## 26 ABSTRACT

Plasmids are common in natural bacterial communities, facilitating bacterial evolution via horizontal gene transfer. Bacterial species vary in their proficiency to host plasmids: Whereas plasmids are stably maintained in some species regardless of selection for plasmid-encoded genes, in other species, even beneficial plasmids are rapidly lost. It is, however, unclear how this variation in host proficiency affects plasmid persistence in communities. Here, we test this using multispecies bacterial soil communities comprising species varying in their proficiency to host a large conjugative mercury resistance plasmid. Plasmids reached higher community-level abundance where beneficial and when introduced to the community in a more proficient host species. Proficient plasmid host species were also better able to disseminate the plasmid to a wider diversity of host species. These findings suggest that the dynamics of plasmids in natural bacterial communities depend not only upon the plasmid's attributes and the selective environment, but also upon the proficiency of their host species. 

#### 52 INTRODUCTION

53 Mobile genetic elements (MGEs) like plasmids, temperate bacteriophages, and transposons, are 54 important agents of horizontal gene transfer (HGT) driving the diversification of bacterial genomes 55 (Frost et al. 2005; Hall, Brockhurst and Harrison 2017a; Brockhurst et al. 2019). Conjugative plasmids 56 contain genes encoding core plasmid functions – including their own propagation, replication, stability 57 and transfer - along with accessory genes that encode traits like antibiotic and metal resistance 58 (Norman, Hansen and Sørensen 2009). While the plasmid's accessory genes can directly benefit the 59 host cell by providing them with new ecological functions, the plasmid's core functions can impose a 60 heavy burden on the host cell, the accessory genes can directly benefit the host cell by providing them 61 with new ecological functions (Baltrus 2013; San Millan and Maclean 2017). Mathematical models of 62 plasmid population dynamics suggest that the plasmid cost, conjugation rate, segregation rate, and the 63 strength of positive selection are key parameters determining plasmid survival in bacterial populations 64 (Stewart and Levin 1977; Levin, Stewart and Rice 1979; Simonsen et al. 1990; Bergstrom, Lipsitch and 65 Levin 2000).

66 Plasmids are expected to spread under positive selection for their encoded accessory genes (San 67 Millan et al. 2014; Harrison et al. 2015), however, because accessory genes can be captured by the 68 bacterial chromosome rendering the plasmid redundant, positive selection does not guarantee the long-69 term survival of plasmids (Bergstrom, Lipsitch and Levin 2000). Meanwhile, in the absence of positive 70 selection, plasmids are expected to go extinct due to purifying selection because the benefits of 71 accessory genes do not outweigh the costs of plasmid carriage (Bergstrom, Lipsitch and Levin 2000). 72 Since rates of conjugation appear to often be too low for plasmids to persist as infectious elements 73 (although see: Lopatkin et al. (2017) and Stevenson et al. (2017)), it has been argued that the widespread 74 distribution of plasmids is paradoxical (the plasmid paradox: Harrison and Brockhurst (2012)). Yet, 75 plasmids have been found to stably persist in natural bacterial communities in the absence of measurable 76 positive selection, where the factors allowing plasmid stability are puzzling (Heuer and Smalla 2012).

Most studies of plasmid dynamics focus on a single-host species, whereas, in natural bacterial
 communities, many potential host species co-exist, potentially broadening the range of conditions under

which plasmids can survive. This limitation of current understanding is particularly interesting
considering that several studies have shown that plasmids are not equally stable across host species (De
Gelder *et al.* 2007; Kottara *et al.* 2018; Sakuda *et al.* 2018). For example, while the mercury resistance
plasmid pQBR103 was highly stable for >400 generations with or without mercury selection in *P. fluorescens* and *P. savastanoi*, it was unstable to varying degrees in *P. stutzeri* (generally lost within
~100-400 generations), *P. aeruginosa* and *P. putida* (<6 generations) even with strong mercury</li>
selection (Kottara *et al.* 2018).

86 Hall et al. (2016) showed, by tracking the dynamics of the mercury resistance plasmid pQBR57 87 in a two-species soil community of P. fluorescens and P. putida, that between-species transfer of the 88 plasmid from a proficient host, P. fluorescens, to an unstable host, P. putida, allowed the plasmid to 89 persist in P. putida both with and without mercury selection. This finding suggests that the dynamics 90 of a plasmid in a bacterial community is likely to depend on the proficiency of the plasmid host species 91 to stably maintain the plasmid. This leads to the prediction that, at the community-level, plasmid 92 abundance will be higher in communities where it is carried by a proficient original plasmid host, since 93 this species will both be able to maintain the plasmid in its own population, and then disseminate the plasmid to other species in the community. 94

95 To test this prediction, we tracked the dynamics of pQBR103 in a three-species community of 96 P. fluorescens, P. stutzeri and P. putida with and without mercury selection. We varied which of the 97 species carried the plasmid at the start of the experiment. We hypothesised that the community-level 98 plasmid abundance would vary according to the proficiency of the original plasmid host species to act 99 as hosts to pQBR103, which varies hierarchically -P. fluorescens > P. stutzeri > P. putida (Kottara et 100 al. 2018). Replicate communities were propagated in effectively sterile potting soil microcosms, which 101 provide spatial structure and a low resource environment that more closely resemble the natural physical 102 and chemical conditions in soil and promote the stable co-existence of multiple bacterial species 103 (Gómez and Buckling 2011; Heuer and Smalla 2012; Hall et al. 2015; Hall et al. 2016).

104

#### 105 MATERIALS AND METHODS

#### 106 Bacterial strains and plasmid

107 Three Pseudomonas species - P. fluorescens SBW25 (Rainey, Bailey and Thompson 1994), P. stutzeri JM300 (DSM 10701) (Busquets et al. 2012) and P. putida KT2440 (Bagdasarian et al. 1981) - were 108 109 utilised in this study. Pseudomonas species were labelled by directed insertion of either streptomycin (Sm<sup>R</sup>) or gentamicin resistance (Gm<sup>R</sup>) marker using the mini-Tn7 transposon system (Lambertsen, 110 Sternberg and Molin 2004). The plasmid used in this study, pQBR103 is a large conjugative plasmid 111 112 (425 kb) that confers mercury resistance via a mer operon encoded on a Tn5042 transposon (Lilley et al. 1996; Tett et al. 2007). pQBR103 plasmid is part of a group of 136 plasmids that were isolated from 113 114 the bacterial community inhabiting the sugar beet rhizosphere and phyllosphere during a long-term field experiment (Lilley et al. 1996). pQBR103 was acquired by conjugation into labelled strain of P. 115 *fluorescens* that was introduced onto the naturally occurring bacterial community colonising the sugar 116 beet rhizosphere with the primary plasmid-host remaining unknown (Lilley et al. 1996). To obtain the 117 118 initial plasmid-bearing clones of each host species to start the selection experiment, pQBR103 plasmid was conjugated into P. stutzeri Gm<sup>R</sup>, P. putida Sm<sup>R</sup> and P. fluorescens Sm<sup>R</sup>lacZ from the plasmid-119 bearing *P. fluorescens* SBW25 Sm<sup>R</sup> or Gm<sup>R</sup> stocks. Plasmid conjugation was performed by mixing 1:1 120 each of the plasmid-free with the plasmid-bearing strains, incubating for 48 h and spreading on King's 121 B growth (KB) agar plates containing 5 µg mL<sup>-1</sup> gentamicin or 50 µg mL<sup>-1</sup> streptomycin (50 µg mL<sup>-1</sup> 122 X-Gal) and 20 µM of mercury(II) chloride to select for transconjugant colonies (Simonsen et al. 1990). 123 The conjugation assays were conducted in 6 mL KB medium in 30 mL universal vials ('microcosms') 124 125 at 28°C in shaking conditions (180 rpm).

126

#### 127 Selection experiment

To account for the high segregation rate of the plasmid in *P. putida* KT2440 (Kottara *et al.* 2018) and to ensure high starting frequencies of plasmid carriage across all the tested bacterial strains, single colonies of each plasmid-bearing species were reconditioned overnight and then transferred in fresh media containing mercury. Specifically, individual colonies (n=12) of each plasmid-bearing *Pseudomonas* species were picked into separate 6 mL KB microcosms and incubated overnight at 28°C with shaking 180 rpm after which time 1% of each population was transferred to grow for 24 h in fresh
KB microcosms containing 50 µM of mercury(II) chloride at same temperature and shaking conditions;
this concentration of mercury was used to select for the pQBR103 plasmid based on previous findings
(Kottara *et al.* 2018). Similarly, 24 colonies of each plasmid-free *Pseudomonas* species were each
grown overnight in KB 6 mL microcosms and transferred to grow for 24 h in fresh KB microcosms at
same temperature and shaking conditions.

139

## 140 Bacterial communities

We used soil microcosms to evolve three different bacterial communities differing by which species carried the plasmid at the beginning of the experiment (original plasmid host). To prepare the soil microcosms, we added 10 g of John Innes No. 2 compost soil in 30 mL universal vials which we autoclaved twice. By autoclaving the compost soil two times, we established an effectively sterile micro-environment with the physical and chemical properties of soil which did not contain other culturable bacteria than our inoculum (Gómez and Buckling 2010; Hall *et al.* 2015; Hall *et al.* 2016).

147 Three different bacterial communities were then constructed: P. fluorescens (carrying pQBR103) with 148 P. stutzeri and P. putida; P. fluorescens with P. stutzeri (pQBR103) and P. putida; P. fluorescens with 149 P. stutzeri and P. putida (pQBR103). Six replicates of each community were grown either without mercury or with mercury (16  $\mu$ g g<sup>-1</sup> Hg(II)); this concentration of mercury was used to select for the 150 pQBR103 plasmid while could allow the survival of the plasmid-free species based on previous findings 151 152 (Hall et al. 2015). Each community had a starting ratio of 1:1:1 of each Pseudomonas species such that 153 the starting frequency of pQBR103 in the community was approximately 33%. To remove spent media 154 and residual mercury from overnight cultures each inoculum was briefly vortexed, then centrifuged for 155 1 min at 10,000 rpm and resuspended in 1 mL M9 salt solution (Cold Spring Harbor Protocols). 100 µL 156 was then inoculated into soil microcosms and incubated at 28°C at 80% humidity (Hall et al. 2016).

157

## 158 Serial transfers and bacterial counts

Every 4 days, 10 mL of M9 buffer and 20 glass beads were added to each soil microcosm and mixed
by vortexing for 1 min, and 100 μL of soil wash was transferred to a fresh soil microcosm as previously

described by Hall *et al.* (2016). Bacterial counts for each species were estimated by plating onto
selective media: 50 µg mL<sup>-1</sup> streptomycin + 50 µg mL<sup>-1</sup> X-Gal KB agar plates and 5 µg mL<sup>-1</sup> gentamicin
KB agar plates, each of which was then replica plated onto mercury KB agar plates (100 µM mercury(II)
chloride). The bacterial communities were evolved for 10 transfers (~40 days).

- 165
- 166 Plasmid and mercury-transposon screening

167 Twenty-four mercury-resistant colonies of each *Pseudomonas* species were sampled every 2 transfers
168 from the mercury containing plates and tested for the presence of the plasmid and mercury transposon
169 by PCR screening. The PCR used the same sets of primers as previously described [*mer* operon on the
170 Tn*5042* transposon – forward primer: TGCAAGACACCCCCTATTGGAC, reverse primer:
171 TTCGGCGACCAGCTTGATGAAC and origin of replication of the plasmid (*ori*V) – forward primer:
172 TGCCTAATCGTGTGTAATGTC, reverse primer: ACTCTGGCCTGCAAGTTTC] (Harrison *et al.*173 2015; Kottara *et al.* 2018).

174

#### 175 Statistics

176 Statistical analyses were performed using RStudio version 3.2.3 (R Core Team 2013). Shapiro-Wilk 177 test, normal O-O plots, histograms and box-plots were used to examine the normality of the data. We 178 found that in most cases the data were not normally distributed, and in such cases used a non-parametric 179 test. Cumulative plasmid abundance in each community over time was estimated as the area under the 180 curve using the function auc of the package 'flux' (Jurasinski, Koebsch and Hagemann 2012). Community-level plasmid abundances in the plasmid host treatments were compared by using the 181 182 Kruskal-Wallis test. To assess the plasmid-dynamics within each species, we compared plasmid 183 frequencies in the plasmid-recipient species population as the area under the curve. The integral 184 estimates of the plasmid frequency in the recipient species were compared between the mercury 185 conditions using the Kruskal-Wallis test. To assess the timing of chromosomal acquisition of the 186 mercury transposon Tn5042 in P. putida differed between the plasmid host treatments, for each 187 population we recorded the transfer number when we first observed plasmid-free transposon-containing genotypes of *P. putida*. We compared these values between the plasmid host treatments using the Kruskal-Wallis test. The species diversity of plasmid-carriers was calculated as the 1 - D Simpson's Index, 1-  $\left[\sum = \left(\frac{n}{N}\right)^2\right]$  where, n = the end-point population density of each plasmid-bearer species in community, and, N = the end-point population density of all plasmid-bearer species. We compared diversities between the plasmid host treatments and mercury conditions by using the Kruskal-Wallis test.

194

195 RESULTS

## 196 Original plasmid host species identity affects community-level plasmid abundance

197 The bacterial host species vary in their ability to stably maintain pOBR103 hierarchically as follows: 198 *P. fluorescens* > *P. stutzeri* > *P. putida* (Kottara *et al.* 2018). We hypothesised therefore that the identity 199 of the original plasmid host in a community is likely to affect the dynamics of the plasmid-encoded 200 mercury resistance at the community-level. To test this, we quantified the total plasmid abundance in 201 each community (Figure 1). Mercury selection increased total plasmid abundance (effect of mercury; 202  $\chi^2(1, N=24)=17.28$ , p=3.226e-05) and total plasmid abundance varied with original plasmid host identity, such that both with (effect of plasmid treatment;  $\chi^2(2, N=18)=11.556$ , p=0.003) and without 203 (effect of plasmid treatment;  $\chi^2(2, N=18)=11.474$ , p=0.003) mercury selection, the total plasmid 204 abundance was higher when the original plasmid host was P. fluorescens. Together these data suggest 205 206 that community-level plasmid dynamics are affected by both the positive selection for plasmid-encoded 207 traits and the identity of the original plasmid host species, being enhanced when plasmids are beneficial 208 and carried by a proficient plasmid host.

209

## 210 Species-level plasmid dynamics within communities

To understand how the variation in community-level plasmid abundance was driven by original plasmid
host identity, we next examined the species-level plasmid dynamics in each community. As predicted,
when a proficient plasmid-host – *P. fluorescens* – was the original plasmid host it maintained the
plasmid at high frequency within its population both with and without mercury (Figure 2). We detected

215 plasmid dissemination from *P. fluorescens* to the other species at higher frequencies under mercury 216 selection (effect of mercury;  $\chi^2(1, N=24)=4.653$ , p=0.030). This occurred to *P. putida* in all replicates 217 and to P. stutzeri in 2/6 replicates with mercury selection and also to P. stutzeri at low levels in some 218 of the communities without mercury selection. When P. stutzeri was the original plasmid host, it also 219 maintained the plasmid within its own population both with and without mercury, and disseminated plasmids to the other species at a higher rate with mercury (effect of mercury;  $\chi^2(1, N=24)=11.644$ , 220 221 p=0.0006) (Figure 3). Variation in total plasmid abundance between replicate communities in this 222 treatment appear to have been caused by whether or not P. fluorescens acquired the plasmid before it 223 was driven extinct by toxic mercury: where transmission to P. fluorescens occurred, total plasmid 224 abundances were higher (Figure 3). Where P. putida was the original plasmid host, it did not maintain 225 the plasmid within its own population: without mercury, the plasmid was simply lost, whereas, with 226 mercury, plasmid-bearers were replaced by mutants that had inserted the Tn5042 encoding the mer 227 operon into their chromosome (Figure 4). Chromosomal insertions of the Tn5042 in P. putida were 228 observed in the other plasmid host treatments, but arose much later in these communities where P. 229 putida had to acquire the plasmid horizontally from either P. fluorescens or P. stuzeri (effect of treatment;  $\chi^2(2, N=18)=10.947$ , p= 0.004). Although P. putida eventually lost the plasmid from its 230 231 own population, prior to this loss it successfully disseminated the plasmid to P. fluorescens in 6/6 232 replicates and to *P. stutzeri* in 3/6 replicates with mercury selection (Figure 4).

233

## 234 Diversity of plasmid-carriers in communities

Finally, we tested how the original plasmid host identity affected the diversity of plasmid-carriers at the end of the experiment. The diversity of plasmid-carriers was affected by both the original plasmid host species identity (effect of plasmid treatment;  $\chi^2(2, N=36)=12.819$ , p=0.001) and mercury selection (effect of mercury;  $\chi^2(1, N=36)=6.082$ , p=0.013) (Figure 5). Without mercury selection the diversity of plasmid-carriers was highest when *P. stutzeri* was the original plasmid host. Whereas, with mercury selection, the diversity of plasmid-carriers was higher in communities where *P. fluorescens* or *P. stutzeri* were the original plasmid hosts compared to communities where *P. putida* was the original

plasmid host. Consistent with our data on community-level plasmid abundance, these data show that
the diversity of plasmid-carriers is likely to be higher when plasmids are beneficial and are introduced
to the community by proficient plasmid hosts.

245

#### 246 DISCUSSION

247 In natural microbial communities, broad host range plasmids are frequently transmitted to diverse host 248 species thus highlighting the importance of plasmids in HGT and their role in the spread of resistance 249 genes in the environment (Klümper et al. 2015). In this study, we aimed to understand the extent to 250 which plasmid dynamics in a bacterial community are affected by the original plasmid host species 251 identity within that community. Our findings suggest that plasmid abundance at the community-level 252 was driven by the identity of the original plasmid host species. We observed that pQBR103 reached 253 higher community-level abundance when hosted by a proficient plasmid-host, P. fluorescens. Dionisio 254 et al. (2002) have previously shown the importance of species identity in shaping the plasmid dynamics 255 in a community. This was further described by Hall et al. (2016) where a proficient plasmid-host could 256 act as a source of the plasmid for a non-proficient host species in a two-species soil community. These 257 plasmid dynamics were explained in terms of conjugative plasmids persisting in the community as 258 infectious agents via interspecies transfer (Bahl, Hansen and Sørensen 2007). Here, we extend these 259 results to a more complex three-species community, a different plasmid, and a wider range of plasmid 260 host species and proficiencies.

261 The community-level plasmid abundance also varied according to mercury selection. In common with previous studies (Cairns et al. 2018), plasmids were observed at higher frequencies in 262 263 recipient species in the presence versus absence of positive selection. Detecting HGT events is more 264 likely under positive selection, because, while individual conjugation events may be rare, positively 265 selected horizontally acquired genes will rise to high frequency due to clonal expansion. This has led 266 to a generally accepted, but probably incorrect view, that HGT is accelerated under positive selection 267 (Aminov 2011; Fletcher 2015). By contrast, recent experimental data shows that horizontal transmission plays a more important role in plasmid stability in the absence of positive selection 268

269 (Stevenson et al. 2017), leading to higher rates of gene mobilisation and transfer in these environments 270 (Hall et al. 2017b). Mercury selection also drove the invasion of P. putida mutants that had lost the 271 plasmid but captured the Tn5042 carrying the mercury resistance operon to the chromosome, an 272 outcome rarely observed in the other host species. This confirms our previous data that the rate and/or 273 propensity for transposition of traits from the plasmid to the chromosome is variable among 274 Pseudomonas species (Kottara et al. 2018). We show here that the dynamics of this process are affected 275 by the community context, specifically whether or not P. putida was the original plasmid host. 276 Chromosomal capture of mercury resistance transposon in P. putida occurred earlier when it began the 277 experiment with the plasmid, reflecting that transposition is random mutational event and thus more 278 likely to occur in larger – plasmid-bearing – populations. Interestingly, however, our data also show 279 that even low proficiency plasmid hosts, which rapidly capture useful traits and jettison the plasmid, 280 can act as a source of plasmids for other species in community by transferring the plasmid to more 281 proficient host species before it is lost.

282 In contrast to the study of Hall et al. (2016), which used a highly conjugative plasmid, pQBR57, 283 the plasmid used here, pQBR103, has >1000-fold lower conjugation rate ( $\gamma$ ) (Log<sub>10</sub>( $\gamma$ ) pQBR103= ~ -284 13.8,  $Log_{10}(\gamma)$  pQBR57= ~ -10.8; Hall *et al.* 2015). While previous studies of pQBR103 have focused 285 on the importance compensatory evolution in its longer-term stability (Harrison et al. 2015), here we 286 show an effect of between species conjugation increasing the community-level abundance of the 287 plasmid. The role for interspecific conjugation in pQBR103 stability was most notable in communities 288 where it was initially carried by a non-proficient original plasmid host, P. putida. Here, while the 289 plasmid started in ~33% of the population and went extinct in the *P. putida* population, it survived in 290 the community by horizontal transmission, most commonly into P. fluorescens. Through interspecific 291 conjugation, pQBR103 increased the diversity of plasmid-carriers in communities, especially under 292 mercury selection. However, this effect depended upon the original plasmid host species identity. 293 Conjugation also depends on the population density, and in this case the higher population density of 294 P. fluorescens could have enabled the plasmid transfer from P. fluorescens. Surprisingly, although with 295 mercury selection more proficient plasmid host species (i.e. P. fluorescens and P. stutzeri) allowed 296 higher diversities of plasmid-carriers, without mercury it was in communities where the moderately

297 proficient plasmid host, *P. stutzeri*, was original plasmid host where the highest plasmid-carrier 298 diversity was observed. This effect is likely to have been caused by the more equitable distribution of 299 plasmid carriage in these communities, and specifically by higher rates of plasmid carriage in *P. stutzeri* 300 itself compared to communities where this species had to obtain the plasmid via conjugation.

301 Soil microbial communities are highly diverse, which is thought to play a key role in their function (Torsvik and Øvreås 2002) and species diversity has been suggested to play a role in the 302 303 dissemination of conjugative plasmids (Dionisio et al. 2002). Soil habitats are often characterised as 304 hot spots for HGT (van Elsas and Bailey 2002; Sørensen et al. 2005) due to the spatially structured 305 nature of such environments (Bahl, Hansen and Sørensen 2007; Fox et al. 2008; Røder et al. 2013). 306 Here, we show that the identity of original plasmid host species determines the community-level 307 abundance of conjugative plasmids in soil bacterial communities. Proficient plasmid hosts better 308 maintain plasmids within their own population and transmit these plasmids to other species in the 309 community. This implies that proficient plasmid host species could promote the robustness of 310 communities by spreading potentially adaptive genes to more diverse species, allowing their survival 311 upon environmental deterioration in the future.

## 1 Figure Legends

Figure 1. Total plasmid density in the community throughout the selection experiment. Panels data for
communities that varied in mercury selection (without mercury, left-hand set; with mercury, right-hand
set) their initial original plasmid host (from left to right in each set: *P. fluorescens*, *P. stutzeri* or *P. putida*). Brown shaded area shows the mean plasmid abundance in the community ± standard error
(dotted line) from six replicates. Solid lines show the mean total community bacterial density from six
replicates.

8

Figure 2. Population density and mobile genetic element dynamics in communities where *P*. *fluorescens* was the original plasmid host. A-F clonal populations evolving with or without mercury.
Lines show the population densities of *P. fluorescens* (blue); *P. stutzeri* (red); *P. putida* (green). Brown
areas show the density of plasmid carriers; Grey areas show the density of cells that have retained the
Tn5042 but lost the plasmid.

14

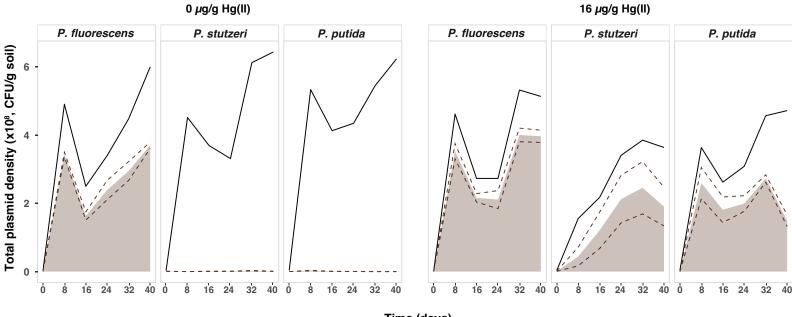

Figure 3. Population density and mobile genetic element dynamics in communities where *P. stutzeri* was the original plasmid host. A-F clonal populations evolving with or without mercury. Lines show the population densities of *P. fluorescens* (blue); *P. stutzeri* (red); *P. putida* (green). Brown areas show the density of plasmid carriers; Grey areas show the density of cells that have retained the Tn5042 but lost the plasmid.

20

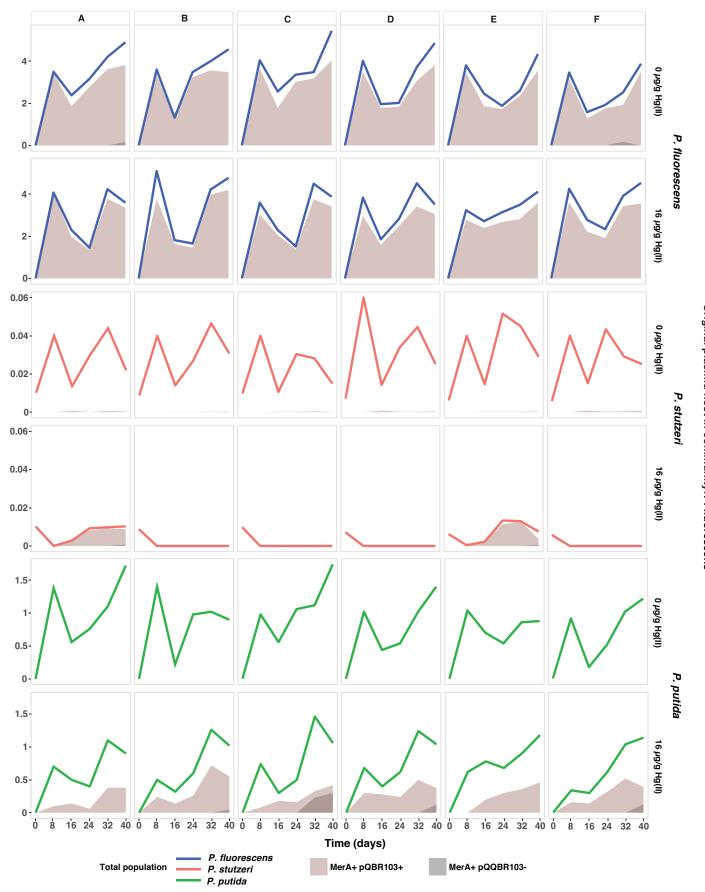

Figure 4. Population density and mobile genetic element dynamics in communities where *P. putida* was the original plasmid host. A-F clonal populations evolving with or without mercury. Lines show the population densities of *P. fluorescens* (blue); *P. stutzeri* (red); *P. putida* (green). Brown areas show the density of plasmid carriers; Grey areas show the density of cells that have retained the Tn5042 but lost the plasmid.

26

Figure 5. Diversity of plasmid-carriers at the end of the experiment. Species diversity was calculated
as the 1-D Simpson's Index by using the end-point population densities of the plasmid-carriers in each
species in each original plasmid host community.

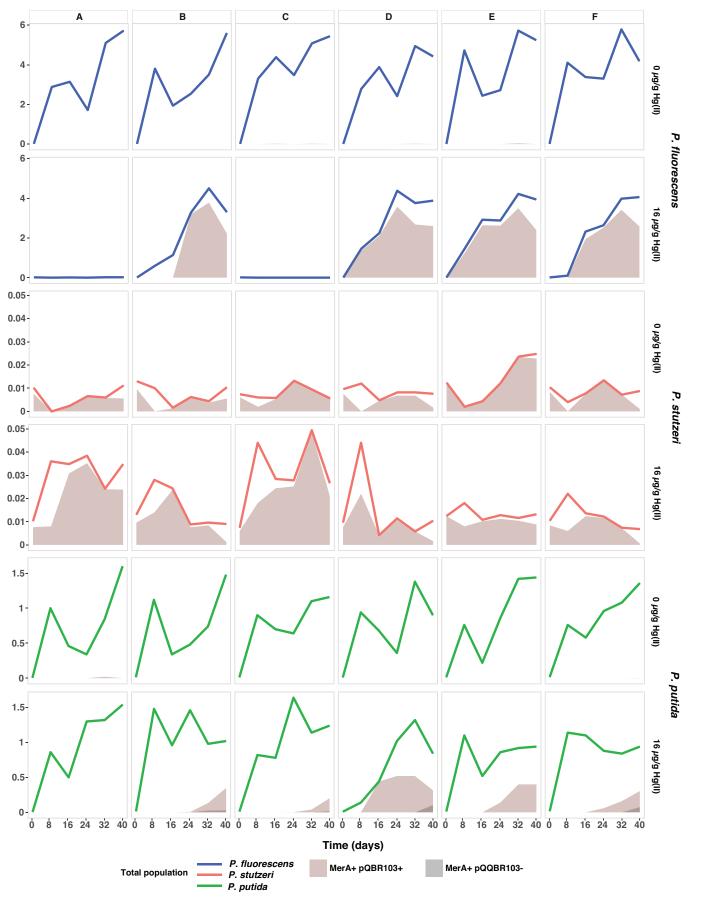

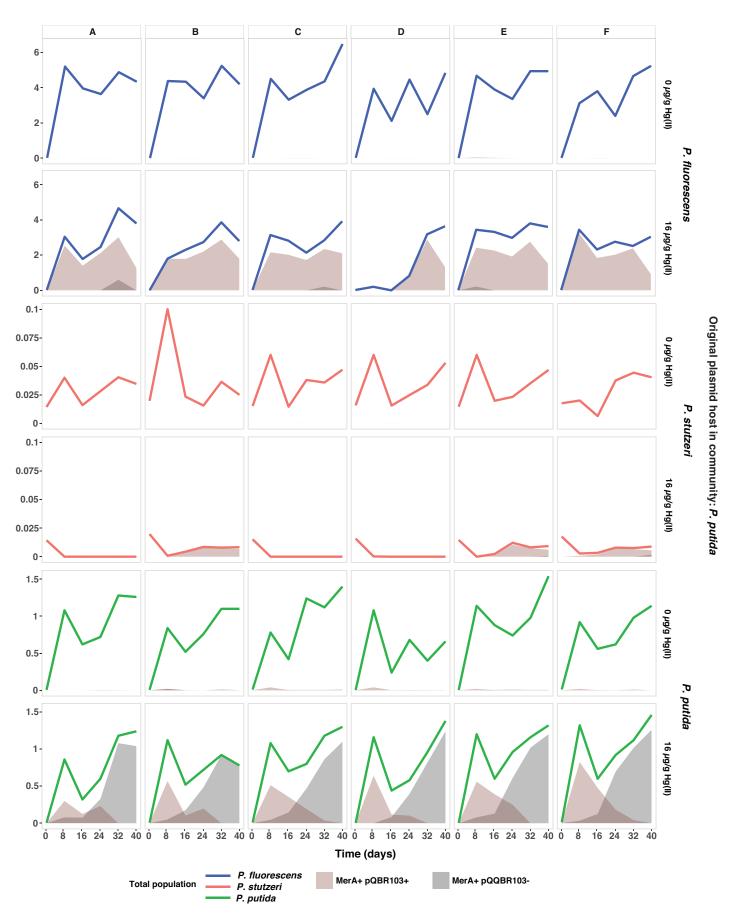

Density (x10<sup>8</sup>, CFU/g soil)

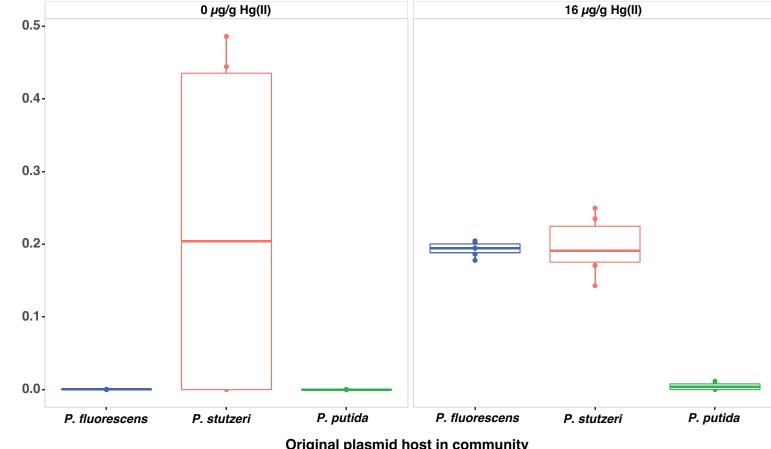

Original plasmid host in community: P. fluorescens

Density (x10<sup>8</sup>, CFU/g soil)

Original plasmid host in community: P. stutzeri

1-D Simpson's Index

Original plasmid host in community
