*equal contribution

Abstract

Bacterial growth within colonies and biofilms is heterogeneous. Local reduction of growth rates has been associated with tolerance against various antibiotics. However, spatial gradients of growth rates are poorly characterized in three-dimensional bacterial colonies. Here, we report two spatially resolved methods for measuring growth rates in bacterial colonies. As bacteria grow and divide, they generate a velocity field that is directly related to the growth rates. We derive profiles of growth rates from the velocity field and show that they are consistent with the profiles obtained by single cell counting. Using these methods, we reveal that even small colonies comprising a few thousand cells of the human pathogen *Neisseria gonorrhoeae* develop a steep gradient of growth rates within two generations. Furthermore, we show that stringent response decelerates growth inhibition at the colony centre. Based on our results, we suggest that aggregation-related growth inhibition can protect gonococci from external stresses even at early biofilm stages.

Introduction

As part of their lifestyle, many if not most bacterial species cluster together and form colonies and biofilms. At the surface of biofilms, bacteria have maximum access to environmental nutrients and space for cell growth and division. At the centre of the biofilm, access to nutrients and space are limited. Therefore, we expect that growth and death dynamics depend on position and time (1-6). However, to determine growth rates with spatial resolution it is necessary to track the offspring of a single cell in space and time. This task is technically demanding within three-dimensional biofilms and there are only few reports that systematically characterize growth rates of biofilm associated bacteria with spatio-temporal resolution (7). Measuring generation times in space and time is crucial for understanding the mechanisms of biofilm development and the development of antibiotic tolerance at the centre of biofilms (8-11).

Bacterial growth has been investigated at the colony level by analysing the colony radius R as a function of time t (3, 12, 13). In young colonies, the colony radius grows exponentially as expected if all cells grow at the same rate. In older colonies, the function $R(t)$ deviates from exponential growth and tends to becomes linear. Simulations indicate that this behaviour is caused by a gradient of growth rates within the colony. Using reporter strains for distinguishing between growing and non-growing cells, it was shown that growth was arrested at the centre of mature biofilms (14-16). However, the corresponding growth rates have not been measured.

Lineage tracking allows for the determination of generation times or growth rates with spatial resolution. Within 2D colonies, individual cell division events are detectable by means of brightfield or fluorescence microscopy and, therefore, lineages arising from a single cell can be tracked (17, 18). In 3D colonies, confocal microscopy or light sheet microscopy enable single cell detection within colonies (19-21). Advanced image analysis techniques have been developed for characterizing local order, gene expression, and stress responses with spatial and temporal resolution (22-24). Growth dynamics of *Vibrio cholerae* has been characterized recently. As a consequence of their rod-like shape, *V. cholerae* shows liquid crystalline order and this structure gives rise to collective, fountain-like motion of bacteria growing in colonies (20). To our knowledge, little work has focussed on the measurement of spatio-temporal growth dynamics within 3D colonies. Given that the size of the bacterial cell body exceeds the limit of optical resolution only ~ (2 - 3) fold, lineage tracking is technically difficult. A recent study reported growth rates in colonies formed by *V. cholerae* (7). Interestingly, the growth rate was constant throughout the colonies and no spatial gradient was observed.

In this study, we investigate collective motion and growth dynamics of spherical bacteria (cocci) within spherical colonies. We show that growth generates radial motion and demonstrate that the spatial profile of growth rates can be inferred from the resulting velocity field. In a complementary approach, we determine the growth rate with spatial resolution by counting the offspring of bacteria within the colony. Combining both techniques, we characterize the growth profile within bacterial colonies during biofilm development. At the edge of the colony, the growth rate remains constant for several hours. Within the colony, a gradient of growth rates develops and growth ceases close to the colony centre. We show that inhibition of stringent response accelerates growth inhibition at the colony centre. We conclude that spatial gradients develop rapidly even in relatively small colonies containing several thousands of bacteria.

Colony growth indicates a transition from homogeneous growth to heterogeneous growth.

In the first step, we characterized the growth of 3D wt* gonococcal colonies. Colonies were formed in liquid and subsequently introduced into a flow chamber where growth was monitored for many hours under constant nutrient flow. The radii R of the growing colonies were measured as a function of time. Assuming constant cell density, we derived the number of cells within the colony relative to the number of cells at the start of the experiment $t = 0$, $N_{col}(t)/N_{col}(0) = (R(t)/R(0))^3$. The number of cells increased exponentially during the initial 2 h (Fig. 1). Using an exponential fit $N_{col}(t)/N_{col}(0) = exp(\lambda_{colony}t)$ we found that the growth rate was $\lambda_{colony} = (0.56 \pm 0.01)h^{-1}$. After 2h, $N_{col}(t)/N_{col}(0)$ deviated from an exponential behaviour. In the next step, *sfgfp* expressing bacteria (*wt* green*) will be used for determining the growth rate at spatial resolution. *sfgfp* was expressed under the strong *pilE* promoter to ensure detectability of all fluorescent cells. We assessed whether expression and illumination of the fluorescent marker caused a growth defect by quantifying growth of *wt* green* colonies and found a transition from exponential growth to sub-exponential growth at the same colony age as for *wt** colonies (Fig. 1). The growth rate was $\lambda_{colony}^{green} = (0.42 \pm 0.01)h^{-1}$. This difference must be considered in the single cell counting analysis discussed later.

3
Fig. 1 Expression of *sfgfp* slightly reduces growth rate. Mean number of cells within colony $N_{col}(t)$ normalized by the number of cells in the colony at $t = 0$, $N_{col}(0)$ for wt* (Ng150, black) and wt* green (Ng194, grey). Full lines: exponential fits with $N_{col}(t)/N_{col}(0) = exp(\lambda_{colony}t)$. $\lambda_{colony,wt*} = (0.56 \pm 0.01)h^{-1}$ and $\lambda_{colony,wt*green} = (0.42 \pm 0.01)h^{-1}$. (mean $\pm$ se, > 40 colonies for each data point).

Based on the growth analysis at the colony level, we predict that the profile of growth rates is homogeneous during the initial 2 h of growth and spatial heterogeneity develops after 2 h.

Lineage tracking within 3D colonies.

We developed a lineage tracking method for measuring growth rates of *N. gonorrhoeae* (gonococcus) within colonies. Recently, the growth rate of rod-shaped cells was measured by quantifying temporal changes in cell length along the major axis of the rod (7). In cocci, this method is hampered by the fact that the change in aspect ratio prior to cell division is small and, additionally, the division plane switches every generation (25). Instead, we track lineages within colonies. *N. gonorrhoeae* form spherical colonies (24, 26). Tracking of all cells individually over multiple generations is prohibited by three factors. Firstly, gonococci are very densely packed (24), and secondly, type 4 pilus mediated interactions between the cells cause them to move actively (27). As a consequence, high time resolution would be necessary to allow for single cell tracking and the associated photodamage would prohibit growth rate analysis. Furthermore, background fluorescence in colonies consisting exclusively of fluorescent cells would prohibit single cell detection.

4

110 To avoid these problems, we tracked the offspring of single or few fluorescent cells. A small

111 fraction of *sfgfp*-expressing cells (*wt green*) was mixed with non-fluorescent wt* cells. This

112 mixture was inoculated into a flow chamber. Medium was continuously flushed through the

113 chamber, providing constant nutrient and oxygen supply for multiple hours. The medium

114 contained propidium iodide (PI), a fluorescent dye that stains dead cells. The fluorescence

115 signals of growing colonies were detected using confocal microscopy (Fig. 2a). Individual

116 fluorescent cells were identified and their positions within the colonies were determined (Fig.

117 2b, Movie S1). The circumference of the colony was determined using the brightfield images

118 (Fig. 2c, Movie S2).

125 single cluster. Blue line: Trajectory of centre of mass of cluster. White line: Edge of colony. Red circle: Circle
126 depicting radius of colony. Scale bars: 10 µm.

127

5

128 A cluster was defined as an assembly of *wt* green* cells residing in close proximity (Movie S3).

129 Given that only few fluorescent (one percent at the beginning of the experiment) cells were

130 immersed within the colony initially, *wt* green* cells can be associated with specific clusters.

131 The cells within the cluster are the offspring of a single or few cells contained within the cluster

132 at time $t = 0$. In the following two paragraphs, we will describe how the analysis of these

133 clusters allows us to measure the growth rate with spatial resolution. First, we counted the

134 number of cells, *N*, within the cluster, reflecting the growth rate of *wt* green* cells within the

135 cluster. Second, we analysed the cluster velocity which is influenced by the growth of all cells

136 (mostly *wt** cells) residing closer to the colony centre than the cluster and pushing the cluster

137 towards the edge of the colony.

138

139 **Cell counting (CC) method: Single cell counting reveals that local growth rates decline**

140 **rapidly at the centre of growing colonies.**

141 The spatially resolved growth rate was measured by counting the number of *wt* green* cells

142 within a cluster, *N*, as a function of time. One example of a cluster arising from a single cell is

143 shown in Fig. 3a, b and Movies S2, S3. In this example, the first three cell division events occur

144 nearly simultaneously for all cells belonging to the cluster with a generation time of ~ 90 min.

145 We determined the effective local growth rate λ by fitting $N(t + \tau)/N(t) = exp(\lambda\tau)$ with $\tau =$

146 $(0 - 1.5) \, h$ as described in the Materials and Methods. The growth rate was $\lambda \approx 0.45 \, h^{-1}$ close

147 to the edge of the colony (Fig. 3c, Fig. S2). This growth rate corresponds to a generation time

148 of $T \approx 1.5 \, h$. While the growth rate at the edge of the colony remained close to $\lambda \approx 0.45 \, h^{-1}$

149 up to 4.5 h after inoculation, the growth rate decreased as a function of the penetration depth

150 into the colony. The spatial profile of growth rates was shallow for young colonies. At $t > 2 \, h$,

151 growth rates dropped severely and growth ceased near the centres of the colonies. The

152 development of heterogeneous growth after 2 h is consistent with the transition from

153 exponential to linear growth of the colony radius at 2 h (Fig. 1).

154 The effective growth rate λ depends on cell duplications and on cell death. Therefore, we

155 determined the fractions of dead cells $f_{dead} = N_{dead}/N_{total}$ with spatial and temporal

156 resolution (Fig. 3d). To this end, we added propidium iodide (PI) to the medium. PI stains cells

157 with permeable membranes, indicating cell death. Please note that for determination of N_{total} we

158 assumed that the density ρ of cells is constant throughout the colony. Within $r_e \leq 3 \, \mu m$ the cell

159 density is lower compared to the remainder of the colony (Fig. 4c) and, therefore, the fraction

6

160 of dead cells is overestimated in this regime. Most importantly, the fractions of dead cells were

161 $f_{dead} < 5\%$ for all positions and timepoints. Therefore, the influence of cell death on the

162 changes in $N(t)$ is negligible and the effective growth rate λ determined in our experiment is

163 very close to the real growth rate and the term "effective" will be discarded in the following. In

164 older colonies, the fraction of dead cells at the centres of the colonies increased most strongly.

170 deviation) as a function of time.

171

7

172   In summary, after a short initial period of exponential growth, complex spatio-temporal growth

173   profiles developed within gonococcal colonies with severely reduced growth at the colony

174   centres.

175

176   **Velocity field (VF) method: The generation time can be determined from the radial flow**

177   **of clusters.**

178   Cell growth and division generate collective cellular movement directed from the centre of the

179   colony towards its periphery (Fig. 4a). In one- and two-dimensional systems, analysis of this

180   cellular movement has been employed to infer concentration profiles of nutrients and nutrient

181   uptake functions bacterial populations (28). Here, we show that the velocity field can be used

182   for determining the growth rate with spatial resolution in spherical colonies. The velocity of

183   cluster movement $\vec{v}(r_c)$ was determined by analysing the trajectories of the centres of mass of

184   individual clusters (Fig. 4a). Because of the spherical symmetry of the colony, the radial

185   velocity associated with growth is $v(r_c) = \vec{v}\vec{e}_r$, i.e. the velocity vector was projected onto the

186   unit vector $\vec{e}_r$ pointing from the colony centre towards its edge, yielding the radial component

187   of the cluster velocity $v(r_c)$. $v(r_c)$ was close to zero at the centre of the colony at $r_c \approx 0$ (Fig.

188   4a, b). With increasing distance from the centre, r_c, the velocity of clusters increased. At a

189   colony age of less than 2 h, the speed increased linearly as a function of r_c with $v(r_c) =$

190     $(0.17 \pm 0.01) \, h^{-1} \cdot r_c$ (Fig. S3). In older colonies, the speed decreased and $v(r_c)$ became

191   nonlinear consistent with heterogeneous growth.

192
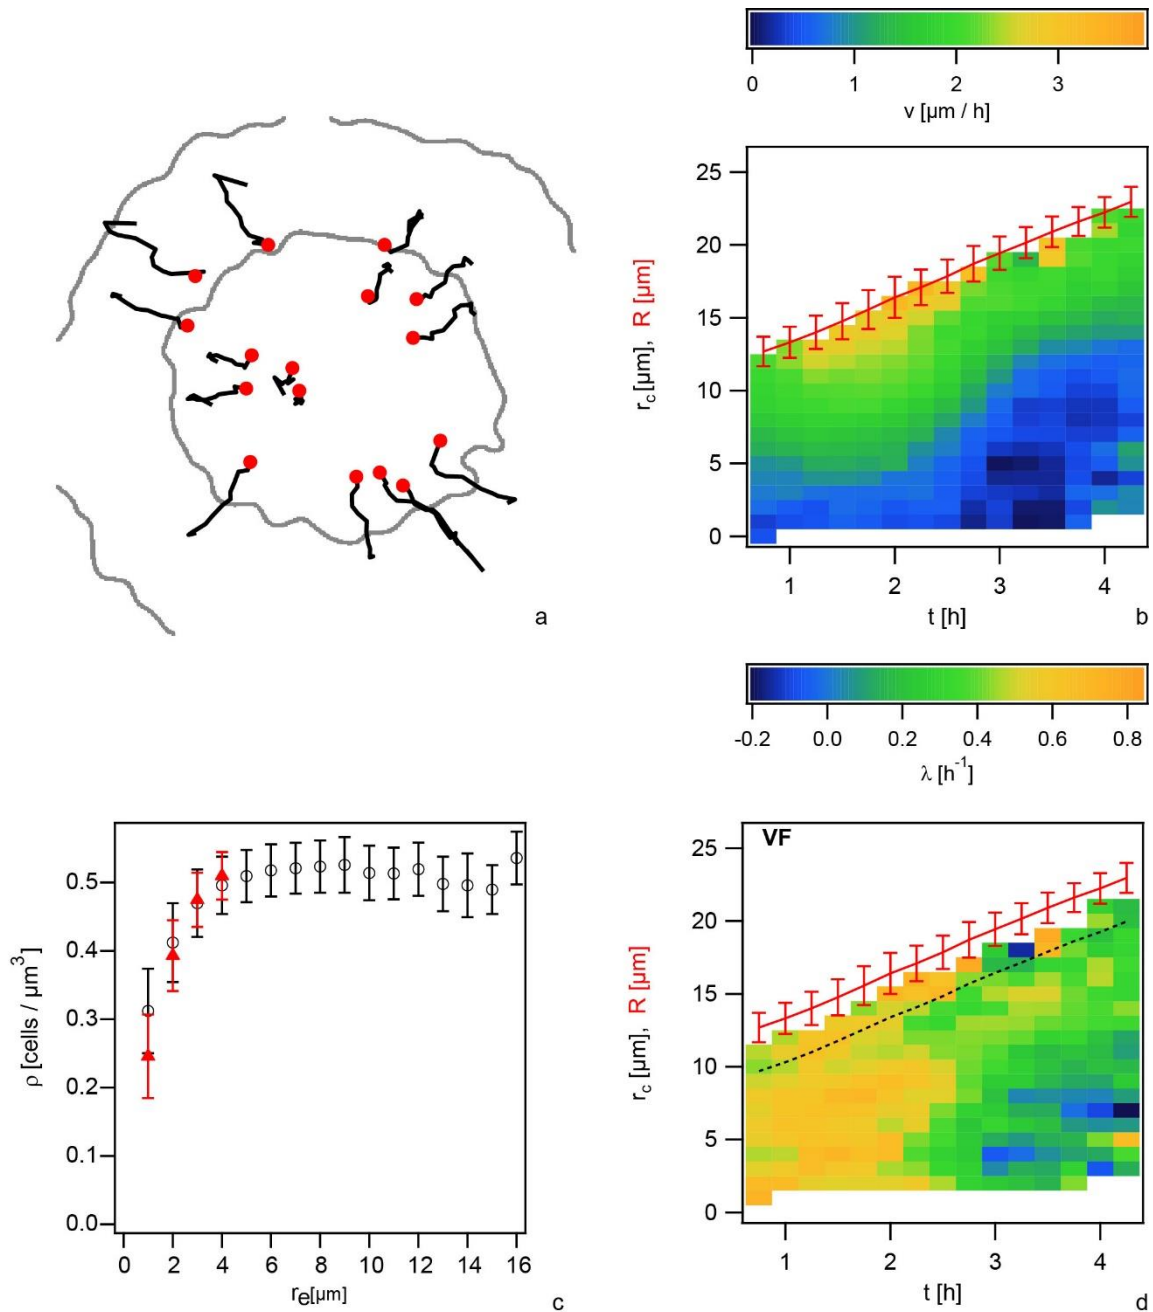

Fig. 4 Growth rates inferred from velocity field of wt* green (Ng194) mixed with wt* (Ng150). a) Trajectories of individual clusters moving within one colony acquired over 3 h. Clusters residing at different heights within the colony are projected into one plane. Red circles: Start of trajectory, black lines: trajectories, grey lines: outlines of colony at 0 h and 3 h, respectively. b) Radial components of cluster velocities v as a function of distance from centre of colony (r_c) and time t. Red: Mean colony radius ($\pm$ standard deviation) as a function of time. c) Cell density ρ profile through colony. Black circles: cylindric coordinates, red triangles: spherical coordinates. d) Growth rates λ (colour coded) inferred from velocity field as a function of distance from centre of colony (r_c) and time t. Red line: Mean colony radius ($\pm$ standard deviation) as a function of time. Black dotted line: denotes area in which reduced cell density introduces a systematic error to λ.

By analysing the flow field $v(r_c, t)$, we can infer the growth rate $\lambda(r_c, t)$. To this end, we formulate the continuity equation with a growth term $\lambda\rho$ which breaks mass conservation

$$\dot{\rho} = -\vec{\nabla} \cdot (\vec{v}\rho) + \lambda\rho \qquad \text{(eq. 1)}$$

207 Here, $\rho(\vec{r}, t)$ is the spatially and temporally varying number density of cells in the colony. We

208 find that the cell density is constant within the colony, but the density decreases at $r_e \leq 3\ \mu m$

209 (Fig. 4c) in agreement with theoretical predictions (29). In the following, we disregard the low-

210 density area at the colony edge. First, we consider colonies with an age t < 2 h. During this

211 period of time, the growth rate is nearly constant in space and time. In this regime, eq. 1

212 simplifies to $\lambda = 3v_{cluster}/r$. The linear fit shown in Fig. S3a provides $\lambda = (0.51 \pm 0.01)h^{-1}$.

213 This value is slightly higher than the growth rate determined by the CC method (Fig. 3).

214 Next, we consider older colonies with an age t > 2 h. In these colonies, the growth rate depends

215 on position. By numerically solving eq. 1 and assuming constant ρ, i.e. $\partial_r(r^2 v_r) = r^2 \lambda$, we

216 calculate the growth rate $\lambda(r_e, t)$ (Fig. 4d). Importantly, we find the same qualitative profiles as

217 by the cell counting method (Fig. 3c, Fig. S3). At t < 2 h, the growth rates are spatially

218 homogeneous. In older colonies, the growth rate decreases as a function of distance from the

219 edge of the colony. The total growth rates in Fig. 4d are slightly but significantly higher

220 compared to the rates shown in Fig. 3c. The reason for this small quantitative discrepancy can

221 be explained as follows. The velocity of the cluster formed by wt* green cells is determined by

222 all cells residing at a position $r_c < r_c^{cluster}$. Given that only 1 % of the cells within the colony

223 was fluorescent, the cluster velocity is determined by the growth of *wt**. By contrast, the cell

224 counting method used for Fig. 3 relies exclusively on wt* green cells which have a lower growth

225 rate (Fig. 1).

226 In conclusion, bacteria move radially from the centre towards the periphery of the colony as a

227 consequence of cell growth and the velocity field allows determining the growth rate. This

228 method confirms that a characteristic growth profile develops after only two generations of

229 growth within the colony.

230

231 **Nutrient supply is nearly saturating.** Unexpectedly, the growth rate decreased even within

232 small colonies continuously supplied with rich medium. We hypothesized that either a

233 metabolite or oxygen were depleted at the centres of the colonies. To assess this hypothesis, we

234 increased the flow rate of the medium 5 fold. Indeed, the growth rate increased slightly (Fig.

235 S4, S5). However, the colony radius grew exponentially only for 2 h, indicating that growth

236 became heterogeneous. Reminiscent of the experiments run under standard flow rates, after 2

237 h of growth, the growth rate decreased strongly as a function of penetration depth (Fig. S4).

238 This behaviour was observed consistently with the cell counting (CC) method and with the

239 velocity field (VF) method. We conclude, therefore, that limitation of nutrients or oxygen is not
240 the main cause for the growth inhibition in gonococcal colonies.

241

Lack of stringent response influences the spatio-temporal growth dynamics.

243 Limitation of nutrients at the centre of colonies is one potential explanation for decreased
244 growth rate. The stringent response is involved in adaptation to nutrient limitation including
245 amino acid, carbon, and fatty acid starvation (30, 31). RelA and SpoT adjust the level of
246 (p)ppGpp, whose accumulation triggers stringent response (32). Deletion of *relA* suppresses
247 (p)ppGpp production in gonococci and deletion of *spoT* unmakes the growth defect caused by
248 *relA* deletion alone (33). We addressed the question whether stringent response affected growth
249 and death in our system. To this end, we mixed *ΔrelA ΔspoT green* cells with *ΔrelA ΔspoT* cells
250 and characterized the spatio-temporal dynamics of growth and death in these mixed colonies
251 (Fig. 5).

252 We found that at early time points the growth rates of the *ΔrelA ΔspoT* colonies were higher
253 compared to the rates in *wt** colonies (Fig. 5, Fig. S5, S6). However, the growth rates dropped
254 even in young colonies after t > 1 h at the colony centre (Fig. 5, Fig. S5, S6). This behaviour
255 was found both by the CC method (Fig. 5a), by the VF method (Fig. 5b, c), and by analysing
256 the total number of cells within colonies (Fig. S6). The fraction of dead cells close to the colony
257 centre was higher by a factor of ~ 2 in the *ΔrelA ΔspoT* compared to the fractions in *wt** colonies
258 (Fig. 5d).

259
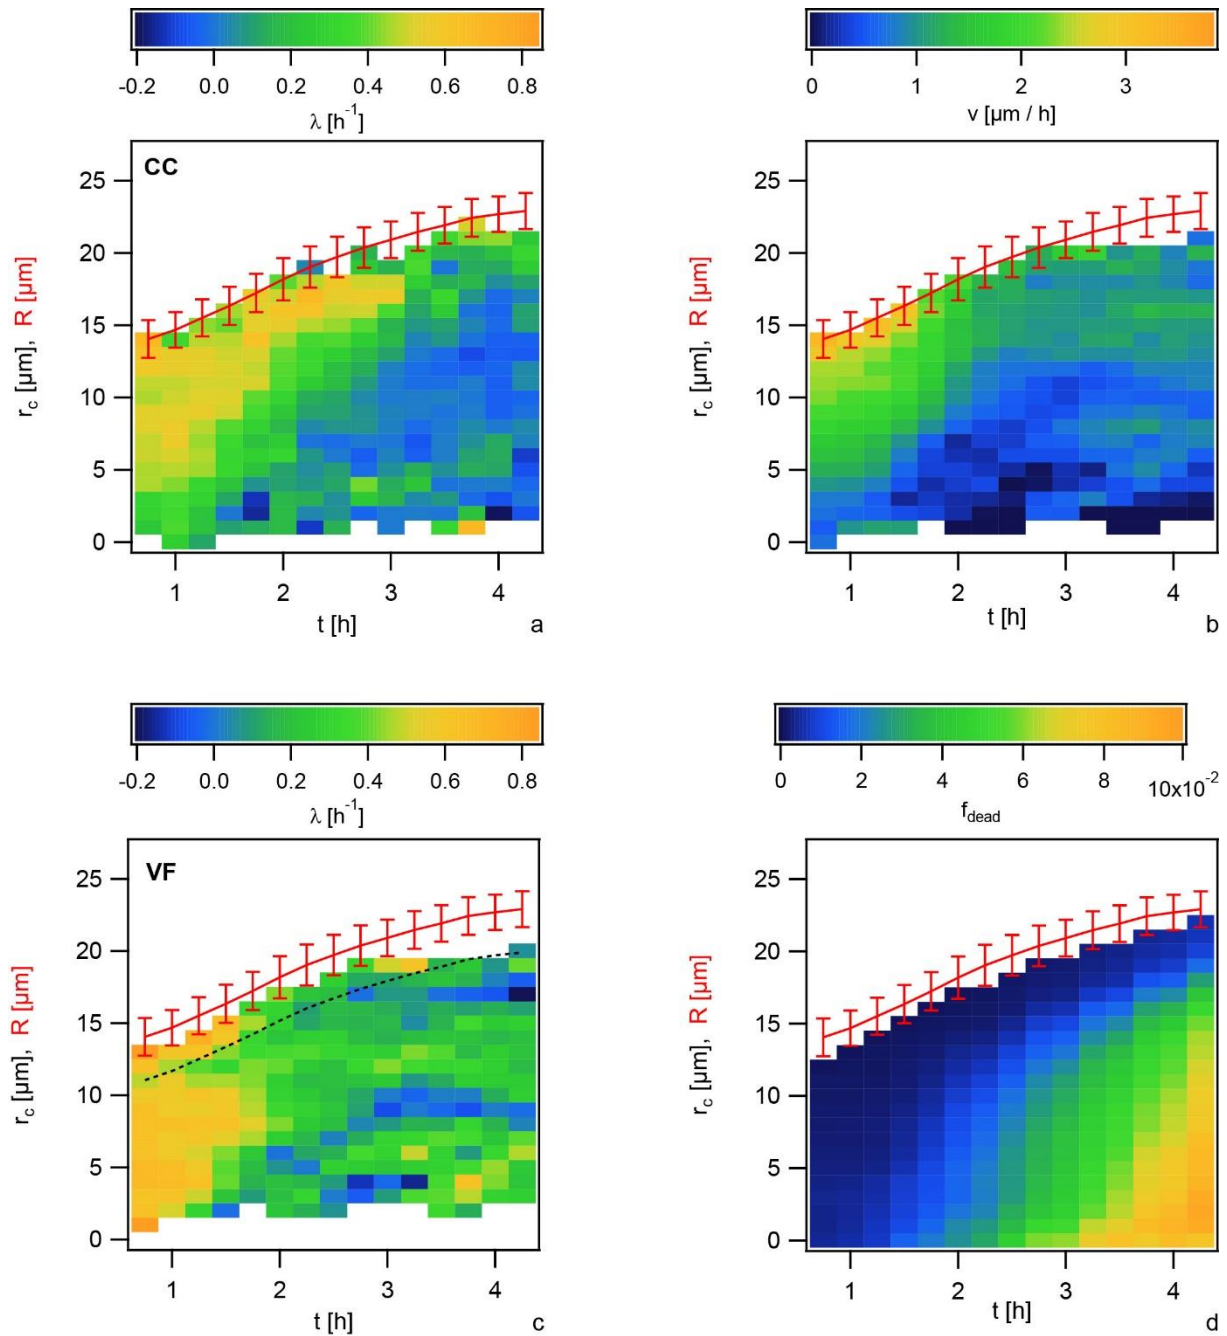

Fig. 5 Stringent response affects growth and death dynamics. *ΔrelA ΔspoT green* (Ng224) were mixed with *ΔrelA ΔspoT* (Ng198). a) Growth rate λ (colour coded) as a function of distance from centre of colony (r_c) and time t. (CC method) b) Radial components of cluster velocities v as a function of of distance from centre of colony (r_c) and time t. c) Growth rates λ (colour coded) as a function of distance from centre of colony (r_c) and time t. Black dotted line: denotes area in which reduced cell density introduces a systematic error to λ. (VF method) d) Fraction of dead cells f_{dead} (colour coded) as a function of distance from centre of colony (r_c) and time t. Red lines: Mean colony radius ($\pm$ standard deviation) as a function of time.

Taken together we found that inhibition of stringent response affects growth and death within the colony. Specifically, growth arrest in stringent response deficient colonies occurs prematurely.

12

272

Discussion

Potentials and limitations of different methods for determining growth rates.

275   Measuring growth rates is tricky and prone to various errors. The classic method for
276   determining growth rates, i.e. the determination of optical density (OD600) as a function of
277   time during bacterial growth, yields the growth rate, aka. Malthusian parameter. While this
278   method is well-accepted, it is prone to various errors often ignored in the literature. For
279   example, adhesion between bacteria and between bacteria and surface reduces the OD600
280   mimicking reduced growth rates (34). Furthermore, the OD600 can be susceptible to changes
281   in gene expression or changes in cell size affecting the optical properties of the bacteria. One
282   of the most accurate methods for determining relative changes in growth rates through
283   mutations is the competition assay (35, 36). But even this method is error-prone; for example,
284   cellular interactions like toxin secretion can falsify the growth rates determined by this method.

285   The methods introduced here, are based on single cell visualization and, therefore, circumvent
286   the problems described above. We developed two different methods allowing to determine
287   growth rates at spatial resolution. As discussed in the following, both methods implicate
288   complementary advantages and disadvantages. We propose combining both methods to
289   robustly characterize the growth profile within bacterial colonies. First, by counting the number
290   of off-spring of one or few fluorescent cells over short periods of time, the growth rates were
291   determined (CC method). Most importantly, this method allows characterising rates with spatial
292   and temporal resolution. It relies on detection of single cells within a large 3D structure and,
293   therefore, sufficiently strong fluorescence signal of individual cells is essential. To achieve a
294   high signal-to noise ratio, *sfgfp* was expressed under the control of the strong *pilE* promoter
295   causing a reduction of growth rate (Fig. 1). Second, we inferred the growth rates from the
296   velocity field caused by cell growth (VF method). This method does not suffer from effects
297   related to *sfgfp* expression or cell damage by laser light because the fraction of *wt* green* cells
298   was only 1 % and the velocity field is dominated by *wt** cells. However, the method is
299   susceptible to changes in cell density. Under the conditions studied, cell density was constant
300   within the bulk of the colony, but decreased considerably at the edge of the colony. Therefore,
301   the growth rate could not be determined in this region with the second method. Some external
302   stresses cause swelling of cells (21). Swelling would cause the colony to expand and would
303   introduce errors to the determination of growth rates. While both methods have complementary
304   problems, they yield comparable growth profiles. Quantitatively, the VF-method tends to

13

305   provide slightly higher growth rates consistent with the values determined for the total numbers
306   of cells within a colony derived from the colony radii.

307   Growth of gonococci was considerably more efficient on agar plates. In earlier work, we
308   characterized gonococcal growth in fluorescent colonies on agar plates by quantifying the
309   fluorescence intensity as a function of time (37, 38). Exponential colony growth proceeded for
310   many hours and the growth rates were considerably higher. In the agar plate assay, bacteria
311   grew into flat colonies for many generations and this geometric difference together with
312   different concentrations of O_2 and CO_2 can explain the discrepancy.

313

314   **Within few generations, growth rates become spatially heterogeneous and stringent**
315   **response retards development of heterogeneity.**

316   Rather unexpectedly we found that a characteristic growth profile develops within small
317   gonococcal colonies after no more than two generations under continuous supply of medium
318   optimized for gonococcal growth. The growth rate is constant as a function of time within a 3
319   µm ring at the periphery of the colony. Remarkably, this is the low-density area. Within the
320   colony, the growth rate decreases continuously as a function of penetration depth and growth
321   stops at a depth of ~ 10 µm corresponding to ~ 10 bacteria. Interestingly, this gradient develops
322   even faster when stringent response is inhibited. This result suggests that stringent response
323   drives the cells to reallocate their resources more efficiently to maintain growth within colonies
324   and we conclude that stringent response plays a role in adaptation to life in colonies as shown
325   for biofilms formed by other species (9).

326   What inhibits growth at the centre of gonococcal colonies? Depletion of nutrients or O_2 might
327   be responsible for growth inhibition. Cells residing at the colony edge are likely to deplete
328   nutrients, generating a gradient of nutrient / O_2 concentration (28). By increasing the flow rate,
329   nutrient concentrations close to the centres of the colonies would increase. Therefore, we would
330   expect a delay of the onset of growth inhibition. However, we showed that increasing the flow
331   rate did not shift the onset of growth arrest at the centre of the colony considerably. Therefore,
332   we think that mechanical constraints are likely to limit growth within the colony (39-41).
333   Gonococci are tightly packed within colonies with an estimated volume fraction of $\Phi \approx 0.5$
334   and mechanical stress building up as cells grow, might inhibit cellular proliferation (6). We
335   have shown that freshly assembled colonies rearrange with a relaxation time of ~ 1 min (24),
336   suggesting that mechanical constraints should not limit proliferation in young colonies. Future

14

337   studies need to address mechanical properties of older colonies and effects of nutrient limitation

338   on the growth profile.

339   To our knowledge, growth rates have been determined with spatial resolution only for *V.*

340   *cholerae* colonies so far (7). There, growth rates were constant even at a penetration depth of

341   30 µm. Different bacterial densities and cell shapes may explain the different growth profiles.

342   The volume fraction Φ of *V. cholerae* of $\Phi \approx 0.2$ (42) was considerably lower compared to *N.*

343   *gonorrhoeae*. Moreover, for rod-shaped *V. cholerae* orient vertically and move collectively as

344   the colony grows and expands (20). For spherical gonococci, however, we find a radial flow at

345   early times whose speed declines as the colony ages.

346

Conclusion

348   The rapid growth arrest at the centres of the gonococcal colonies suggests that aggregation can

349   rapidly cause tolerance against antibiotics acting on growing bacteria. This is consistent with

350   previous reports showing that gonococcal aggregation enhances their survivability under

351   ceftriaxone treatment with the fraction of dead cells being highest at the colony edge (21, 43).

352   Our methods are applicable to all spherical colonies and it will be interesting to compare the

353   growth profiles between different species.

354

Materials and Methods

357   **Growth conditions.** Gonococcal (GC) base agar was made from 10 g/l dehydrated agar (BD

358   Biosciences, Bedford, MA), 5 g/l NaCl (Roth, Darmstadt, Germany), 4 g/l K_2HPO_4 (Roth), 1

359   g/l KH_2PO_4 (Roth), 15 g/l Proteose Peptone No. 3 (BD Biosciences), 0.5 g/l soluble starch

360   (Sigma-Aldrich, St. Louis, MO), and supplemented with 1% IsoVitaleX (IVX): 1 g/l D-glucose

361   (Roth), 0.1 g/l L-glutamine (Roth), 0.289 g/l L-cysteine-HCL x H_2O (Roth), 1 mg/l thiamine

362   pyrophosphate (Sigma-Aldrich), 0.2 mg/l $Fe(NO_3)_3$ (Sigma-Aldrich), 0.03 mg/l thiamine HCl

363   (Roth), 0.13 mg/l 4-aminobenzoic acid (Sigma-Aldrich), 2.5 mg/l β-nicotinamide adenine

364   dinucleotide (Roth), and 0.1 mg/l vitamin B12 (Sigma-Aldrich). GC medium is identical to the

365   base agar composition but lacks agar and starch.

366

367   **Bacterial strains.** All strains used in this study (Table S1) are based on *N. gonorrhoeae* strain

368   Ng150 (4), here called *wt**. In this strain, we deleted the G4 motif responsible for pilin antigenic

15

369   variation. If this motif were present, the primary structure of the major pilin PilE would vary

370   and this variation may affect T4P-T4P interactions and colony dynamics (44).

371   For construction of *wt* green*, the *pilE* promotor region (P_{pilE}) was amplified from genomic

372   DNA of strain NG150 (ΔG4) using primers TC22 (5'-

373   AGTTCTTCACCTTTGCTAACCATAAAATTACTCCTAATT GAAAGGGGAAATG-3')

374   and NB065 (5'-TTTTAATTAATTCCGACCCAA TCAACACACCC-3'). The *sfgfp* gene

375   sequence was amplified from plasmid pET28a-*sfgfp* (Addgene, Plasmid #85492) with primers

376   TC21 (5'-CATTTCCCCTTTCAATTAGGAG

377   TAATTTTATGGTTAGCAAAGGTGAAGAACT-3') and NB066 (5'-

378   TTGGCCGGCCTTATTTATACAGTTCATCCATACCGTG-3'). Both fragments were

379   subsequently merged in a fusion-PCR: fragments were mixed in a 1:1 ratio and a PCR was

380   performed for 20 cycles without the addition of primers. Afterwards, primers NB065 and

381   NB066 were added to the reaction and the PCR was continued for another 20 cycles. The

382   obtained fusion product *PpilE-sfgfp* was subsequently subcloned into the vector pLAS (38) via

383   FseI and PacI (New England Biolabs) digest. The generated plasmid pLAS-*sfgfp* was

384   transformed into *E. coli* DH5α and transformants were selected on LB-agar plates containing

385   kanamycin. The correct sequence of the vector insert was verified by sequencing with primers

386   TC19 (5'- CCTTAATTAAGGTTATTTATACAGTTCATCCATACCGTG-3') and TC20 (5'-

387   TCTGGCCGGCCTTCCGACCCAATCAACACACC-3'). Finally, the plasmid was

388   transformed into strain NG150 (ΔG4) to insert the *PpilE-sfgfp* gene between the *lctP* and *aspC*

389   loci. Transformants were selected on GC-agar plates containing spectinomycin. Expression of

390   *sfgfp* was confirmed via fluorescence microscopy.

391   Strain *ΔrelA ΔspoT* (Ng198) was constructed as follows. Regions upstream and downstream of

392   *relA* gene were amplified from isolated genomic DNA of strain ΔG4 (Ng150). PCRs were

393   performed using primers GS_043 (5'-TATGCTGACCGGGGTTTTGG-3') and GS_044 (3'-

394   TTAAACCAGTTCCT CTCATCATTTACGGTGCATAGGCGGG-5') for amplification of

395   *relA*-5'UTR, whereas GS_047 (5'- TGTCTCATTCCGCTTCCGTA

396   GGATAACGCTTCAGACGGCA-3') and GS_048 (3'- GCG GTCGTTAA AACTCCCGAA-

397   5') were applied for *relA*-3'UTR. *kanR* was amplified from Kanamycin resistant strain Ng050

398   using primers GS_045 (5'- GAT

399   GAGAGGAACTGGTTTAAATATCGTCGCAAGATGCGGT-3') and GS_046 (3'-

400   TACGGAAG CGGAATGAGACA GTCCCGTCAAGTCAGCGTAA-5'). The resulting three

401   single fragments were linked by Fusion-PCR and transformed into strain Ng150. Transformants

402   (Ng197) were selected on GC-agar plates containing kanamycin. Deletion of *relA* was

16

403   confirmed by sequencing with primers GS_043 (5'- TAT GCTGACCGGGGTTTTGG-3'),

404   GS_045 (5'-GATGAGAGGAACTGGTTTAAATATCG TCGCAAGATG CGGT-3') and

405   GS_046 (3'- TACGGAAGCGGAATGAGACAGTCCCGTCAAGTCAGC GTAA-5')

406   Deletion of *spoT* was achieved by amplifying *spoT*-5'UTR from gDNA of ΔG4 strain (Ng150)

407   with primers GS_037 (5'- TGCGCCGGCAAGTATGAATAC-3') and GS_038 (3'-

408   TAATAAGTAAAG CAGGTAAAACGGGTTGC-5'). For amplification of *spo*T-3'UTR

409   primers GS_041 (5'-CACGAGCT CCTTCAGACGGCTTTCGGGATG-3') and GS_042 (3'-

410   GGTTGGAAAATATACAGGTAAAAAATATG TCC-5') were used. Isolated plasmid DNA

411   of *ermR-pIGA* served as template for amplification of *ermC* with primers GS_039 (5'-

412   TTTACCTGCTTTACTTATTAAATAATTTATAGCTATTGAAAAG-3') and GS_040 (3'-

413   GCCGTCTGAAGGAGCTCGTGCTATAATTATAC-5'). PCR-products were merged by

414   Fusion-PCR, transformed strain Ng197 and selected on GC-plates containing erythromycin,

415   resulting in strain *ΔrelA ΔspoT* (Ng198). Replacement of *spoT* by *ermC* was verified via

416   sequencing using primers GS_037 (5'- TGC GCCGGCAAGTATGAATAC-3'), GS_ 049 (5'-

417   ATTGCCGAACCCGCCGTTCT-3'), GS_050 (5`- GCA AACCCGTATTCCACGAT-3') and

418   GS_51 (5'- CGGTCGGTTTGTTATTGCGG-3').

419   *sfgfp* is expressed under the control of the *pilE* promoter with has high expression levels. We

420   investigated whether *sfgfp* expression affects the growth rate of gonococci in our assay by

421   comparing the number of cells per colonies $N_{col}(t)$ as a function of time (Fig. 1). We found that

422   the growth rate of *wt* green* cells expressing *sfgfp* is 14 % lower compared to *wt** cells that do

423   not express fluorescent proteins. Therefore, the growth rate determined by counting the number

424   of *wt* green* cells per cluster, *N(t)*, is expected to be lower compared to the growth rate

425   determined from colony growth during the exponential phase in agreement with Fig. 3a.

426

427   **Confocal microscopy.** *wt** and *wt* green* cells were grown for 14 h on GC + IsoVitaleX plates

428   at 37ºC, 5% CO_2 and re-suspended in 5 mL GC + IVX medium at an OD 0.1. The ratio of non-

429   fluorescent *wt** and fluorescent *wt* green* cells was set to 100:1. Supplementation of 100 µL

430   miliQ water dissolves existing bacterial colonies and shaking at 37ºC, 5% CO2 for 30 minutes

431   allows for colony reassembly. From this suspension, 250 µL are injected into a microfluidic

432   flow chamber (Ibidi Luer 0.8 mm channel height + Ibitreat) connected to a peristaltic pump

433   (model 205U; Watson Marlow, Falmouth, United Kingdom) for constant nutrient supply of 1

434   rpm (standard flow rate) or 5 rpm (five-fold flow rate) (GC + IVX + 0.004%PI). Prior usage,

435   all flow chambers were coated with Poly-L-Lysine (Sigma, Cat. No. P4832, 50 µg/ml).

436   Images were acquired using an inverted microscope (Ti-E, Nikon) equipped with a spinning

437   disc confocal unit (CSU-X1, Yokogawa) and a 100x, 1.49 NA, oil immersion objective lens.

438   The excitation wave lengths were 488 and 561 nm. The sfGFP signal of the cells and a bright-

439   field image were recorded for 5 h every 15 min. Starting from the surface of the glass coverslide,

440   40 µm x 40 µm x 25 µm large image stacks with a voxel size of 0.08 µm x 0.08 µm x 0.4 µm

441   were acquired.

442

443   **Detection of single cell positions and cluster analysis.** Bright-field images were used to

444   determine the colonies' centers of mass and radius. For this purpose, a circle was fitted to the

445   colony contour, which is determined by a threshold applied on the filtered bright-field images.

446   The height of the center of mass of the colony was estimated with 0.85 x colony radius.

447   From the confocal image stacks, single cell positions of *wt* green* cells were determined. All

448   confocal images were registered using the center of mass of the colony and stretched by a factor

449   of 3 in z-direction to obtain spherical intensity profiles of all particles. Every image voxel was

450   taken to the power of 3 to increase the image contrast. The mean intensity profile of several

451   different monococci inside bacterial colonies were used to generate a symmetrical 3D kernel

452   for convolution of all images. Spheroidal features were found using the MATLAB feature3d

453   function written by Yongxiang Gao and Maria Kilfoil (45) based on IDL code written by John

454   C. Crocker and David G. Grier (46). Clusters are defined by spheroidal features, which are less

455   than 2 µm apart from each other. Because the number of clusters is much smaller compared to

456   the number of features, clusters can be tracked by the MATLAB trackmem function written by

457   Maria Kilfoil, again based on IDL code written by John C. Crocker. We applied the tracking

458   algorithm to cluster positions located in time intervals $[t, t + 1.5h]$ with $t \in [0h: 0.25h: 3h]$.

459   Only trajectories with a length of 1.5 h were used for further analysis.

460   We derived the mean growth rate as a function of the distance r_e from the edge of the colony

461   by fitting $< N^*(r_e, t + \tau) >= \exp(\lambda \tau)$, where N^* is the normalized and averaged data of

462   individual clusters within position intervals $[r_e, r_e + 2\mu m]$ within 1.5 h time intervals. The

463   mean distance to the colony edge was defined for each cluster by averaging every distance to

464   the colony edge within the 1.5 h time intervals. The velocity of each cluster depends on the

465   distance to the centre of mass of the colony. Hence, we sorted the data relative to the colony

466   centre of mass in the intervals $[r_c, r_c + 2\mu m]$. In general, we did not select for a specific colony

467   size. However, it was necessary for the heatmaps illustrations. Hence, we determined the mean

468   colony radius R and its standard deviation at every timepoint. Colonies, which were larger or

469 smaller than a standard deviation from the mean colony radius were discarded. Growth rates

470 were plotted relative to the mean colony radius and velocities were plotted relative to the centre

471 of mass of the colonies.

472 To assess the robustness of our algorithm with respect to the order of data averaging and

473 exponential fitting, we fitted the *N(t)* data of individual clusters as follows. To obtain Fig. S1,

474 we derived growth rates of single clusters by fitting an exponential function $\frac{N(t+\tau)}{N_0(t)} = \exp(\lambda\tau)$

475 to the number of cells, *N*, inside a cluster within the time interval indicated. The medians of the

476 distributions in Fig. S1 agree well with the data shown in Fig. 3c. We note, however, that there

477 are pronounced peaks at $l_{single} = 0$, indicating that some clusters do not start replicating.

478

479 **Determination of growth rate from velocity fields.** The growth rate λ was calculated by $\lambda =$

480 $div(v) = 2 * \frac{v}{r_c} + \frac{dv}{dr_c}$ using spherical coordinates. Given the velocities shown in the heat maps,

481 the previous equation simplifies to $\lambda(r) = 2 * \frac{v(r)}{r_c(r)} + \frac{v(r-1)-v(r+1)}{2\,\mu m}$. Thus, the growth rates were

482 directly calculated from the velocities given in the heatmaps.

483

484 **Determination of fraction of dead cells.** The medium (GC + IVX) which was continuously

485 supplied to the flow chamber, was supplemented with 0.004% PI (propidium iodide) to stain

486 dead cells during image acquisition. Spheroidal features (dead cells) were detected using the

487 same method as described in the previous paragraph for detecting living cells. The number of

488 dead cells, δ, was normalized: $\delta^*(r) = \frac{\delta(r)}{\rho(r)V(r)}$, where the cell density $\rho(r)$ is set to be

489 constant (19). Due to a lower cell density up to 2 μm away from the colony edge, the fraction

490 of dead cells is underestimated there. The volume of interest $V(r_e)$ is determined as a function

491 of the distance from the colony edge r_e within $[r_e, r_e + 2\mu m]$. For better comparison between

492 the heat maps, the fractions of dead cells were averaged within 1.5 h time intervals.

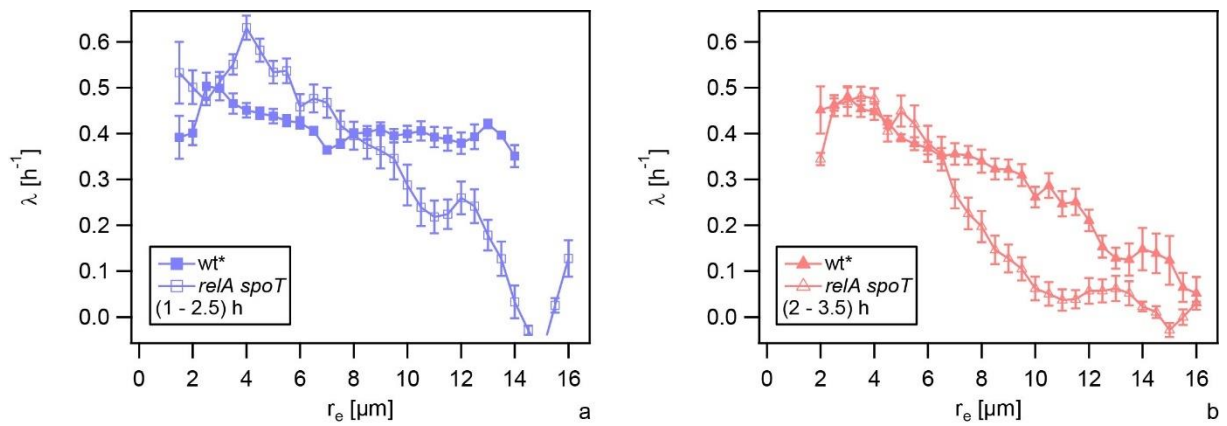

Fig. S6 Comparison of growth profiles between wt* and *ΔrelA ΔspoT* strains. Mean growth rate λ derived by the CC method as a function of the distance r_e from the edge of the colony different time intervals (a, b). N > 10 clusters for each data point.
