circ}C$ and 60% relative humidity. To obtain 183 developmentally synchronised embryos the agar plate was supplemented with fresh yeast 184 paste to promote laying of retained eggs and replaced after one hour. Females were then 185 allowed to lay eggs for 30min. The collected eggs were placed back in the incubator and 186 allowed to develop for 18*h*, when they were harvested, dechorionated with bleach for 3.5*min* 187 and rinsed with water. Not all embryos were dechorionated by this gentle treatment, and the 188 chorion was then removed mechanically with a brush. 189

Time-lapse image acquisition

We developed a novel method to image the living larvae over several consecutive days causing 191 as little interference as possible. Briefly, after each imaging session individuals were kept at 192 $25^{\circ}C$ and 60% relative humidity in a separate $500\mu l$ Eppendorf tube filled with $200\mu l$ standard 193 cornmeal-agar fly food. To regain the test subject the fly food was dissolved in water and the larvae were localised under a binocular microscope (Figure 1A). To keep animals immobilised 195 for imaging, but alive through the imaging sessions, we utilised three different physical 196 immobilisation techniques at different stages. **Embryo**: We created a grid with 6 chambers of 197 approximately $1mm \times 0.5mm \times 0.5mm$ on an object slide using adhesive strip. Dechorionated embryos were placed in the grid, covered with halocarbon oil 700 (Sigma) and oriented in such a way that the dorsal class IV ddaC neurons faced towards the coverslip. L1 and L2 larvae: 200 Images of L1 and L2 larvae were acquired under a custom-made object slide (Dimitrova et al., 201 2008). The metal custom object slide fitted a round coverslip onto which the larva was placed, 202 oriented and covered with halocarbon oil. A plastic net on a round plastic support was then 203 placed on top of the coverslip and fixed with screws to the metal slide. Detailed information 204 about the design is available upon request. L3 larvae: L3 larvae were physically immobilised 205

177

Dendrite growth rule

Baltruschat, Tavosanis & Cuntz

in halocarbon oil in-between an objective slide and a coverslip. Double-sided adhesive tape 206 served as spacer. On average two out of five individuals survived through all imaging steps. 207 During this procedure, development until the pupal stage was extended from typical five 208 days at $25^{\circ}C$ to about seven days in our preparation. Given the increased development time in 209 these conditions from ~ 120h to ~ 168h, embryo images were taken 18h - 19h AEL, L1 images 210 at 42h AEL, L2 at 90h AEL and L3 images 138h AEL. The measured ddaC dendrite size at 90h 211 and at 138h corresponded to our previous measures of L2 and feeding L3 animals in control 212 conditions, respectively. Images were acquired with a Leica TCS SP2 Confocal Microscope 213 (http://www.leica-microsystems.com), maintaining minimal laser intensity to reduce 214 tissue damage. To avoid issues due to larval movement, we minimised imaging time per 215 z-stack and thus chose a relatively large z-step of $2\mu m$ combined with a larger pinhole size 216 ($85 - 150\mu m$) to obtain a voxel depth of $1.7 - 2.2\mu m$. For embryos, we used a $40 \times$ oil immersion 217 objective and for all the other stages a $20 \times$ oil immersion objective. 218

Data analysis

All data analysis was performed in *Matlab* (www.mathworks.com) using our own software 220 package, the *TREES toolbox* (www.treestoolbox.org, version 1.15 and interim version, 221 Cuntz et al., 2010, 2011). A number of new TREES toolbox functions were custom-made 222 for this study and will be incorporated in the existing *TREES toolbox* with the publication 223 of this work: span_tree, scaleS_tree, scaleV_tree, theta_tree, compare_tree, ui_comp_tree, 224 theta_mc_tree, growth_tree. See below for details on the individual functions. In the fol-225 lowing italic function names with _tree suffix are *TREES toolbox* functions. All data will be 226 made available on www.NeuroMorpho.Org and all code and data will be made available on 227 www.treestoolbox.org. 228

Anatomical data of CIVda neurons

Image stacks from the confocal microscope were imported in the *TREES toolbox* and manual ²³⁰ reconstructions of all dendrites were performed individually (total amount of neurons $N = ^{231}$ 168) using the dedicated reconstruction user interface cgui_tree. During the reconstruction ²³² process we determined (1) adequate internode distances i.e. spatial resolution at which to ²³³ resample (resample_tree) the dendritic structures, (2) parameters for a diameter taper toward ²³⁴ the root (quaddiameter_tree) that best reproduced the overall diameter values of the real cells, ²³⁵ 235

Dendrite growth rule

239

(3) soma length and soma diameter values to best map soma diameters (soma_tree) *post hoc* ²³⁶ on the existing reconstructions, and (4) region codes for dendrite, soma and axon. Axon nodes ²³⁷ were discarded for the remaining analysis. ²³⁸

Classical branching statistics

A large palette of branching statistics were collected for each dendrite reconstruction separately 240 using simple combinations of TREES toolbox functions: (1) Total dendrite length L was the 241 sum of all internode lengths (len_tree), (2) number of branch points B were calculated 242 as the sum of all nodes that are branch points (B_{tree}), (3) covered surface area S was 243 calculated with a novel custom written *TREES toolbox* function span_tree that counts 1 - bins244 after morphological closing with a disc of $4\mu m$ radius of a binary matrix with 1 - bins245 at tree node locations after resampling the trees to $1\mu m$ internode distances – similarly to 246 previous work on fly lobula plate tangential cells (Cuntz et al., 2008), (4) Sholl analysis 247 (Bird and Cuntz, 2019) that calculates the number of intersections of a tree with a growing 248 circle centred on the dendrite root was done by using the dedicated TREES toolbox function 249 sholl_tree, (5) normalised Sholl analysis was done by normalising the Sholl radii to $6 \times$ the 250 mean Euclidean distance in the tree (eucl_tree) and normalising the number of intersections 251 with the integral over the Sholl intersections diagram, (6) **branch order** distributions were 252 calculated by identifying how many nodes and the overall dendritic cable length of their ²⁵³ connected segments in the tree had a given branch order (BO_tree), (7) normalised branch 254 orders were normalised to the next integer of $2.5 \times$ the mean branch order in any given 255 tree and the cable distribution was normalised to the total length of dendrite, (8) branch 256 **length** distributions were obtained by combining two *TREES* toolbox functions that calculate ²⁵⁷ the path length from each node to the root (Pvec_tree) and that dissect the trees into their 258 individual branches (dissect_tree), (9) normalised branch lengths were normalised to $3\times$ 259 the mean branch length in the tree and branch length frequency was normalised to the 260 integral over the distribution, (10) compression value distributions were calculated as the 261 ratio between Euclidean distances (eucl_tree) and the path distances (Pvec_tree) to the 262 root for all nodes, (11) the **Strahler order** distributions were calculated as the percentages of 263 dendrite length per given Strahler order (strahler_tree) (Vormberg et al., 2017), (12) branch 264 angle distributions were obtained by calculating the angles in the branching plane of each 265 branch point (angleB_tree). 266

Dendrite growth rule

Mathematical calculations for maximal space filling

Iterating over *n* and starting at n = 2 we distribute $N = n^2$ targets on a hexagonal grid ²⁶⁸ within diamond-shaped boundaries, *n* being the number of targets on an edge of the diamond ²⁶⁹ (**Figure 3A**). The targets form a space divided into equilateral triangles where neighbours are ²⁷⁰ distance *l* away from each other. If the basis of one triangle is set to be horizontal, the height ²⁷¹ of the equilateral triangle relates to *l* with $h = \frac{\sqrt{3}}{2}$ and the total surface of the diamond is: ²⁷²

$$S = h \cdot (n-1)^2 \cdot l^2.$$
 (2)

273

267

Circles of radius $\theta = \frac{l}{2}$ surrounding the targets on the hexagonal grid are packed optimally 274 and fill the surface area. It can easily be shown that the surface area covered by the circles 275 within the diamond shape follows $S' = (n - 1)^2 \times$ the surface of the circle since the four 276 corners together cover the surface of one circle, each edge point covers half of a circle and 277 each centre point covers one entire circle each, so: 278

$$S' = \frac{\pi}{4}(n-1)^2 \cdot l^2,$$
(3)

279

which corresponds to a portion of $\frac{\pi}{2\sqrt{3}} \approx 90.69\%$ of the total surface *S* (see **Equation 2**). ²⁸⁰ Combining **Equation 2** and $\theta = \frac{l}{2}$, we find that θ decreases with *N* and increases with *S* in ²⁸¹

$$\theta = \frac{h^{-\frac{1}{2}}}{2} \cdot S^{\frac{1}{2}} \cdot N^{-\frac{1}{2}} \tag{4}$$

282

Connecting the points on the grid optimally (in terms of total length of cable) yields a tree 283 with length $L = (N - 1) \cdot l$ since for each target (except the first) exactly one piece of length l 284 is required to connect it to the rest of the tree. Note that the minimum spanning tree has many 285 solutions since all the distances between neighbours are equal, being precisely l. An inherent 286 relation exists between L and θ : 287

Dendrite growth rule

$$L = 2\left(N - 1\right) \cdot \theta \tag{5}$$

288

289

Combining $L = (N - 1) \cdot l$ with $N = n^2$ and Equation 2 results in

$$L = h^{-\frac{1}{2}} \cdot S^{\frac{1}{2}} \cdot \frac{(n^2 - 1)}{(n - 1)} \approx h^{-\frac{1}{2}} \cdot S^{\frac{1}{2}} \cdot N^{\frac{1}{2}}$$
(6)

290

293

reminiscent of the power law that we described previously for planar dendritic minimum ²⁹¹ spanning trees generally (Cuntz et al., 2012) and in this case providing an upper bound. ²⁹²

Further combining Equations 6 and 4:

$$\theta \approx \frac{S}{2 \cdot h \cdot L} \tag{7}$$

294

For a 2*D* square grid, the equations are similar although the coverage $\frac{S'}{S} = \frac{\pi}{4} \approx 78.54\%$ is not 295 as good with:

$$S = (n-1)^{2} \cdot l^{2} \qquad \theta = \frac{1}{2} \cdot S^{\frac{1}{2}} \cdot N^{-\frac{1}{2}} \qquad L \approx S^{\frac{1}{2}} \cdot N^{\frac{1}{2}} \qquad \theta \approx \frac{S}{2 \cdot L}$$

297

298

299

300

while $N = n^2$, $\theta = \frac{l}{2}$, and $S' = \frac{\pi}{4} (n-1)^2 \cdot l^2$ remain unchanged.

Similarly, a 3*D* cubic grid can be constructed with:

$$V = (n-1)^3 \cdot l^3 \qquad \theta = \frac{1}{8} \cdot V^{\frac{1}{3}} \cdot N^{-\frac{1}{3}} \qquad L \approx V^{\frac{1}{3}} \cdot N^{\frac{2}{3}} \qquad \theta \approx \frac{1}{8} \cdot V^{\frac{1}{2}} \cdot L^{-\frac{1}{2}}$$

and $N = n^3$, $\theta = \frac{l}{2}$, $V' = \frac{\pi}{6} (n-1)^3 \cdot l^3$ and a poorer coverage even of $\frac{V'}{V} = \frac{\pi}{6} \approx 52.36\%$ and a ³⁰¹ $\frac{2}{3}$ power between N and L as we have shown previously for 3D cases (Cuntz et al., 2012). ³⁰²

Dendrite growth rule

Baltruschat, Tavosanis & Cuntz

Scaling of real trees

In order to compare real trees with our simple maximal space filling example, all reconstructions were scaled to the same surface area S as our reference diamond $(h \cdot 1, 000, 000 \mu m^2)$ by scaling the trees twice while measuring S (span_tree, see above) to make sure that target S is reached precisely in all cases (new *TREES toolbox* function scaleS_tree). Real trees in **Figures 3C, 4, 6, 7, and 8** were scaled in such a manner.

Space-filling measure $\frac{1}{\theta}$

A custom-written new *TREES toolbox* function theta_tree was used to calculate how space 310 filling a tree is. θ is the distance one has to move away from the tree to cover 90.69% of the 311 spanning surface of the tree, in analogy to our maximal space filling mathematical framework, 312 see above. Similarly to calculating the surface area S we calculated a binary matrix with 313 1-bins after morphological closing with a disc of $4\mu m$ radius and used the *Matlab* function 314 bwdist to calculate the distance from each bin within this spanning area and the closest bin 315 occupied by the dendritic tree. This approach would allow comparing distance distributions 316 in histograms, which for the example in **Figure 6** would yield similar results as comparing 317 single values of θ (not shown). The iterative growth process followed a slightly different 318 but equivalent approach using a Monte Carlo method since for 3D cases the binary matrices 319 would have been very large (see below). 320

Dendritic minimum spanning trees

Optimal wiring was implemented as previously described (Cuntz et al., 2007) to minimise 322 total cable length with a minimum spanning tree algorithm connecting a given set of targets. 323 Similarly here an additional cost to reduce path lengths to any target along the tree towards 324 the root of the tree was required. This second cost was weighted by the balancing factor bf, the 325 only parameter that the wiring algorithm takes: $total cost = wiring cost + bf \cdot path length cost$. 326 This method was successfully used previously (Cuntz et al., 2008, 2010) and all algorithms 327 are available in the *TREES toolbox* (www.treestoolbox.org, MST_tree). Targets were distributed uniformly in the target area and connected with the minimum spanning tree. Two 329 different configurations were used, see the following two paragraphs. 330

303

309

Dendrite growth rule

Baltruschat, Tavosanis & Cuntz

Random morphological model

To validate that real dendrites were all well represented by optimal wiring on randomly ³³² distributed targets we distributed targets randomly uniformly in the surface area of each real ³³³ dendrite one at a time (**Figure 3D**). We generated minimum spanning trees connecting as ³³⁴ many targets as required to reproduce the number of branch points *B* in the original tree and ³³⁵ matched the resulting synthetic tree surface area *S* each using the same scaling procedure ³³⁶ used for real reconstructions (see above). We then scanned the parameter *bf* of the model ³³⁷ between 0 and 1 in steps of 0.025. An error function comparing mean total length, branch ³³⁸ order, compression and path length between synthetic trees and their real counterparts yielded ³³⁹ an optimal *bf* of 0.225. The corresponding synthetic trees were then used with this *bf* value ³⁴⁰ (**Figure 3D**). For visual purposes, all synthetic trees were smoothed (smooth_tree), and a ³⁴¹ slight jitter was added (jitter_tree) that did not affect the branching statistics. ³⁴²

Scaling model

In a simplified model that reproduced the scaling behaviour of real dendrites precisely, we ³⁴⁴ distributed random targets uniformly in the diamond area of our maximal space-filling ³⁴⁵ model (**Figure 3B**). Targets were connected using the same minimum spanning tree as above ³⁴⁶ (MST_tree) with bf = 0.225 obtained from the random morphological model. These simplified ³⁴⁷ trees were used with the original surface area ($h \cdot 1,000,000\mu m^2$) for **Figures 3B**, **and 4A**. In ³⁴⁸ a simple modification of this configuration for **Figure 4B** the number of targets N (from 130 ³⁴⁹ to 1,700 in steps of 50) scaled with the side $S^{\frac{1}{2}}$ of a square area (from $67.5\mu m$ to $765.0\mu m$ in ³⁵⁰ steps of $22.5\mu m$) with an initial phase with constant branch point numbers for the embryo ³⁵¹ case (N = 130 for $S^{\frac{1}{2}} = 22.5\mu m$ and $45.0\mu m$) to simulate the phase transition. ³⁵²

Time-lapse analysis

Before registration of the branch and termination points, the morphologies of identified pairs ³⁵⁴ of dendrites (the same cell in two consecutive time steps, N = 47 pairs) we rotated, translated ³⁵⁵ and scaled them separately in both dimensions to maximise the overlap of dendritic branches. ³⁵⁶ Branch and termination points were then registered using first a custom written algorithm that ³⁵⁷ compared paths and topological order of all nodes in the two dendrites (new *TREES toolbox* ³⁵⁸ function compare_tree). The preliminary registration was then corrected by a custom-written ³⁵⁹ user interface (new *TREES toolbox* function ui_comp_tree) to associate branch and termination ³⁶⁰

331

353

Dendrite growth rule

points of both time points to one another. For the stretching analysis, the individual scaling 361 steps were ignored and the vectors were drawn between branch and termination points of 362 time points 1 and 2 for all pairs. Newly formed branches or disappearing branches were 363 ignored. For the space filling analysis, only new branches in time point 2 were considered — $_{364}$ disappearing branches were negligible --- that appeared within the confines (tight hull using 365 *Matlab* function boundary with parameter alpha = 0.5) of branch and termination points in 366 time point 1. This constraint was necessary because in some cases an entire region of the distal 367 dendrite became visible only in the time point 2 reconstruction. Values for θ , N and L were 368 calculated similarly to reconstructions in Figure 3. 369

Iterative growth model

The iterative growth model (new TREES function growth_tree) was fit to reproduce the 371 statistics of dendritic reconstructions in time point 2 given the reconstruction in time point 1 $_{372}$ as a starting point (Figure 6). The iterations were subsequently used to grow entire trees from 373 scratch. At each time point, the surface area (or spanning volume for 3D cases) was probed 374 with 25,000 random points (or 100,000 in the 3D cases). For each probe, the nearest distance 375 *eucl* to the tree was detected. The resulting distances were capped at a maximal growth range 376 radius (120 μ m) and normalised to the maximum distance. In a mixed model, the selected 377 probing point was calculated by finding the maximum of $(k \cdot R + (1 - k) \cdot eucl)$ for k the 378 amount of noise between 0 and 1 and *R* a random number between 0 and 1 for each probing 379 point. The noise parameter k was saturated using $tanh(8 \cdot k)$. In the random filling model 380 (orange, **Figure 6**) one probing point was chosen at random (k = 1). In the maximal filling ³⁸¹ model (blue, **Figure 6**) the probing point with the maximum distance was selected (k = 0). In 382 the mixed model, k was chosen as 0.45. The selected probing point was then connected to the closest point on the tree according to cable length and path length cost with a bf = 0.225. The 384 new branch was subdivided into $1\mu m$ segments and jittered slightly before the next iteration 385 started. The growth process stopped when a target L was reached, in this case, the length of $_{386}$ the tree in time point 2 or the length of the tree that was simulated. At each iteration L and N387 were stored and θ was calculated in this case as the largest value in *eucl* among the 90.69% 388 lowest values of *eucl*. 389

Dendrite growth rule

Synthetic morphologies of other planar and 3D dendrites

Five synthetic dendrites were grown from scratch using the growth_tree iterative growth ³⁹¹ model. Synthetic **mouse cerebellar Purkinje cells** (Martone et al., 2003) were obtained using ³⁹² bf = 0.6, $radius = 450\mu m$, k = 0.15; **Fly lobula plate tangential cells** (Cuntz et al., 2008) ³⁹³ were obtained using bf = 0.175, $radius = 800\mu m$, k = 0.45; **Rat dentate granule cells** (Rihn ³⁹⁴ and Claiborne, 1990) were obtained using bf = 0.935, $radius = 500\mu m$, k = 0.40; **Guinea** ³⁹⁵ **pig hippocampus pyramidal cells** (Wittner and Miles, 2007) were obtained using bf = 0.935, ³⁹⁶ $radius = 1,000\mu m$, k = 0.45; **Rat cortical layer 5 pyramidal cells** (Hay et al., 2013) were ³⁹⁷ obtained using bf = 0.75, $radius = 750\mu m$, k = 0.30.

Appendix

Figures 1–8 Overview of all reconstructions showing maximum intensity projections of the microscopy image stacks and the skeletons of all relevant reconstructions (red – dendrite, green – soma, blue – axon). The reconstructions are ordered by specimen (e.g. #9A) and by developmental stages (Embryo, Larval Instar 1–3). All reconstructions are labelled by larval segment identifiers (e.g. 3l, 4l, 5l, and 3r, 4r, 5r). The maximum intensity projections are shown for multiple tiled stacks when available. The reconstructions were not necessarily done in the shown image stack since in the overlap region of neighbouring tiled image stacks only one image can be shown.

Figures 9–12 Overview of skeletons for all individual reconstructions, scaled to cover the same surface area (contour is drawn in light grey). Soma location is shown with a large dot. Dark grey shaded area indicates the ~ 10% of the surface area that is furthest away (> θ) from the tree. Specimen number, developmental stage and segment identifier (similar to **Appendix Figures** 1–8) are shown under each reconstruction.

Figures 13–16 Overview of all pairs of reconstructions (left – time 1; right – time 2) for which the same cell was imaged at two consecutive developmental stages. Registered branch and termination points in each pair are shown with the same colour. Shaded area indicates the conserved spanning area from time 1 in the reconstruction at time 2. Differences in the spanning area can be due to occlusion in time 1 and only the new branches within the spanning area of time 1 were used for the time-lapse analysis in **Figures 5 and 6**.
