11 Abstract

12 Respiratory complex I is a multi-subunit membrane protein complex that reversibly couples

13 NADH oxidation and ubiquinone reduction with proton translocation against trans-membrane

14 potential. Complex I from *Escherichia coli* is among the best functionally characterized

15 complexes, but its structure remains unknown, hindering further mechanistic studies to

16 understand the enzyme coupling mechanism. Here we describe the single particle cryo-

17 electron microscopy (cryo-EM) structure of the entire catalytically active *E. coli* complex I

18 reconstituted into lipid nanodiscs. The structure of this mesophilic bacterial complex I

19 displays highly dynamic connection between the peripheral and membrane domains. The

20 peripheral domain assembly is stabilized by unique terminal extensions and an insertion loop.

21 The membrane domain structure reveals novel dynamic features. Unusual conformation of the

22 conserved interface between the cytoplasmic and membrane domains suggests an uncoupled

23 conformation of the complex. Based on these structural data we suggest a new simple and

24 testable coupling mechanism for the molecular machine.

25

Introduction

Complex I, NADH:ubiquinone oxidoreductase, is a multi-subunit enzyme found in many bacteria and most eukaryotes. It facilitates transfer of two electrons from NADH to ubiquinone, or its analogues, coupled reversibly with translocation of four protons across the membrane against trans-membrane potential (Galkin et al., 2006; Sazanov, 2015). Structures of the complete complex I from several eukaryotes (Fiedorczuk et al., 2016; Hunte et al., 2010; Kampjut and Sazanov, 2020; Zhu et al., 2016), one thermophilic bacterium (Baradaran et al., 2013), and the partial structure of the membrane domain of *Escherichia coli* complex I (Efremov and Sazanov, 2011), have been determined.

The composition of complex I differs significantly between species. Mitochondrial complex I has molecular weight 1 MDa and comprises more than 35 subunits (Wirth et al., 2016) whereas bacterial analogues are much smaller with molecular weights approximately 500 kDa. Complex I from all characterized species contains homologues of 14 core subunits; seven subunits each assemble into peripheral and membrane arms, joined at their tips and form the complex with a characteristic L-shape.

The peripheral arm, exposed to the cytoplasm in bacteria or the mitochondrial matrix in eukaryotes, contains binding sites for NADH, ubiquinone, and flavin mononucleotide (FMN) as well as eight or nine iron-sulfur clusters, seven of which connect the NADH and ubiquinone-binding sites (Sazanov, 2015) enabling rapid electron transfer (Verkhovskaya et al., 2008) .

The membrane-embedded arm includes a chain of three antiporter-like subunits, NuoL, NuoM, and NuoN (*E. coli* nomenclature is used for the subunits hereafter) (Efremov and Sazanov, 2011), which are also found in the Mrp family of multisubunit H^+/Na antiporters (Steiner and Sazanov, 2020). Each antiporter-like subunit contains two structural repeats comprising five trans-membrane helices (TMH, TMH4-8, and TMH9-13). TMH7 and

51 TMH12 are interrupted by an extended loop in the middle of the membrane and the helix

52 TM8 at the interface between symmetric motifs is interrupted by the π-bulge (Baradaran et

53 al., 2013; Efremov and Sazanov, 2011). Membrane-embedded NuoH mediates interaction

54 with the peripheral arm and also contains five-helix structural repeats found in antiporter-like

55 subunits (Baradaran et al., 2013). Together with subunits NuoB and NuoD it forms an

56 extended ubiquinone-binding cavity (Q-cavity) spanning the membrane bilayer hydrophobic

57 region to the ubiquinone-binding site (Q-site) in the proximity of the terminal iron-sulfur

58 cluster N2 (Baradaran et al., 2013).

59 The membrane arm features a continuous chain of conserved and functionally important

60 ionizable residues positioned in the middle of the membrane. These are suggested to be

61 involved in proton translocation and its coupling to electron transfer (Baradaran et al., 2013;

62 Efremov and Sazanov, 2011). Attempts to visualize conformational changes in the membrane

63 domain (Kampjut and Sazanov, 2020; Parey et al., 2018) have revealed rotation of the

64 cytoplasmic half of TMH3 of NuoJ in mammalian complex I (Agip et al., 2018) and were

65 associated with active-deactive transition. Recently, proton translocation mechanisms without

66 conformational changes in antiporter-like subunits were suggested (Kampjut and Sazanov,

67 2020; Steiner and Sazanov, 2020). However, all proposed coupling mechanisms remain

68 largely speculative and require further validation by functional, biochemical, and structural

69 methods.

70 *E. coli* complex I is among the best functionally characterized complex I. It has been studied

71 using many biophysical and biochemical techniques (Verkhovskaya and Bloch, 2012).

72 Combined with the possibility of fast and extensive mutagenesis (Pohl et al., 2007;

73 Verkhovskaya and Bloch, 2012), it represents a highly attractive system to study the coupling

74 mechanism. However, owing to its fragile and dynamic nature (Verkhovskaya and Bloch,

75   2012), high-resolution structures of this complex remain limited to a partial structure of the

76   membrane domain (Efremov and Sazanov, 2011).

77   Here we present a single particle cryo-EM structure of the entire *E. coli* complex I

78   reconstituted into lipid nanodiscs, with the peripheral arm structure solved at 2.1 Å resolution

79   and that of the membrane domain at 3.7 Å.

Results

Overall structure

83   Twin-strep tag was added to genomically encoded subunit NuoF using a CRISPR-Cas9 based

84   system (Jiang et al., 2015) (Figure 1 - figure supplement 1). This enabled single-step

85   purification of solubilized complex (Figure 1 - figure supplement 2A), which was further

86   reconstituted into lipid nanodiscs comprising *E. coli* polar lipids and membrane scaffold

87   protein MSP2N2 (Grinkova et al., 2010) (Figure 1 - figure supplement 2A,B). Mass

88   photometry indicated that reconstituted complex I was homogeneous and monodispersed

89   (Figure 1 - figure supplement 2C,D).

90   NADH:potassium ferricyanide (FeCy) and NADH:ubiquinone-1 (Q1) activities of the

91   reconstituted complex I (Figure 1 - figure supplement 2E,F) were similar to those of

92   detergent-purified protein supplemented with native *E. coli* lipids (Sazanov, 2003).

93   Furthermore, NADH:Q1 activity was completely inhibited by piericidin-A (Figure 1 - figure

94   supplement 2F) indicating that complex I reconstituted in lipid nanodiscs was intact and

95   catalytically active in a detergent-free environment.

96   We determined the single particle cryo-EM structure of the reconstituted complex (Figure 1,

97   Figure 1 - figure supplement 3,4, Table 1, Movie 1). Multiple conformations of the complex

98   that differed by relative positions of the peripheral and membrane arms were revealed by 3D

99   classification (Figure 1 - figure supplement 4,5). Three conformations of the entire complex

100   were reconstituted to average resolutions between 3.3 and 3.7 Å (Figure 1 - figure

4

101   supplement 4) resolving the interface between the arms; however, due to high-residual

102   mobility of the arms, the antiporter-like subunits were resolved at below 8 Å (Figure 1 -

103   figure supplement 4).

104   Focused refinement of each arm separately and subtraction of nanodisc density (Figure 1 -

105   figure supplement 3) improved the resolution of peripheral and membrane arms to 2.7 Å and

106   3.7 Å, respectively (Figure 1 - figure supplement 3,4, Table 1).

107   Micrograph analysis, in contrast to mass photometry, revealed that large fraction of the

108   particles corresponds to the peripheral arm only (Figure 1 - figure supplement 3) that may

109   have dissociated during cryo-EM sample preparation. These yielded 3D reconstruction to 2.8

110   Å resolution (Figure 1 - figure supplement 3), similar to the map of the peripheral arm of

111   intact complex I. Joining two subsets improved resolution of the peripheral arm to 2.1 Å

112   (Table 1, Figure 1 - figure supplement 4). Using the resulting maps, an atomic model of the

113   entire *E. coli* complex I was built, comprising 4618 residues and accounting for 94.7% of the

114   total polypeptide constituting the complex (Table 2).

115   Arrangement of the arms and individual core subunits in *E. coli* complex I is very similar to

116   that of *Thermus thermophilus* (RMSD 6.3 Å over 2593 Cα atoms, 4.0 Å membrane arm over

117   1604 atoms, and 2.2 Å for peripheral arm 855 Cα) and mammalian enzyme (8.3 Å over 2420

118   Cα atoms (3.8 Å MD 1710 atoms, PD 2.0 767 Cα)) (Figure 1B) apart from the relative long-

119   range twisting and bending of arms observed between complex I from different species

120   (Baradaran et al., 2013; Vinothkumar et al., 2014).

121   Comparison of *E. coli* complex I conformations reconstructed to better than 4 Å resolution

122   revealed two modes of relative arm rotation (Figure 1C): 1) rotation around an axis that

123   passes through the NuoH-NuoB interface and is tilted around 45 degrees out of the plane

124   formed by the arms with an amplitude of at least 13 degrees, and 2) rotation around an axis

125   parallel to the membrane and roughly perpendicular to the long axis of the membrane arm

126   with an amplitude of approximately 4 degrees. Although relative arm movements were

127   observed in mammalian (Kampjut and Sazanov, 2020; Zhu et al., 2016) and *T. thermophilus*

128   complex I (Gutiérrez-Fernández et al., 2020), their amplitudes were smaller and movement

129   directionality was less diverse. Despite significant relative arm movements, the structure of

130   each arm was rigid and did not reveal different conformations apart from the specific local

131   dynamics discussed below.

132   Structure of the peripheral arm

133   Architecture of the peripheral arm reveals a novel evolutionary strategy to stabilize the

134   subcomplex

135   At an average resolution of 2.1 Å with the local resolution in the core reaching 2.0 Å (Figure

136   1 - figure supplement 4) conformations of most side chains in the peripheral arm, positions of

137   ions, and multiple water molecules were resolved unambiguously (Figure 2, Figure 1 - figure

138   supplement 6).

139   The overall architecture of the conserved core of the peripheral arm subunits is very similar to

140   other homologues. Unlike other structurally characterized homologues, *E. coli* subunits NuoC

141   and NuoD are joined in a single polypeptide. The 35 amino acid-long linker includes an α-

142   helix (residues 180-194) that interacts with subunit NuoB (Figure 2A). The relative positions

143   of all redox centers with FMN and nine iron-sulfur clusters, including off path cluster N7

144   (Sazanov, 2006), are particularly well conserved (Figure 2C).

145   A distinctive feature of the *E. coli* peripheral arm is the presence of ordered C-terminal

146   extensions in subunits NuoB, NuoI, and NuoF with a length of 22 to 45 residues and a large

147   94 residue insertion loop in subunit NuoG, referred to as the G-loop (Figure 2A, Table 3).

148   These extensions are unique among structurally characterized complex I homologues and

149   have a well-defined structure. While the G-loop has a compact fold, the conformation of the

150   C-terminal tails is extended. They line the surface of the conserved fold of the peripheral arm

151 with high shape complementarity (Figure 2A, Figure 2 - figure supplement 1). Apart from a

152 few helical turns, these extensions have no secondary structure elements (Table 3). They

153 create additional inter-subunit contacts with some surface areas exceeding 1,000 Å^2 and

154 involving polar interactions (Table 3). Similarly, the G-loop fills a crevice between NuoCD,

155 NuoI, and NuoG subunits (Figure 2A). Together the extensions and G-loop increase the

156 interaction surface between the electron acceptor module (NuoEFG) and connecting module

157 (NuoICDB) by a factor of three (from 1400 to 4600 Å^2), thus stabilizing the peripheral arm

158 assembly. These structural features are conserved within the Enterobacteriaceae family and

159 are very common in the phylum Gammaproteobacteria. They display high conservation of

160 interfacial residues, particularly for the G-loop (Figure 2 - figure supplement 1) and

161 demonstrate a new evolutionary strategy for complex stabilization that was not observed to

162 date in complex I structures from other species.

163 A strong density near the NuoG surface coordinated by [G]Asp617, [G]Gln632, [G]Glu647,

164 [G]Asp731 and four water molecules (Figure 2B) was assigned to a Ca^{2+} ion. The coordination

165 number, geometry, and ion-ligand distances of ca 2.5 Å (H. Zheng et al., 2008) as well as the

166 2 mM concentration of Ca^{2+} in the buffer support this assignment. Divalent ions are known to

167 increase both the activity and stability of *E. coli* complex I (Sazanov, 2003). One of the

168 calcium ligands, [G]Asp731, is part of the G-loop, suggesting that Ca^{2+} stabilizes the fold of the

169 G-loop and consequently, the peripheral arm.

170 The extensions spatially overlap with the supernumerary subunits of complex I from *T.*

171 *thermophilus* (Sazanov, 2006) and the structurally conserved supernumerary subunits of

172 eukaryotic complex I (Zhu et al., 2016) (Table 3), consistent with the suggestion that the

173 primary role of supernumerary subunits is to stabilize the complex (Fiedorczuk et al., 2016).

7

Bound water molecules

174

175   At 2.1 Å resolution, 1165 water molecules associated with the peripheral arm were modelled

176   (Figure 2D). The positions of 180 water molecules are conserved with those identified in the

177   peripheral arm of ovine complex I (Kampjut and Sazanov, 2020) (Figure 2D, red spheres).

178   Most of conserved waters are buried in the interior of the subunits, shielded from the solvent,

179   and most likely play a structural role in maintaining the subunit fold. Only a few water

180   molecules interact closely with iron-sulfur clusters and may influence their potential (Table 4,

181   Figure 1 - figure supplement 5). The water molecules located close to or between iron-sulfur

182   clusters are not more conserved than those in the other parts of the complex, suggesting that

183   they were not evolutionary selected to optimize the rate of electron transfer as was suggested

184   by Schulte et.al. (Schulte et al., 2019a).

185   At 2.1 Å resolution, several unusual density features were observed next to some surface-

186   exposed histidines and between some cysteine-methionine pairs as listed in Table 6 and

187   depicted in Figure 3 - figure supplement 1.

Electron input and output sites

189   The FMN conformation and key water molecules in the NADH-binding pocket of *E. coli*

190   complex I are conserved (Kampjut and Sazanov, 2020; Schulte et al., 2019b). This includes

191   the position of W1060 that forms a hydrogen bond with the isoalloxazine ring N5 atom in

192   FMN and with [F]Glu92, which likely acts as the activating group during catalysis of hydride

193   transfer from NADH (Fraaije et al., 2000) (Figure 3A). Schulte et.al. (Schulte et al., 2019b)

194   suggested a mechanism for regulation of reactive oxygen species (ROS) generation by *E. coli*

195   complex I that involves flipping the carbonyl oxygen of [F]Glu93 upon enzymatic reduction.

196   Our structure unambiguously places the corresponding carbonyl oxygen in a conformation

197   that points away from FMN (Figure 3A) similar to conformations found in the reduced and

198 oxidized ovine complex I (Kampjut and Sazanov, 2020), which does not support its

199 involvement in ROS regulation.

200 *E. coli*-specific features in the FMN-binding pocket include [F]His400 that replaces the Leu

201 residues found in other homologues. [F]His400 is in Van der Waals contact with the

202 isoalloxazine ring of FMN; its imidazole ring interacts directly with the N3 cluster iron atom

203 and forms a hydrogen bond with Sγ of [F]Cys357 coordinating N3 (Figure3A). [F]His400 is

204 solvent-accessible even in the presence of NADH, and therefore, may become protonated

205 upon N3 reduction. [F]Arg320 is positioned such that it can form hydrogen bonds with the

206 ribose moiety of the NADH nicotinamide group and may stabilize bound dinucleotide (Figure

207 3A). Both Arg320[F] and His400[F] may serve to counter-balance the negative charges of

208 electrons on N1a and N3 clusters and to increase protein stability. The structure does not

209 reveal specific features explaining the decreased affinity for FMN in the reduced enzyme

210 (Holt et al., 2016). This can be attributed to minor conformational changes in the pocket upon

211 enzyme reduction.

212 The Q-binding site in complex I is formed at the end of a crevice between NuoD and NuoB

213 subunits (Baradaran et al., 2013). In *E. coli,* this wedge is formed by the 58–69 stretch of

214 NuoB and the tip of the 220–225 loop from subunit NuoD. Both [D]Tyr273 and [D]His224, found

215 in the proximity of bound decylubiquinone (Baradaran et al., 2013) are conserved in *E. coli*

216 and point towards the quinone binding site, whereas the tip of the 218–223 loop is disordered

217 as in most complex I structures.

218 Environment and potentials of iron-sulfur clusters

219

220 At a resolution of 2.1 Å the atoms constituting the iron-sulfur clusters are resolved as

221 independent density blobs. The conformation of side chains as well as the positions of

222 hydrating waters in the primary and secondary interaction spheres are mostly unambiguously

223 resolved (Figure 3). In *E. coli* complex I, cluster N1a can be reduced by NADH due to its

9

224   uniquely high potential (~ -0.3 V), differentiating it from other characterized species in which

225   N1a cannot be reduced by NADH (Birrell et al., 2013; Zu et al., 2002). The potential of iron-

226   sulfur clusters in proteins among other factors depends on solvent exposure, proximity of

227   charged residues, and the number of hydrogen bonds formed between the cluster environment

228   and sulfur atoms of clusters or coordinating cysteines (Denke et al., 1998; Fritz et al., 2002).

229   Comparison of the chemical environment of N1a with other high-resolution structures of

230   complex I revealed three specific differences explaining the higher potential of the N1a

231   cluster (Table 5): (1) *E. coli*-specific [E]Asn142 forms a hydrogen bond with Sγ of [E]Cys97

232   coordinating the N1a cluster and with N1a S1 (Figure 3B), consistent with its mutation to Met

233   decreasing potential by 53 mV (Birrell et al., 2013). (2) In *E. coli*, water molecule W74 forms

234   a hydrogen bond with Sγ of [E]Cys97. This water molecule resides in a hydrophilic cavity

235   created by *E. coli* specific [E]Gly140, replacing the alanine residue found in other species. (3)

236   Because of small differences in the backbone conformation of NuoF, the backbone nitrogen

237   of [F]Gly97 can form a hydrogen bond with Sγ of [E]Cys133 in *E. coli* and *Aquifex aeolicus* but

238   not in *Ovis aries* (Figure 3B, Table 5).

239   The environment of the other iron-sulfur clusters is mainly conserved. The differences in

240   hydrogen donors to the clusters, cysteine sulfur atoms, and water molecules in the cluster

241   vicinity are listed in Table 4. Clusters N3 and N2 are briefly discussed below as being the

242   most interesting.

243   Cluster N3 interacts with [F]His400, which is absent in other structurally characterized species;

244   however, the potential of N3 is very similar between species (Leif et al., 1995; Yagi and

245   Matsuno-Yagi, 2003). The effect of proximal His residue is likely compensated by [F]Trp363

246   replacing the hydrogen bond donors (Glu or Gln) found in other species (Table 4).

247   The potential of cluster N2, the electron donor to quinone, varies in different species (Hirst

248   and Roessler, 2016) notably being lower in *E. coli* compared to its mammalian analogues (-

249 220 mV *vs.* -140 mV, respectively). However, the structure shows that the polar environment

250 of N2 is very conserved (Figure 3C), including two water molecules, W211 and W438. Two

251 arginines found in close proximity to the N2 cluster, Arg270[D] and Arg250[D], have conserved

252 positions despite [49kDa]Arg85 in the mammalian homologue ([D]Arg250) being dimethylated

253 (Carroll et al., 2013). This modification prevents it from forming a hydrogen bond with

254 [B]Cys63, which should decrease N2 potential in the mitochondrial enzyme. Therefore, finer

255 structural differences including those in cluster geometry, are likely responsible for

256 differences in potential, which can likely be explained by high-resolution structure-based

257 modeling.

Structure of the membrane arm

259 The model of complete membrane arm, including the previously missing subunit NuoH

260 (Efremov and Sazanov, 2011), was built into the density map with local resolution better than

261 3.5 Å at the arm center and approximately 4.0 Å at its periphery (Figure 1A, Figure 1 - figure

262 supplement 4). An additional density belt corresponding to the lipid nanodisc is clearly visible

263 (Figure 1A, Movie 1) around the membrane-embedded region. It is flat in the plane of the

264 membrane with a thickness of approximately 30 Å, and closely matches hydrophobic surface

265 of the membrane arm. The belt locally bends next to the subunit NuoL at the region where it

266 interacts with the long amphipathic helix and is thinned next to the [H]TMH1 (Movie 1).

267 The structure of the membrane arm in the lipid nanodisc is very similar to the crystal structure

268 of the detergent-solubilized membrane arm (Efremov and Sazanov, 2011) (RMSD of 1.1 Å

269 over 12662 atoms) (Figure 4 - figure supplement 1). The curvature of the membrane arm

270 observed previously (Efremov and Sazanov, 2011) was unchanged in the lipid environment,

271 and therefore, is not an artifact of crystallization or solubilization (Verkhovskaya and Bloch,

272 2012). Local structural differences in crystal structure include expected repositioning of

273   ^{A}TMH1 next to ^{H}TMH2 (Baradaran et al., 2013), and a change in conformation of the

274   ^{M}TMH5-TMH6 loop (Figure 4 - figure supplement 1).

275   The fold of subunit NuoH is similar to the structures of *T. thermophilus* and of eukaryotic

276   complexes with one important exception. The density for the N-terminus of NuoH (residues

277   1-52) that includes ^{H}TMH1 and a part of ^{H}TMH1-TMH2 loop, is completely missing in the

278   reconstructions of the membrane fragment and of complete complex I (Figure 1, Movie 1)

279   suggesting that ^{H}TMH1 is very mobile in the lipid nanodisc. This helix is close to the border

280   of the nanodisc, and nanodisc belt is thinned on the cytoplasmic surface of the nanodisc at the

281   position where the density of ^{H}TMH1 disappears (Movie 1). Simultaneously there is sufficient

282   room to accommodate the trans-membrane helix within the nanodisc.

283   The structures of the membrane fragment and entire complex I visualize a complete chain of

284   charged residues connecting the Q-site with charged residues in antiporter-like subunits.

285   (Figure 4A). We analyzed the environment of ionizable residues found within the 'E-channel'

286   (Baradaran et al., 2013), a region situated between the Q-cavity and antiporter-like subunit

287   NuoN, to evaluate the existence of a continuous proton translocation path linking the Q-cavity

288   with the antiporter-like subunits suggested for ovine complex I (Kampjut and Sazanov, 2020).

289   The trans-membrane region of *E. coli* NuoH contains fewer charged residues than its

290   homologues from other structurally characterized species (Figure 4 - figure supplement 2).

291   Here, only *E. coli*-specific ^{H}His208, separated from ^{H}Glu157 by 12 Å, is found in the center

292   of the membrane-embedded region of NuoH (Figure 4A). However, a large hydrophilic cavity

293   stretches from the Q-site towards the center of subunit NuoH, ending next to the invariant

294   **^{H}Glu157** (hereafter, invariant residues are marked in bold). Although **^{H}Glu157** is not directly

295   linked to the cavity, DOWSER++ (Morozenko and Stuchebrukhov, 2016) placed waters

296   linking it to the cavity, suggesting that this glutamic acid can exchange protons with the Q-

297   cavity.

298   The region between NuoH and NuoN includes 6 ionizable side chains located in the middle of

299   the membrane bilayer, 4 of which are invariant (Figure 4A,B). The distances between the

300   residues vary from 5 Å to 12 Å which requires either displacement of the side chains or

301   presence of water molecules to enable proton exchange between them. Analysis of cavities

302   and potential hydration sites using DOWSER++ shows that the cluster of ^{H}**Glu157** and

303   ^{A}**Asp79** along with the carbonyl oxygen of ^{J}Gly61 forming a π-bulge on the ^{J}TM3 (similar to

304   the X-ray structure) (Efremov and Sazanov, 2011), indicate a hydrophilic cavity that can

305   accommodate several water molecules, enabling proton exchange between these two residues.

306   Carboxyl groups of a chain comprising ^{J}Glu55-^{K}**Glu36**-^{K}Glu72-^{N}**Glu133** are separated by

307   cavities that can potentially be hydrated, enabling proton exchange between the residues. In *E.*

308   *coli* complex I, residues ^{A}**Asp79** and ^{J}**Glu55**/ ^{K}**Glu36** are separated by a distance exceeding 12

309   Å and a region packed with hydrophobic residues, making proton exchange between the Q-

310   site and NuoN unlikely. ^{A}**Glu81,** located opposite ^{A}**Asp79** on ^{A}TMH2, apparently does not

311   participate in linking ^{A}**Asp79** with ^{N}**Glu133.** However, it faces hydrophilic environment of

312   ^{J}Ser145, *E. coli*-specific ^{J}Glu142, and ^{A}Glu102, potentially linking it to the periplasmic

313   surface (Figure 4A). Our analysis indicated that in *E. coli,* the E-channel is less pronounced

314   than in *T. thermophilus* and that no continuous proton path exists between the Q-site and

315   NuoN.

316   Curiously, ^{H}Lys274 almost universally conserved in complex I and related hydrogenases is

317   found in the ^{H}TMH7 off the main pathways proposed for proton translocation. In our

318   structure, its ammonium group is oriented towards the periplasm (Figure 4A); however, the

319   length and flexibility of the side chain would allow it to reach the center of the membrane

320   upon structural rearrangement.

321   The cytoplasmic half of ^{J}TMH3 was found to assume two alternative conformations in

322   eukaryotic complex I (Agip et al., 2018; Kampjut and Sazanov, 2020). In *E. coli* complex I,

323   the density in this region is very well-resolved, suggesting the absence of alternative

324   conformations. A peculiar feature is observed in the density of subunit NuoM instead.

325   The density of the cytoplasmic half of ^{M}TM8 is poor and fragmented between residues 255

326   and 265, indicating the existence of multiple conformations (Figure 4C, Movie 2). This region

327   is buried in the middle of NuoM and the density of surrounding helices is very well-resolved

328   indicating the local character of the disorder. This region spans the invariant **Lys265**

329   including the π-bulge, and found in some bacteria ^{M}Asp258. Interestingly, though the helix

330   structure in mammalian complex I is similar to that in *E. coli* (the equivalent Asp is missing),

331   the corresponding region in *T. thermophilus* differs significantly (Figure 4C). The

332   cytoplasmic region of ^{13}TM8 is rotated by 2 residues. This is achieved by extending TMH8 at

333   *T. thermophilus* ^{13}**Lys 235** (equivalent to *E. coli* ^{M}**Lys265**). In *E. coli*, ^{M}**Lys265** is buried in

334   the center of the second structural repeat whereas in *T. themophilus*, ^{13}**Lys 235** is positioned at

335   the interface between the structural repeats facing ^{13}**His218** (in *E. coli* ^{M}His248). This rotation

336   places ^{13}Asp228 (equivalent to *E. coli* ^{M}Asp258) pointing towards central axis of the first

337   structural repeat (TM4-8) and exposed to the cytoplasm, whereas in *E. coli*, it is buried on the

338   central axis of the second structural repeat (TM9-TM13). Thus, higher mobility of the helical

339   fragment situated at a critical position at the interface of symmetry-related modules may

340   indicate π-bulge-enabled helical rotation with a possible role in proton translocation.

The peripheral-membrane arm interface

342   The interface between membrane and peripheral arms presents an important element of the

343   complex that mediates the coupling of ubiquinone reduction above the cytoplasmic surface to

344   proton translocation across the membrane. The interface between peripheral and membrane

345   arms is primarily formed through interaction between subunits NuoB and NuoD of the

346   peripheral arm with the cytoplasmic surface of NuoH and the TMH1-TMH2 loop of subunit

347   NuoA in the membrane domain. The residues involved in the direct interaction between the

348   arms and the interface structure are highly conserved (Figure 5 - figure supplement 1)

349   between all complex I and related membrane-bound hydrogenases (Baradaran et al., 2013;

350   Grba and Hirst, 2020; Kampjut and Sazanov, 2020; Yu et al., 2020; 2018).

351   Local resolution (Figure 1 - figure supplement 4) and B-factors (Figure 5 - figure supplement

352   2) of the *E. coli* peripheral arm show that the membrane-facing surface (subunits NuoD and

353   NuoB) including the residues lining the Q-cavity are significantly less ordered than the

354   remaining subcomplex. The mobility in the interfacial region of the arm is very similar in the

355   reconstructions of the peripheral arm dissociated from and complexed with the membrane

356   arm. However, several interfacial regions of subunits NuoB, NuoD, and NuoI become more

357   ordered upon complex formation and their density can be observed in the reconstruction of

358   isolated conformations of the entire complex I (Figure 5 - figure supplement 2, Table 2).

359   Similar to complex I from *T. thermophilus* (Baradaran et al., 2013), there are no specific

360   conformational changes at the interface upon association of the arms. These results suggest

361   that the interfacial region of the peripheral arm is inherently flexible and likely responsible, at

362   least in part, for the high relative mobility of the arms.

363   Structure of the surface of subunit NuoH and relative arrangement of subunits NuoB and

364   NuoD in *E. coli* complex I is similar to that of complex I from other species (RMSD 1.2 Å

365   over 324 Cα atoms with *T. thermophilus* complex I). However, their relative positions differ.

366   Thus, in *E. coli* complex I, NuoB and NuoD are rotated around an axis passing through the

367   center of NuoH and the interface between NuoF and NuoG anticlockwise when observed

368   from the top of peripheral arm at approximately 15 degrees (Figure 5A). This results in the

369   shift of NuoD interfacial regions with an amplitude exceeding 10 Å and the separation of

370   NuoD from NuoH, which reduces the interaction between the four-helical bundle domain of

371   NuoD with NuoH (Figure 5B). The highly conserved fragment of the [A]TMH1-TMH2 loop

15

372   (residues 46-53), that forms a plug between subunits NuoD and NuoB (Figure 5 - figure

373   supplement 1B) and interacts with the ^{D}221-228 loop containing ubiquinone-coordinating

374   His224, is also disordered in our structure (Figure 5B).

375   On the opposite side of the interface, structural rearrangements include a 7-degree tilt of

376   ^{A}TMH1 that becomes more perpendicular to the membrane plane and approximately 15-

377   degree rotation of the amphipathic helix in the loop connecting ^{H}TMH1-TMH2, residues 57–

378   68, in the direction of ^{H}TMH1 and towards the membrane center (Figure 5C). Analysis of the

379   three full conformations identifies this helix as the main membrane arm element that performs

380   rearrangement together with the cytoplasmic domain. Its rotation reduces the opening to the

381   Q-cavity (Figure 5D). Homology modeling indicates that the observed rearrangements are

382   still compatible with ^{H}TMH1 occupying its expected position without any steric clashes

383   (Figure 5D) suggesting that ^{H}TMH1 is highly mobile in the lipid environment rather than

384   being absent from its expected position.

385   Rotation of the NuoB/NuoD subunits module creates multiple openings on the interface

386   between the arms (Figure 5B). The size of the openings is compatible with the diffusion of

387   water molecules and likely, of protons from the outer space towards the Q-cavity. Such

388   openings suggest that ubiquinone bound to the Q-site can receive protons directly from the

389   solvent.

Discussion

Structural features of *E. coli* complex I

392   *E. coli* complex I is composed of the smallest number of subunits among all complex I

393   structures characterized so far. Yet it still evolved a strategy to stabilize peripheral arm

394   assembly without involving additional subunits. The interactions between subunits are

395   stabilized by extended C-termini and a large G-loop (Figure 2), in turn stabilized by the Ca^{2+}

16

396   ion, which is known to modulate the complex stability (Sazanov, 2003). This indicates an

397   evolutionary pressure on maintaining the peripheral arm integrity, which was 'solved' in a

398   species-dependent manner.

399   There is no apparent continuous proton translocation path between the Q-cavity and subunit

400   NuoN in *E. coli* complex I. Further, there are no indications for the existence of different

401   conformations in the cytoplasmic half of ^{J}TMH3 observed in mammalian complex I (Agip et

402   al., 2018; Kampjut and Sazanov, 2020) attributed to deactive-active transition (Agip et al.,

403   2018) or more recently, to different catalytic intermediates (Kampjut and Sazanov, 2020).

404   This suggests that these states are either suppressed in the resting state of the bacterial

405   complex or do not occur at all. Conversely, ^{M}TMH8 displays localized disorder next to the π-

406   bulge, indicating involvement of this helix in the structural rearrangements associated with

407   proton translocation, and to our knowledge, represents the first indication of specific

408   conformational changes in antiporter-like subunits.

409   *E. coli* complex I is known to be a dynamic complex (Morgan and Sazanov, 2008; Sazanov,

410   2003). Our cryo-EM reconstructions reveal the reasons for its high flexibility. The peripheral

411   and membrane arms are mainly rigid, whereas the connection between arms is flexible

412   (Figure 1C, Figure 1 – figure supplement 5). Two reasons can be identified for this: 1) high

413   mobility of the interfacial regions of subunits NuoB and NuoD (Figure 1 - figure supplement

414   4, Figure 5 - figure supplement 2) and 2) the 15-degree rotation of the interfacial subunits

415   NuoB and NuoD relative to NuoH, observed uniquely in *E. coli* (Figure 5A). The rotation

416   disrupts many conserved complimentary interactions between the arms and renders the

417   interface porous such that the Q-cavity is exposed to the solvent. This is different from all the

418   other known structures of complex I and evolutionarily related complexes in which the

419   interface is solvent-inaccessible. Therefore, we interpreted the observed conformation of *E.*

420   *coli* complex I as an uncoupled state. Our preparation of the complex is competent in

421   ubiquinone reduction (Figure 1 - figure supplement 2); however, unless conformational

422   changes sealing the Q-cavity occur during the catalytic cycle, ubiquinone reduction by NADH

423   in the present conformation is expected to occur without proton translocation.

424   The reasons for this difference in interface conformation with other structurally characterized

425   complexes are not clear. It may represent a resting state described in *E. coli* complex I

426   (Belevich et al., 2017), which like in eukaryotes (Babot et al., 2014), is characterized by lower

427   catalytic activity and is activated by NADH:ubiquinone oxidoreduction cycles. However,

428   reactive states in eukaryotic complex I are associated with local conformational changes

429   involving loop rearrangement (Agip et al., 2018; Parey et al., 2018), rather than displacement

430   of the complete domains observed in *E. coli* complex I. Other reasons for the observed

431   rotation of arms may include the higher concentration of divalent ions used in our sample that

432   weakens multiple salt bridges linking the arms, or displacement of the amphipathic termini of

433   subunits NuoB and NuoI due to the limited size of the nanodisc, resulting in weakened

434   interaction between the arms.

435   The absence of density for [H]TMH1 is another unique feature of *E. coli* complex I. It likely

436   reflects the higher dynamics of this helix in lipid environment. Possibly, tilted [A]TMH1

437   (Figure 5C) displaces the periplasmic end of [H]TMH1 disrupting its interaction with the

438   TMH2-3 loop and TMH6 of NuoH, rendering this helix dynamic. It may also have a

439   functional role because helix displacement facilitates the otherwise too narrow access to the

440   Q-cavity for ubiquinone (Baradaran et al., 2013). Further insights into the role of [H]TMH1

441   might be obtained once conditions stabilizing the coupled complex conformation are

442   identified.

443   Revised coupling mechanism
444   Based on structural features of *E. coli* complex I and the wealth of available structural

445   information, we would like to propose a coupling mechanism that differs from those

18

446   suggested previously (Figure 6), which is simple, compatible with the microscopic

447   reversibility principle (Onsager et al., 1996), has evolutionary meaning, and is applicable to

448   the entire class of evolutionarily related complexes.

449   We propose that the key to the coupling is the formation of a cavity isolated from external

450   protons and accessible to ubiquinone such that ubiquinone can exchange electrons with the

451   N2 cluster. The necessity of having a tightly coupled cavity explains the high conservation of

452   the subunit interface. Notably, as the ubiquinone entrance is situated in the hydrophobic

453   region of the bilayer, these two requirements do not contradict each other.

454   The potential of benzoquinone-hydroquinone couple depends on the pH (Chambers, 1988),

455   similar to that of any redox reaction involving protons, and has been shown experimentally to

456   decrease by over 400 mV to below -300 mV upon pH change from 2 to 10 (Lemmer et al.,

457   2011). Rough estimations indicate that addition or extraction of a single proton from a cavity

458   with the characteristic dimensions of the Q-cavity, alters the activity of protons within the

459   cavity by hundreds of millivolts. Thus, the redox potential of ubiquinone bound within the

460   cavity enclosed from the environment will be strongly modulated by the extraction/addition of

461   single protons from/to the cavity. *Vice versa*, reduction or oxidation of ubiquinone/ubiquinol

462   is equivalent to adding/removing proton binding groups to/from the Q-cavity. Thus,

463   ubiquinone serves as a transformer that converts the energy of electrons to the chemical

464   potential of protons in a fully reversible manner. In the coupled complex during the forward

465   cycle, ubiquinone reduction decreases proton activity in the cavity, which is rectified by

466   protons entering the cavity and performing work. Questions of how the protons perform the

467   work and where they come from are thus critical to formulate the coupling mechanism.

468   Multiple proton pathways have been suggested (Baradaran et al., 2013; Efremov and

469   Sazanov, 2012; Kampjut and Sazanov, 2020; Verkhovskaya and Bloch, 2012; Yu et al., 2020;

470   2018). However, they all end up on intracellular/matrix side of the membrane, which makes it

19

471   difficult to explain the energy conversion mechanism. Instead, we propose that the protons re-

472   protonate ubiquinone through NuoH and/or adjacent trans-membrane subunits from the

473   periplasmic/inter membrane side of the membrane as shown in Figure 6. The fold of subunit

474   NuoH contains a set of 5 TMH with a helical arrangement similar to the symmetric module in

475   antiporter-like subunits including broken TMH (Baradaran et al., 2013) and invariant

476   [H]Glu157 in a position similar to the invariant [M]Glu144, suggesting that it can translocate

477   protons. Proton transport through NuoH is coupled to the transport of three protons by three

478   antiporter-like subunits in the opposite direction. This coupling must involve both the

479   interaction of ionizable residues in the middle of the membrane (Baradaran et al., 2013;

480   Efremov and Sazanov, 2011) as well as conformational changes, and likely proceeds through

481   a classical alternating access mechanism (Jardetzky, 1966). Thus, the entire membrane

482   module functions as a reversible proton antiporter with the stoichiometry of $1H^+_{in}/3H^+_{out}$. Four

483   protons are translocated outside in two pumping cycles per one reduced ubiquinone molecule

484   (Figure 6). In this mechanism, ubiquinone reduction creates a local enhanced membrane

485   potential on the NuoH subunit between the Q-cavity and periplasmic space. Moreover, only

486   the equilibrium potential of NADH and ubiquinone as well as the transmembrane potential

487   are important for the directionality of the reaction and energy balance as expected for a

488   molecular machine (Astumian et al., 2016).

489   Under equilibrium, the potential of ubiquinone in the Q-cavity is equilibrated with the

490   potential of NADH, and of protons in the Q-cavity, which results in trans-membrane

491   potential-dependent semiquinone species as observed by EPR spectroscopy in tightly coupled

492   submitochondrial particles (Yano et al., 2005) .

493   The proposed mechanism is applicable to all the complexes that are evolutionary related to

494   complex I (Efremov and Sazanov, 2012; Yu et al., 2020; 2018). In all of these, the cavity

495   formed between the peripheral arm and NuoH subunit is sealed. The peripheral arm-NuoH

20

496 complex is undoubtably one of the stand-alone evolutionary modules. This is supported by the

497 differences in its position between complex I and membrane-bound hydrogenases (Yu et al.,

498 2020; 2018), and its susceptibility to dissociation from the membrane arm in *E. coli*

499 (Baranova et al., 2007; Efremov and Sazanov, 2011) as expected for a late evolutionary

500 addition (Levy et al., 2008). The initial association of the hydrogen-evolving module with an

501 antiporter may have had an evolutionary advantage with the proton-translocating module

502 serving as a source of protons (Yu et al., 2018), biasing H_2 evolution towards the reaction

503 product or to enhance Na^+ extraction from the cells (Boyd et al., 2014).

504 Complex uncoupling is achieved by opening the Q-cavity to the solvent, consistent with

505 elegant experiments by Cabrera-Orefice et.al (Cabrera-Orefice et al., 2018) in which the

506 locking conserved the ^{A}TMH1-2 plug with the cysteine bridge reversibly uncoupled the

507 enzyme. Close examination of the crosslinked structure indicates that crosslinking fixes the

508 plug conformation in a way that the Q-cavity is accessible to the solvent.

509 The exact proton translocation mechanism within the antiporter-like module is unknown and

510 requires further experimental and computational investigation. Here, we can only speculate

511 that given the high conservation of ^{H}Glu157, it plays an important role in the coupling and

512 likely changes its protonation state during the pumping cycle. Thus, it can influence the pKa

513 of neighboring ionizable residues. In membrane-bound hydrogenase (MBH), an equivalent

514 ^{M}Glu141 is separated from the closest ionizable ^{H}Lys409 by distance of 20 Å, which in a

515 hydrophobic environment with a dielectric constant of 10, allow them to mutually modulate

516 the pKa of each other by approximately 1 pH unit, similar to the free energy conserved upon

517 ferredoxin oxidation by the protein complex. This distance is reduced to around 13 Å in

518 membrane-bound sulfane sulfur reductase (MBS) and to around 6 Å in complex I, consistent

519 with the proportionally higher free energy of catalyzed reactions (Yu et al., 2020; 2018).

21

520   The proposed coupling mechanism also suggests how the different conformational states

521   associated with proton translocation might be trapped. A pH jump applied to purified coupled

522   complex I will create a difference in potential between the Q-cavity and periplasmic surface,

523   which depending on the direction of the jump, may trap different equilibrium conformations

524   of this molecular machine.

525

Materials and Methods

526

Generation of an *E. coli* strain expressing Twin-Strep-tagged respiratory complex I

527

528   The native *nuo* operon encoding the 13 subunits of respiratory complex I (NuoA-N) was

529   engineered with a Twin-Strep-tag (WSHPQFEKGGGSGGGSGGSAWSHPQFEK, IBA

530   GmbH) at the N-terminus of NuoF using CRISPR-Cas9-enabled recombineering(Jiang et

531   al., 2015). The DNA sequence encoding the C-terminal region of NuoE and N-terminus of

532   NuoF was retrieved from GenBank (Acc. No. NC_012971.2 region 2288438 – 2289174). The

533   tag-coding sequence followed by a TEV protease recognition site (Tropea et al., 2009) was

534   appended upstream of the NuoF N-terminus and was codon-optimized, together with the

535   2288766–2288807 region of the genomic fragment. Such designed, linear DNA knock-in

536   cassette was synthesized (GenScript). The vectors pCas and pTargetF were gifts from Sheng

537   Yang (Addgene plasmids #62225 and #62226). The N20 sequence

538   (GGTCAGCGGATGCGTTTCGG) was introduced into pTargetF by inverse PCR. Genomic

539   engineering was performed according as described by Jiang *et al* (Jiang et al., 2015). Briefly,

540   pCas vector was transformed into the chemically competent *E. coli* BL21AI strain (Thermo

541   Fisher Scientific Inc.). The transformants were grown in shake-flask culture at 30ºC in

542   Lysogeny Broth (LB) medium containing 25 µg mL^{-1} (w/v) kanamycin monosulfate and 10

543   mM L-arabinose. Upon reaching OD_{600} 0.5, the bacteria were rendered electrocompetent and

22

544 were co-electroporated with the linear DNA cassette and the mutated pTargetF vector. The

545 transformants were selected on LB-agar plates supplemented with 25 μg mL^{-1} (w/v)

546 kanamycin and 50 μg mL^{-1} (w/v) streptomycin, or 50 μg mL^{-1} (w/v) spectinomycin. The

547 positives, identified by colony PCR and DNA sequencing, were cured of the plasmids as

548 described previously (Jiang et al., 2015). We further refer to the modified strain as *E. coli*

549 BL21FS (NuoF-Strep).

550 Expression and purification of respiratory complex I

551 *E. coli* BL21FS was cultivated in LB medium for 48 hours at 37°C in a microaerobic

552 environment. The cells were harvested by centrifugation and the membrane fraction was

553 isolated as described by Sazanov *et al* (Sazanov, 2003). All subsequent steps were performed

554 at 4°C. The homogenate was solubilized in 2% (w/v) n-Dodecyl β-D-maltoside (DDM,

555 Anatrace) for 2 hours while stirring, after which the non-solubilized fraction was removed by

556 ultracentrifugation at 225 000 × *g* for 1 hour. The supernatant was adjusted to 200 mM NaCl

557 and loaded on a 5 mL Strep-Tactin® Superflow® high capacity column (IBA GmbH). After

558 washing with 25 column volumes (CV) of buffer A (50 mM Bis-tris pH 6, 2 mM CaCl$_2$, 200

559 mM NaCl, 0.04% (w/v) DDM, 10% (v/v) sucrose, 0.003% (w/v) *E. coli* polar lipid extract

560 (Avanti Polar Lipids, EPL), 0.2 mM PMSF), complex I was eluted with 2 CV of buffer B

561 (buffer A containing 5 mM D-desthiobiotin (IBA GmbH). The purity of the eluted protein

562 was assessed by SDS-PAGE and activity assays (Figure 1 - figure supplement 1). The

563 purified complex I was concentrated using an Amicon Ultra-4 100K centrifugal filter (Merck)

564 to 0.5 mg mL^{-1} (w/v), fast-frozen in liquid nitrogen and stored at -80°C.

565 Reconstitution of respiratory complex I into lipid nanodiscs

566 The membrane scaffold protein MSP2N2 was expressed and purified following a published

567 protocol (Grinkova et al., 2010). Purified complex I at concentration 520 nM was mixed with

568 10.4 μM MSP2N2 (1:20 protein:MSP molar ratio) and incubated for 1 hour at 4°C.

23

569   Subsequently, the detergent was removed by adding 0.5 g mL^{-1} (w/v) Bio-Beads (Bio-Rad)

570   overnight at 4°C. The reconstituted protein was further purified on the Superose 6 Increase

571   10/300 GL column (GE Healthcare) equilibrated in a buffer comprising 20 mM Bis-Tris pH

572   6.8, 200 mM NaCl and 2 mM CaCl$_2$. The protein-containing fractions were pooled and

573   concentrated to 0.1–0.2 mg mL^{-1} (w/v) using Amicon Ultra-0.5 100K centrifugal

574   concentrators.

Activity assays

576   NADH:ferricyanide (FeCy) and NADH:ubiquinone-1 (Q1) activities were measured as

577   described previously (Sazanov, 2003). For the assays, 3 nM of detergent-solubilized or

578   nanodisc-reconstituted complex I and either 1 mM FeCy (Sigma Aldrich BVBA) or 100 μM

579   Q1 (Sigma Aldrich BVBA) were added to the assay buffer (10 mM Bis-Tris pH 6.8, 200 mM

580   NaCl, 10 mM CaCl$_2$) in a stirred quartz cuvette at 30°C. The reaction was initiated by adding

581   100 μM NADH (Carl-Roth GmbH) and followed as reduction in absorbance at 340 nm using

582   a Varian Cary 300 UV-Vis spectrophotometer (Agilent Technologies, Inc). During the

583   inhibition assay, complex I was incubated with 20 μM Piericidin A (Cayman Chemical) for 5

584   min in the assay buffer at 30°C prior to Q1 addition.

Mass photometry

586   The composition of the protein preparation was assessed using mass photometry on a Refeyn

587   OneMP instrument (Refeyn Ltd.), which was calibrated using an unstained native protein ladder

588   (NativeMark™ Unstained Protein Standard A, Thermo Fisher Scientific Inc.). Measurements

589   were performed on the reconstituted complex I at a concentration of 0.015 mg ml^{-1} using

590   AcquireMP 2.2.0 software and were analyzed using the DiscoverMP 2.2.0 package.

24

Preparation of cryo-EM samples

591   The cryo-EM samples were prepared using a CP3 cryoplunge (Gatan). Quantifoil R0.6/1

592   Cu300 holey carbon grids were cleaned with chloroform, acetone, and isopropanol as

593   described by Passmore *et al* (Passmore and Russo, 2016) . The grids were glow discharged in

594   the ELMO glow discharge system (Corduan Technologies) from both sides for 2 min at 11

595   mA and 0.28 mbar. Four microliters of the reconstituted protein solution at 0.15 mg ml^{-1}

596   concentration were applied on a grid and blotted from both sides for 2.2 s with Whatman No.

597   3 filter paper at 97 % relative humidity. The grid was then plunge-frozen in liquid ethane at -

598   176°C and stored in liquid nitrogen.

Cryo-EM data collection

601   Cryo-EM images were collected on a JEOL CryoARM 300 microscope equipped with an in-

602   column Ω energy filter (Fislage et al., 2020) at 300 kV, automatically using SerialEM 3.0.8

603   (Mastronarde, 2005) at a nominal magnification of 60,000 and the corresponding calibrated

604   pixel size of 0.771 Å. Five images per single stage position were collected using a cross

605   pattern with 3 holes along each axis (Efremov & Stroobants, 2021 in press). The 3 s

606   exposures were dose-fractionated into 61 frames with an electron dose of 1.06 e- Å^{-2} per

607   frame. The energy filter slit was set to 20 eV width. In total, 9122 zero-loss micrographs were

608   recorded with the defocus varying between -0.9 and -2.2 μm (Table 1).

EM image processing

610   The dose-fractionated movies were motion-corrected using MotionCor2 (Zheng et al., 2017)

611   in the patch mode. The Contrast Transfer Function (CTF) parameters were estimated using

612   CTFFIND-4.1 (Rohou and Grigorieff, 2015). 40 micrographs of various defoci were selected,

613   manually picked, and used to train the neural network of crYOLO 1.4 (Wagner et al., 2019).

614   After training, 1,256,734 particles were picked automatically from the complete dataset,

615   extracted in RELION 3.0 (Zivanov et al., 2018), and imported into cryoSPARC 2.11[11].

616   Following 2D classification, six initial models were generated, among which one

617   corresponded to the cytoplasmic arm-only and another corresponded to the complete complex

618   I. Using hetero-refinement, 441,265 and 525,680 particles were assigned to the cytoplasmic

619   arm and complete complex, respectively. Further processing was performed in RELION

620   3.1(Zivanov et al., 2020). After per-particle CTF estimation and Bayesian polishing, 3D auto-

621   refinement of the complete complex produced a map at an average resolution of 3.4 Å (Figure

622   1 - figure supplement 3). However, the map was very heterogeneous with the peripheral arm

623   resolved at 3.0–3.6 Å whereas the membrane arm was resolved at over 10 Å.

624   To address this heterogeneity, both arms were refined independently using multi-body

625   refinement (Nakane et al., 2018) (Figure 1 - figure supplement 3) and the peripheral domain

626   signal was subtracted. After two rounds of 3D classification applied to the membrane domain

627   and nanodisc signal subtraction, a subset of 48,745 particles was 3D refined to an average

628   resolution of 3.6 Å. However, the density map was anisotropic. To improve the

629   reconstruction, the original stack of 525,680 particles was refined against the masked

630   cytoplasmic arm, followed by subtraction of the signal from the peripheral arm. Next,

631   membrane arm map obtained above was filtered to 9 Å and used as an initial model for the 3D

632   refinement of all resulting membrane arm particles. Next, to prevent model bias, the refined

633   map was low-pass filtered to 20 Å and used in the subsequent 3D classification with 10

634   classes, τ of 12 and 24° local angular search range and 1.8° angular step. The best class

635   (110,258 particles and 8 Å resolution) was auto-refined using the starting model low-pass

636   filtered to 15 Å, which produced the reconstruction to a resolution of 4.4 Å. Next, the

637   nanodisc density was subtracted, which further improved the resolution to 3.9 Å. Following

638   3D classification without alignment with τ of 40, 8 classes, and resolution in the E-step

639   limited to 4 Å, a subset of 37,441 particles was identified, which after auto refinement,

640   produced a density map at an average resolution of 3.9 Å with better resolved peripheral

641   regions. Finally, density modification with the resolve_cryo_em tool available in PHENIX

642   1.18.2 (Terwilliger et al., 2020) improved the resolution to 3.7 Å (Figure 1 - figure

643   supplement 3,4).

644   After multibody refinement of the arms described above, peripheral arm particles with the

645   subtracted membrane arm were 3D classified into 12 classes without alignment using τ of 40

646   and resolution of the expectation step limited to 4 Å. The best class contained 134,976

647   particles and was further refined to 2.9 Å resolution.

648   A subset of 166,580 particles was selected after a similar 3D classification procedure that was

649   applied to the 441,265 particles of dissociated peripheral arm particles. It was further cleaned

650   from the remaining particles of the complete complex I by 2D classification, resulting in a

651   subset of 151,357 particles that produced a density map to a resolution of 3.0 Å. As the

652   reconstructions of the dissociated and membrane arm-subtracted cytoplasmic arms were

653   virtually identical, both stacks were combined. After two cycles of per-particle CTF

654   refinement, aberration corrections, and Bayesian particle polishing in RELION 3.1, the

655   resolution improved to 2.4 Å. Consecutive density modification in PHENIX further improved

656   the resolution to 2.1 Å (Figure 1 - figure supplement 3,4, Table 1).

657   To resolve the conformation of entire complex I, a stack of 525,680 particles was aligned to

658   the peripheral arm using auto-refinement with a mask around the peripheral arm in RELION

659   3.1. Next, 3D classification without alignment into 30 classes with resolution of the

660   expectation step limited to 20 Å and τ of 4 was performed, followed by auto-refinement of

661   each resulting class, which produced maps to a resolution in the range of 9-20 Å (some of the

662   classes are shown in Figure 1 - figure supplement 5).

663   Three high-resolution conformations of complete complex I were obtained as follows.

664   Conformation 1 was resolved by applying the 3D classification into 15 classes, τ of 6, a 24°

665   local angular search range, and 1.8º sampling interval to the subset of 110,258 particles that

666   produced the 3.9 Å reconstruction of the membrane arm (see above). The best class consisted

667   of 23,445 particles that were refined to a resolution of 3.9 Å.

668   Conformations 2 and 3, were identified by applying 3D classification without image

669   alignment into 12 classes with τ of 40 and resolution of the expectation step limited to 4 Å, to

670   the stack of 525,680 intact complex I particles. Two of the best classes, consisting of 21,620

671   and 21,234 particles were refined to 4.6 Å and 4.5 Å, respectively. Following density-

672   modification in PHENIX, the resolution of the maps was improved to 3.3, 3.8, and 3.7 Å, for

673   conformations 1, 2, and 3, respectively (Figure 1 - figure supplement 4C, Table 1).

674   Model building

675   Peripheral arm subunits constituting NuoB, CD, E, F, G, and I were first homology modelled

676   in the SWISS-MODEL server (Waterhouse et al., 2018) based on the structure of *T.*

677   *thermophilus* (PDB ID:4HEA (Baradaran et al., 2013)) and were rigid-body fitted into the

678   density map in UCSF Chimera 1.13.1. Following manual rebuilding in Coot 0.9 (Casañal et

679   al., 2020), the model was subjected to real-space refinement against the final 2.1 Å map of

680   the cytoplasmic arm in PHENIX 1.18.2 using the default parameters. Secondary structure

681   restrains were applied only to the interfacial region resolved at a lower resolution. The value

682   of the nonbonded_weight parameter was optimized. Water molecules were added to the map

683   and validated using the "Check/delete waters" tool in Coot 0.9 . Molecular dynamics-based

684   model idealization was conducted in ISOLDE 1.0b5 (Croll, 2018), followed by several

685   iterations of real-space refinement without atomic displacement parameter (ADP) restraints

686   and manual rebuilding in Coot 0.9.

687   For the membrane domain, the previously obtained *E. coli* model (PDB ID: 3RKO) was real-

688   space-refined in PHENIX. The missing NuoH subunit was homology-modelled using the *T.*

689   *thermophilus* structure (PDB ID: 4HEA) in Coot 0.9. The final model was obtained after

690   several rounds of manual rebuilding and real-space refinement using standard parameters with

691   Ramachandran restrains, secondary-structure restrains applied to the NuoL TMH9-13,

692   without ADP restrains, and with the optimized nonbonded_weight parameter. To generate the

693   model of the complete complex I, the separate peripheral and membrane arm structures were

694   combined and the missing parts at the interface (Table 2) were built manually. As the density

695   of NuoL and NuoM was very poor in all the resolved full conformations, these subunits were

696   subjected to rigid-body refinement in PHENIX, whereas the others were subjected to real-

697   space refinement with minimization_global, local_grid_search, morphing, and ADP

698   refinement. Ramachandran, ADP, and secondary-structure restrains were used. After manual

699   rebuilding in Coot, real-space refinement of the full complex was performed with standard

700   parameters and restrains. The models were validated in MolProbity (Williams et al., 2018) .

701   Structural conservation was evaluated using the ConSurf server (Ashkenazy et al., 2016). The

702   figures and movies were generated in UCSF ChimeraX version 1.1. (Goddard et al., 2018)

703   and PyMOL (The PyMOL Molecular Graphics System, Version 2.4.1 Schrödinger, LLC).

704

712

713   Data availability
714   Cryo-EM density maps and atomic models are deposited into the PDB and EMDB databases with the following
715   accession codes: cytoplasmic domain (PDB ID: 7NZ1, EMD-12661), membrane domain (PDB ID: 7NYH,
716   EMD-12652), entire complex conformation 1 (PDB ID: 7NYR, EMD-12653), conformation 2 (PDB ID: 7NYU,
717   EMD-12654), conformation 3 (PDB ID: 7NYV, EMD-12655).
718
719   The following data sets were generated:

945   Figures
946
947
948   **Figure 1 Architecture of *Escherichia coli* respiratory complex I**. (A) Segmented density
949   map of the complete complex I shown together with the nanodisc density. (B) Comparison of
950   the structures of the *E. coli* (green), *Thermus thermophilus* (PDB ID: 4HEA, yellow), and the
951   core subunits of ovine (PDB ID: 6ZKD, orange) complex I. (C) Conformational differences
952   between three conformations resolved at high resolution. The structures are aligned on the
953   membrane arm. The rotation axes and angles are indicated.
954
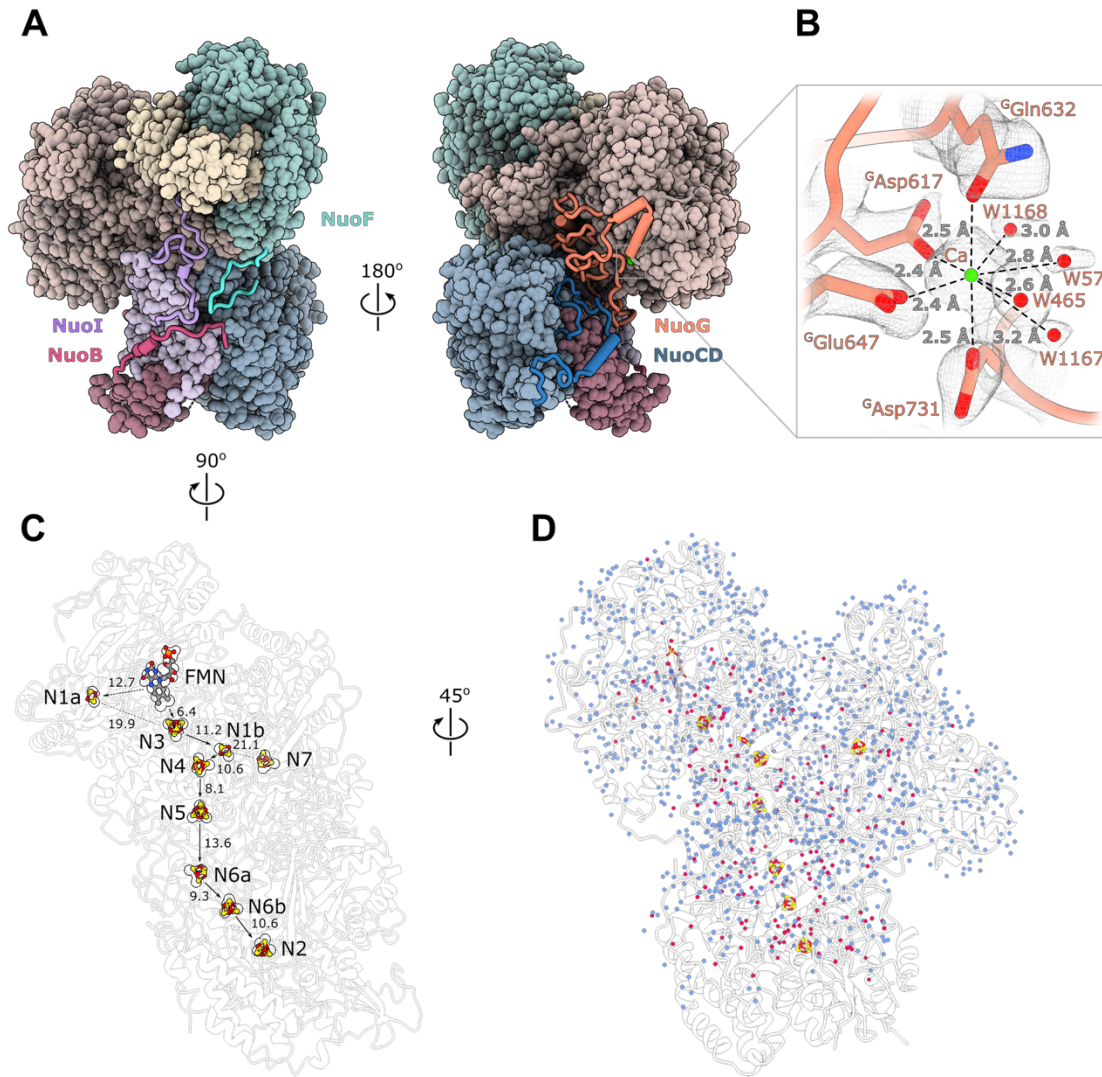

Figure 2 Structure of the peripheral arm. (A, B) The *Escherichia coli*-specific extensions in the peripheral arm subunits: (A) C-termini of NuoI (violet), NuoB (pink), NuoF (turquoise), (B) NuoG insertion (orange), and NuoCD linker (blue). (C) Structural details of the calcium-binding site. (D) Comparison of the FMN and Fe-S clusters positions in *E. coli* (shown as atoms) and *Thermus thermophilus* (shown as outline around *E. coli* atoms). Edge-to-edge distances and the electron pathway are indicated. (E) Water molecules modelled into the 2.1 Å resolution density of the peripheral arm are show in blue. Water molecules conserved with the peripheral arm of ovine complex I (PDB ID: 6ZK9, red) are shown as red spheres. FMN and iron-sulfur (Fe-S) clusters are shown as spheres.
Figure 3 Details of the electron transport chain. (A) The NADH-binding pocket and environment of the Fe-S cluster N3. (B, C) Environment of the Fe-S clusters N1a and N2.
Figure 4 Structural details of the membrane arm. (A) The E-channel. Top: Side view, bottom: view from the cytoplasm. Charged residues between NuoH and NuoN subunits are indicated as along with the distances between them. The cavities allowing entrance of ions and water molecules are shown as grey surfaces. (B) Conformational heterogeneity within the NuoM subunit. The *E. coli* structure and amino acids are green-colored, whereas the aligned structure of *T. thermophilus* is grey. The *E. coli* membrane arm density is depicted.
Figure 5 Interface between the peripheral and membrane arms. (A) Comparison of the interface between *E. coli* (green) and *T. thermophilus* (PDB ID:4HEA, grey) complex I. Structures were aligned on the subunit NuoH/Nqo8. The rotation axis of the subunits NuoB/D module relative to Nqo6/4 is indicated. (B) Interfacial contacts between the peripheral and membrane arms in *T. thermophilus* (upper panel) and *E. coli* (middle and bottom panel). A gap in the subunit interface is apparent in the absence of the conserved ATMH1-2 loop fragment. The corresponding loop from *T. thermophilus* is shown in grey in the cartoon representation (bottom panel). (C) Differences in the structures of NuoH and NuoA subunits between *E. coli* (colour coded as in Figure 1) and *T. thermophilus* (grey). (D) View from the membrane on the entrance to the Q-cavity. Homology model of HTM1, absent in the *E. coli* structure, is shown in the cartoon representation. The protein surface is coloured by lipophilicity.

39

997

Figure 6 Proposed mechanism of coupling in respiratory complex I. Ubiquinone reduction decreases the proton potential in the Q-cavity, generating/enhancing electrochemical potential between the Q-cavity and periplasmic space. It is subsequently neutralized by protons translocated through NuoH from the periplasm into the Q-cavity and this translocation is coupled with the reversible translocation of three protons into the periplasm. Colour coding of schematic subunits in the membrane arm is similar to that described in Figure 1, negatively charged states of ubiquinone are shown in red.

1007

1008

Figure 1 - figure supplement 1 Schematic representation of Crispr-Cas9-enabled incorporation of the twin-strep tag into the N-terminus of the genomically-encoded NuoF subunit. The Cas9 enzyme introduces a double-stranded DNA (dsDNA) break into the nuof locus within the *E. coli* BL21-AI genome at the 20-nucleotide target sequence (N20), located 23 base-pairs (bp) downstream of the nuof +1 site. Subsequently, the λ-Red mediated homologous DNA recombination incorporates the supplied dsDNA template comprising the knock-in cassette flanked by 370 bp long homologous regions into the genome. The recombination results in insertion of sequences coding for the Twin-Strep tag and TEV protease recognition site right after the nuof transcription start site.

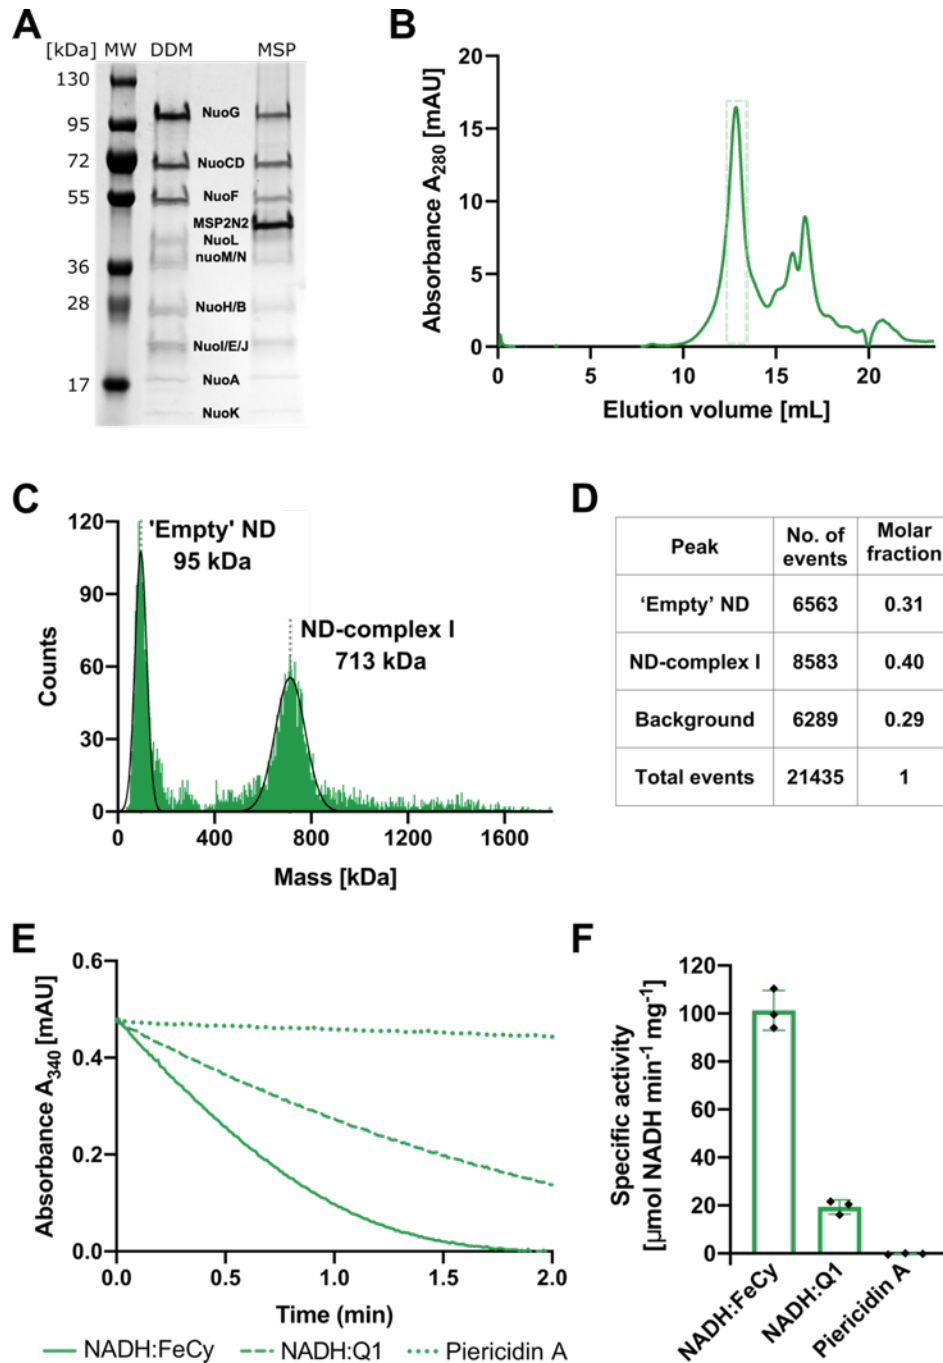

Figure 1 - figure supplement 2 Purification and biochemical characterization of *E. coli* complex I reconstituted into lipid nanodiscs. (A) SDS-PAGE depicting the sample solubilized in detergent after affinity chromatography (DDM) and the sample reconstituted into lipid nanodiscs after size-exclusion chromatography (ND). (B) Size-exclusion chromatography profile after complex I reconstitution into lipid nanodiscs. The main peak at 13 mL consists mostly of the intact reconstituted complex I. Fractions marked by the green, dashed-rectangle were pooled, concentrated, and used for cryo-EM and activity assays. The second peak (retention volume 15 ml and higher) contains empty nanodiscs and the dissociated cytoplasmic arm. (C,D) Mass photometry of the reconstituted complex I pooled form the main gel filtration peak. (C) The representative mass histogram, showing two main peaks: 'Empty' nanodiscs at 95 kDa and the nanodisc-reconstituted complex I at 713 kDa. (D) Molar fractions of components identified in the histogram C. (E) Representative traces of the spectrophotometric activity assays: NADH:FeCy (solid line), NADH:Q1 (dashed line), and NADH:Q1 in the presence of 20 μM Piericidin A (dotted line). The concentration of complex I was 2.5 times lower for NADH:FeCy compared to that for the NADH:Q1 assay. (F) Values of V_{max} for the three assay conditions described in panel (E). The graph shows mean ± SD, n=3. Individual measurement results are indicated as diamonds.

1064 **Figure 2 - figure supplement 1 Conservation of *E. coli*-specific tails in the peripheral arm subunits.** (A)
1065 Insertion into subunit NuoG, the G-loop. (B) C-terminal tails in subunits NuoF, NuoI and NuoB. Color coding of
1066 the subunits is the same as in Figure 1. Conservation was calculated using ConSurf server and is color coded from
1067 green to white to purple as the degree of conservation increases.
1068
Figure 3 - figure supplement 1 Unusual density features. (A) Several surface-exposed histidines (Table 6) have extended density protruding from the imidazole ring in the plane of the ring. These extensions may represent a tightly bound heavy atom, but these features are heterogeneous (length between 2 and 4 Å) and have a very heterogeneous chemical environment; therefore, they cannot be attributed to a single type of bound atom or modification. We tentatively modelled them as water molecules. (B) In three locations, density bridging sulfur atoms of surface-exposed and closely positioned cysteine-methionine couples are bridged by density with reproducible elongated features (Cys-Met: [F]Met76-[F]Cys215, [F]Met94-[E]Cys132, [B]Met106-[B]Cys102). We could not assign the density to any known modification or tightly bound chemical present in the protein purification buffer. Because complex I was purified without reducing agents, the corresponding Cys residues were tentatively modelled as cysteines oxidized to sulfenic acid.
48

Figure 4 - figure supplement 1 Comparison of X-ray and cryo-EM structures of the membrane domain. The cryo-EM structure is colored as in Figure 1, the X-ray model is shown in black. Significant shifts in the cytoplasmic loop of NuoM and the shift of ᴬTM1 are indicated with red arrows. Part of the β-hairpin observed in the crystal structure forms an extension of ᴹTM6a in the cryo-EM structure. This happens despite this loop not being involved in direct crystal contact.
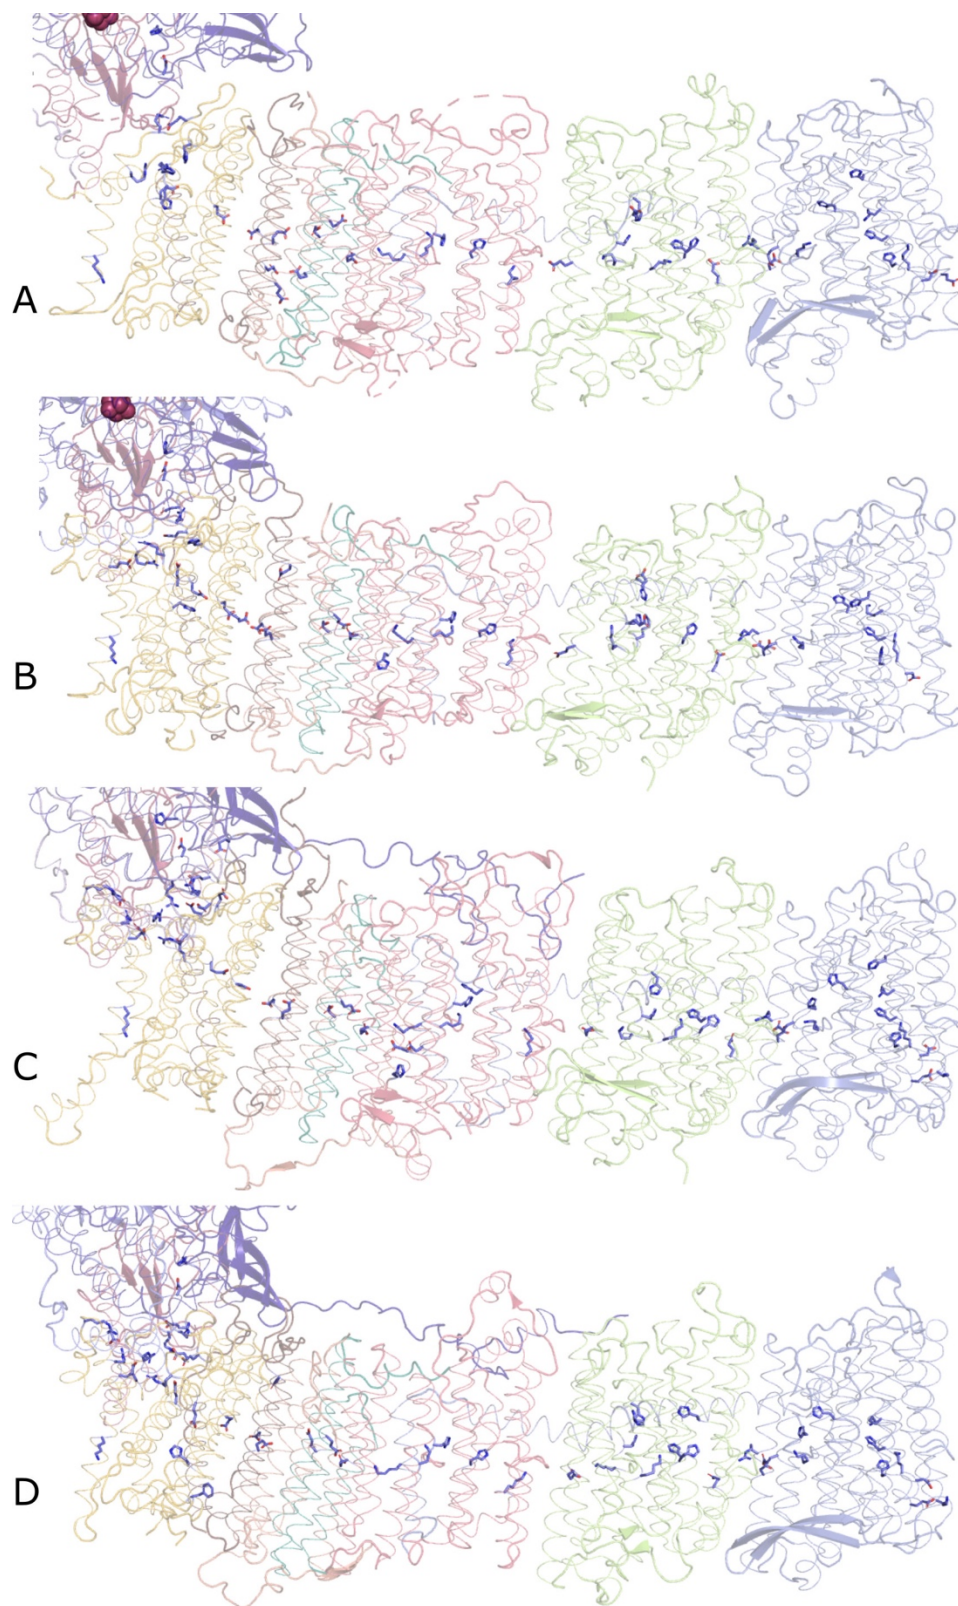

Figure 4 - figure supplement 2 Conserved chain of ionizable residues. Comparison of the chains of ionizable residues lining the Q-cavity and positioned in the hydrophobic region of the lipid membrane in (A) *E. coli*, (B) *T. thermophilus*, (C) *Yarrowia lipolytica,* and (D) *Ovis aries* complex I. In C and D, only the core subunits are shown.
Figure 5 - figure supplement 1 Conserved interface between the arms. (A) Conservation of subunits contributing to the interface between the peripheral and membrane arms, calculated in ConSurf and color-coded from green to white to purple as the degree of conservation increases. Residues directly contributing to the interaction between arms are highlighted. (B) The conserved region of the NuoA TMH1-TMH2 loop forms a plug, which fills a crevice between the subunits NuoD, NuoB, and NuoH.

1105
1106
1107 **Figure 5 - figure supplement 2 B-factors of the peripheral arm show higher mobility at the arms interface**.
1108 The cartoon representation is shown. The peripheral arm is colored by B-factors. The rainbow color palette scales
1109 from 5 Å^2 - blue to 100 Å^2- red. Regions completely disordered in the map of focused reconstruction of the
1110 peripheral arm but showing density in in the reconstructions of the intact complex are colored in black. The
1111 membrane arm is shown in grey for reference.

Table 5 Differences in the hydrogen bond network of iron-sulfur clusters in complex I structures solved at high resolution and water molecules in the immediate cluster environment. (Only the clusters for which such comparison could have been done and clusters displaying differences in the environment are listed)

Cluster, Subunit	Organism		
	E. coli this work	*A. aeolicus* [pdb: 6hla]	*O. aries* [pdb: 6zk9]
N3, NuoF	His400 (+)	Leu395(-)	Leu407(-)
	Trp363(-)	Glu349(+)	Gln361(+)
	Asn196(+)	His198(-)	Lys202(-)
N1b, NuoG	HOH386		HOH1070
N7, NuoG	HOH441		
	HOH577		
	Cys228		Asp229
	Cys231		Asp232
	Cys235		Ser236
	Cys263		Ser264
			HOH929*
			HOH933*
			HOH1005*
N4, NuoG	Thr203(+)		Val205(-)
N5, NuoG	conserved		
N6a, NuoI	Phe92(-)		Tyr109(+)
			HOH539
N6b, NuoI	Leu48(-)		His65(+)
	Cys74(+)		Ala91(-)
	Leu116(-)		Glu133(+)
N2, NouB	HOH438		HOH353
	HOH211		HOH579
	Arg250^D		Arg85 dimethylated
	Ser62		Ala53

* Water molecules replacing the N7 cluster

1194 **Table 6** Histidine residues with unassigned features extending from the imidazole ring
1195

Residue	Modelled atom	Comments
[E]His87	None	Interaction with [E]D146
[E]His150	HOH	Distance 2.1 Å
[E]His152	HOH	Distance 2.4-2.6 Å
[G]His5	HOH	Density on both sides
[G]His101	HOH	Positive environment
[G]His123	HOH	Distance 2.2Å
[G]His427	HOH	Distance 2.85 Å
[G]His653	HOH	Distance 2.5 Å very strong
[CD]His163	HOH	Distance 2.5 Å
[CD]His507	HOH	Distance 4.2 Å
