ABSTRACT

Defects in mitochondrial function and mitochondrial-related redox deregulation have been attributed to Huntington's disease (HD), a genetic neurodegenerative disorder largely affecting the striatum. However, whether these changes occur in early stages of the disease and can be detected *in vivo* is still unclear. Thus, in the present study, we analyzed changes in mitochondrial function and overreduced states associated with production of reactive oxygen species (ROS) at early stages and along disease progression *in vivo* in the brain by positron emission tomography (PET) and in skin fibroblasts of premanifest/early and manifest HD patients, and in YAC128 transgenic mouse brain (striatum and cortex) at early-symptomatic (3 month-old, mo) and symptomatic (6 to 12 mo) stages. *In vivo* human and mouse brain PET imaging was assessed using [⁶⁴Cu]-ATSM; analysis of oxygen consumption rates was assessed by Seahorse analysis, hydrogen peroxide levels were determined using fluorescent probes and mitochondrial morphology by transmission electron microscopy in human skin fibroblasts and mouse striatal and cortical isolated mitochondria. Premanifest and prodromal HD carriers exhibited enhanced whole-brain (with exception of caudate) [⁶⁴Cu]-ATSM labelling, correlating with CAG repeat number, concomitantly with enhanced basal and maximal respiration, proton (H⁺) leak and increased hydrogen peroxide levels, the later progressing to advanced HD stage, in human fibroblasts. Mitochondria from fibroblasts of premanifest HD carriers also showed reduced roundness, while higher number of mitochondrial DNA copies correlated with maximal respiratory capacity. *In vivo* animal PET analysis showed increased accumulation of [⁶⁴Cu]-ATSM in YAC128 mouse striatum. Pre/early-symptomatic YAC128 mouse striatal, but not cortical, isolated mitochondria exhibited a rise in basal and maximal mitochondrial respiration and in ATP production along with increased complex II and III activities, enhanced mitochondrial hydrogen peroxide and roundness, as revealed by brain ultrastructure analysis, further presenting defects in Ca²⁺ handling, supporting increased striatal susceptibility in the YAC128 mouse model. Data demonstrate both human and mouse mitochondrial overactivity and altered morphology at early HD stages, facilitating redox unbalance, the latter extending over late disease stages.

Keywords:

[⁶⁴Cu]-ATSM, human skin fibroblasts, YAC128 mice, reactive oxygen species, mitochondrial bioenergetics

INTRODUCTION

Huntington's disease (HD) is an inherited neurodegenerative disorder characterized by psychiatric, motor and cognitive symptoms, strongly affecting the striatum and the cortex. HD is linked to a dynamic mutation, an expansion in CAG repeats, located in the exon 1 of the *HTT* gene which encodes for the huntingtin (HTT) protein¹. Expression of mutant HTT (mHTT) has been associated with mitochondrial dysfunction, including reduced mitochondrial transmembrane potential, bioenergetic abnormalities, defects in Ca²⁺ handling, alterations in organelle morphology and neurite movement, and increased production of reactive oxygen species (ROS)²⁻⁴ largely attributed to HD late symptomatic stages.

Evidence of mitochondrial bioenergetic dysfunction emerged from studies in post-mortem HD striata demonstrating defects in activities of respiratory complexes (Cx) II, III and IV and aconitase⁵⁻⁷. HD genetic models also showed mitochondrial defects, namely reduced levels and assembly of Cx II subunits, as observed in R6/1 and Htt171-82Q transgenic mice⁸. These studies supported that mitochondrial dysfunction could contribute to the hypometabolism and progressive atrophy of the caudate in HD. Conversely, no differences were observed in respiratory activity in YAC128 mouse brain synaptic and non-synaptic mitochondria and striatal neurons^{9,10}, or in isolated brain mitochondria and striatal neurons from R6/2 mice¹¹. Conversely, we recently showed reduced respiratory profile and decreased mitochondrial membrane potential in YAC128 mouse cortico- and striatal neurons, and unexpected increased complexes activity in isolated striatal mitochondria from pre/early symptomatic YAC128 mouse, at 3 mo¹². In addition, we found reduced activity of complex I and citrate synthase in mitochondrial platelets from pre-manifest HD carriers¹³. Results in skin fibroblasts from HD patients also demonstrated a reduction in ATP levels, suggesting a deficit of mitochondrial oxidative metabolism^{14,15}. Gardiner and co-authors established a correlation between the age of onset and bioenergetic profile, as patients with earlier onset displayed more severe mitochondrial defects, independently of CAG repeat number¹⁴. These data implicated imbalanced mitochondrial activity in HD human peripheral cells. Mitochondrial dysfunction and altered mitochondrial calcium accumulation are also interconnected. Previously, we observed increased Ca²⁺ loading capacity in brain mitochondria isolated from R6/2 and YAC128 mice¹⁶, and reduced Ca²⁺ handling in YAC128 mouse striatal neurons following elevated cytosolic Ca²⁺ due to selective activation of *N*-methyl-D-aspartate receptors¹⁷. A close relationship between mitochondrial deregulation and excessive ROS

levels, namely superoxide anion and hydrogen peroxide, was also previously demonstrated in HD human cybrids (retaining HD platelet mitochondria) following a stress stimulus^{18,19}. Evidences of redox deregulation were also found by us in *STHdh*^{Q111/Q111} striatal cells^{20,21}. Other studies in HD human skin fibroblasts and lymphoblasts showed increased ROS levels and upregulation of antioxidant enzymes (e.g. superoxide dismutase 2, glutathione reductase, catalase)^{15,22,23}.

Despite several findings indicating deregulated mitochondrial function in HD brain and peripheral cells, data is not totally consistent while *in vivo* mitochondrial related oxidative stress namely in living HD patients requires further elucidation. The PET radioisotope [⁶⁴Cu]-ATSM ((⁶⁴Cu)-labeled diacetyl-bis(N(4)-methylthiosemicarbazone)) has been applied to visualize regional oxidative stress in patients with mitochondrial dysfunction associated diseases²⁴⁻²⁶. The mechanism of [⁶⁴Cu]-ATSM accumulation is based on the electron rich environment induced by mitochondrial impairment, as demonstrated in cells that are in overreduced states due to impaired mitochondrial electron transport chain (ETC)²⁷. Therefore, to further elucidate the mechanisms of mitochondrial dysfunction in HD, in the present study we investigated redox changes linked to mitochondrial deregulation both in premanifest/early and manifest HD patients and in YAC128 transgenic mouse model (at pre/early-symptomatic to symptomatic stages) and its relationship with disease severity using [⁶⁴Cu]-ATSM. Furthermore, we correlated *in vivo* brain data with analysis of mitochondrial function, production of mitochondrial hydrogen peroxide and mitochondrial morphology in human fibroblasts and in isolated mitochondria derived from YAC128 mouse brain striatum and cortex at different stages of the disease to assess their relevance during disease progression.

MATERIALS AND METHODS

Human study

Participant's characterization

Patients and controls were selected according to clinical evaluation performed at Neurology consultation of Hospital Center of the University of Coimbra (CHUC). Nine subjects were selected, six were mutant *HTT* gene carriers (HD carriers) with ages ranging from 25-66 years-old, including two premanifest (pre-M1 and pre-M2), one prodromal/early manifest (pre-M3) and three manifest (HD1-3), as defined by an expert neurologist, based on motor, psychiatric, and cognitive symptoms, and three noncarriers/controls. The age at onset was based on the date of clinical diagnosis, while the age at symptom onset was estimated on the information provided by the patient and the patient's family (**Table 1**). This study was performed following an informed consent of all participants, by following the guidelines of the Hospital Center of the University of Coimbra and after approval by the Ethic Committee of the Faculty of Medicine of the University of Coimbra (ref. CE-137/2015).

PET [⁶⁴Cu]-ATSM PET acquisition and processing

Preparation of [⁶⁴Cu]-ATSM was performed as described elsewhere²⁸. Cyclotron produced [⁶⁴Cu]CuCl₂ solution was added to a reactor containing H₂-ATSM in CH₃COONa 1 M. The mixture was purified in a Sep-Pak tC18 light. [⁶⁴Cu]-ATSM was obtained in a 10% ethanol saline sterile solution, with ≥ 99% of radiochemical purity and specific activity > 200 GBq/μmol. A Philips Gemini GXL PET/CT scanner (Philips Medical Systems, Best, the Netherlands) was used to perform a dynamic 3-dimensional PET [⁶⁴Cu]-ATSM scan of the entire brain (90 slices, 2-mm slice sampling) and a low-dose brain CT scan, for attenuation correction. Antioxidant vitamin supplements were suspended 24 hours prior to the scan; and to prevent possible head movement during acquisition, patients' head was restrained with a soft elastic tape. PET scan was acquired in a group of eight subjects (two control participants and five HD patients) over a period of 60 minutes (24 frames: 4x15s + 4x30s + 3x60s + 2x120s + 5x240s + 6x480s) and started immediately after the intravenous bolus injection of approximately 925 MBq of [⁶⁴Cu]-ATSM. PET data were reconstructed using a LOR-RAMLA algorithm, with attenuation and scatter correction. Standard uptake value (SUVr) images were calculated offline (with in-house written Matlab® quantification software) for each participant. PET and MRI data were

normalized to Montreal Neurological Institute (MNI) space, the same geometric transformation was used, after the PET scan had been rigidly coregistered with the correspondent anatomical MRI scan (using SPM toolbox with default parameters; standard MRI brain was used when subject's MRI were not available). We performed an exploratory whole-brain and region-of-interest (ROI)-based analyses. Data was exported for a set of distinct regions of interest including the cerebellum, basal ganglia and subregions (putamen, caudate and subthalamic nucleus) (regions known to be affected in HD patients). The SUVr image was calculated per subject using the vessels uptake values as reference. We defined the vessels uptake as the average of the max uptake values over the first 3 minutes of the dynamic acquisition. Next, we calculated the individual time-activity curves for the different ROIs and the uptake sum during 10 to 26 minutes of acquisition.

***In vivo* animal study**

Animal's characterization

YAC128 transgenic hemizygous (line HD53; 128 CAG repeats), and littermate non-transgenic wild-type (WT) mice (FVB/N background) with 3, 6, 9 and 12 months of age (mo) were used. All animals were generated from our local colony, with breeding couples gently provided by Dr. Michael Hayden (University of British Columbia, Vancouver, Canada). All animals were genotyped by common procedures as described in "Supplemental Methods" section. All studies were carried out in accordance with the guidelines of the Institutional Animal Care and Use of Committee and the European Community directive (2010/63/EU) and protocols approved by the Faculty of Medicine, University of Coimbra (ORBEA_189_2018/11042018).

[⁶⁴Cu]-ATSM PET/MRI acquisitions

Animal PET acquisitions were performed by using the radiopharmaceutical [⁶⁴Cu]-ATSM in YAC128 and WT mice at 3, 6, 9 and 12 mo. In all PET scans a prototype of a high-acceptance small-animal PET based on resistive plate chambers (RPC-PET) was used²⁹. A mean activity of 418± 85 kBq/g was injected. The PET acquisition lasted for 60 minutes post injection. Volumetric images were reconstructed using OSEM algorithm and cubic voxel of 0.5 mm width. Two structural volumetric MRI T2 images were acquired per mouse using a MRI scan. In this precise case, the goal was to facilitate the registration (geometric alignment) of the functional volumetric PET images with the volumetric MRI images, and thus allows the

segmentation of the regions of interest. A fiducial marker that can be viewed both in the PET and MRI imaging was placed in the mice bed. MRI imaging was done after PET without moving the mice from the bed. Mice were kept anesthetized by isoflurane (1-2%) with 100% O₂ with body temperature and respiration monitoring (SA Instruments SA, Stony Brook, USA). All MRI experiments were performed in a BioSpec 9.4T MRI scanner (Bruker Biospin, Ettlingen, Germany) with a volume head coil. High resolution morphological images were acquired with a 2D T₂-weighted turbo RARE sequence and axial slice orientation. The sequence for fiducial marks had the following parameters: TR/TE=8372/33 ms, FOV=25.6x25.6 mm, acquisition matrix=256x256, averages=1, rare factor=8, echo spacing=11 ms, 80 axial continuous slices with 0.4 mm thick and acquisition time of 4m28s. The sequence for head mouse had the following parameters: TR/TE=4500/33 ms, FOV=25.6x25.6 mm, acquisition matrix=256x256, averages=8, rare factor=8, echo spacing=11 ms, 42 axial continuous slices with 0.4 mm thick and acquisition time of 19m12s.

[⁶⁴Cu]-ATSM uptake quantification

First, based on the fiducial marker, the volumetric images obtained from the PET were manually registered by the volumetric MRI images using the 3D Slicer 4.4 software. The volumetric MRI images were manually segmented using the ITK-SNAP 2.2 software and the segmentation results applied to the registered volumetric PET images. Finally, the mean counts per mm³ in each ROI were computed and normalized by the activity injected per gram. Only the counts between 20- and 60-minutes post injection were considered.

***In vitro* human and animal study**

Cell culture

Fibroblasts from HD carriers and controls were generated from a small skin sample (i.e., 3 mm diameter) from the abdominal region via a punch biopsy, as described previously³⁰ (see “Supplemental Methods” for detailed description). Fibroblasts were cultured in DMEM medium (Gibco), supplemented with 15% FBS (Gibco) and 1% penicillin/streptomycin (Gibco) and maintained to a maximum of 15 passages.

Isolation of functional mitochondria by Percoll gradient

Mice were weighted and then sacrificed by cervical dislocation and decapitation. Brains were removed from the skull and washed once in phosphate saline buffer (PBS) containing (in mM): 137 NaCl, 2.7 KCl, 1.8 KH₂PO₄, 10 Na₂HPO₄·2H₂O, pH 7.4; followed by striatum and cortex dissection. Striatal and cortical mitochondrial-enriched fractions were then isolated using discontinuous Percoll density gradient centrifugation as previously described³¹. Briefly fresh striatal and cortical tissues were homogenized in ice-cold buffer (225 mM mannitol, 75 mM sucrose, 1 mM EGTA, 5 mM HEPES, pH 7.2/KOH, plus 1 mg/mL BSA) and centrifuged at 1100 *xg* for 2 minutes at 4°C. The resulting supernatant was mixed with 80% Percoll (1 M sucrose, 50 mM HEPES, 10 mM EGTA, pH 7.0) and then carefully layered on the top of freshly made 10% Percoll (prepared from 80% Percoll) and centrifuged at 18500 *xg* for 10 minutes at 4°C. Supernatant was discarded and the pellet was resuspended in 1 mL of washing buffer (250 mM sucrose, 5 mM HEPES-KOH, 0.1 mM EGTA, pH 7.2) and centrifuged again at 10000 *xg* for 5 minutes at 4°C. Finally, the mitochondrial pellet was resuspended in ice-cold washing buffer and the amount of protein quantified by the Bio-Rad protein assay. Isolated mitochondria-enriched fractions were kept on ice for further functional analysis or frozen at -80°C.

Bioenergetic assay

The fibroblasts oxidative phosphorylation and glycolytic profile were obtained by measuring the oxygen consumption rate (OCR) and extracellular acidification ratio (ECAR) on a Seahorse XF24 or XF96 apparatus. OCR was also analyzed in fresh striatal and cortical mitochondria isolated from YAC128 *versus* WT mice in coupling and uncoupling conditions, respectively, on a Seahorse XF24 apparatus (see “Supplemental Methods” for detailed description).

Measurement of cellular and mitochondrial hydrogen peroxide levels

Cellular or mitochondrial hydrogen peroxide (H₂O₂) levels were measured in fibroblasts using mitochondria peroxy yellow 1 (MitoPY1) (Sigma) or Amplex Red reagent and horseradish peroxidase from the Amplex[®] Red Catalase Assay Kit (Molecular Probes), respectively. H₂O₂ production by YAC128 and WT striatal and cortical mitochondria was measured by the Amplex[®] Red method. These are detailed in “Supplemental Methods”.

Transmission electron microscopy

Fibroblasts were pelleted by centrifugation and striatum dissected out from 3 mo WT and YAC128 mice brain were processed for transmission electron microscopic (TEM) ultrastructural analyses, as detailed in “Supplemental Methods”.

Genomic DNA extraction and mitochondrial DNA copies

Genomic DNA was isolated from fibroblasts by means of high-salt/ethanol precipitation. All DNA samples were considered pure when A260/A280 ratio was comprised between 1.8–2.0. To quantify the average mtDNA copy number of the fibroblasts the Absolute Human Mitochondrial DNA Copy Number Quantification qPCR Assay Kit from ScienCell's was used according to manufacturer protocol. Briefly, a mtDNA primer set recognizes and amplifies human mtDNA and another reference primer set recognizes and amplifies a 100 bp-long region on human chromosome 17 and serves as reference for data normalization. The reference genomic DNA sample with known mtDNA copy number serves as a reference for calculating the mtDNA copy number of target samples.

Mitochondrial Ca²⁺ handling capacity

Mitochondrial Ca²⁺ uptake was measured fluorimetrically, as described elsewhere³⁴ with minor modifications³¹ in the presence of the Ca²⁺-sensitive fluorescent dye Calcium Green 5N (150 nM) that exhibits an increase in fluorescence emission intensity upon binding to Ca²⁺; thus, a decrease in the Calcium Green fluorescence is function of external Ca²⁺ concentration which indicates the capacity of mitochondria to handle Ca²⁺. Briefly, 5 µg of YAC128 and WT striatal or cortical isolated mitochondria was added to the incubation medium contained 125 mM KCl, 0.5 mM MgCl₂, 3 mM KH₂PO₄, 10 mM HEPES, 10 µM EGTA, supplemented either with 3 mM pyruvate, 1 mM malate, 3 mM succinate, 3 mM glutamate, 0.1 mM ADP and 1 µM oligomycin, pH 7.4. After a basal fluorescence record, using excitation and emission wavelengths of 506 nm and 532 nm, respectively, six pulses of 10 µM CaCl₂ were added every 4 minutes. Data are presented as traces of calcium handling capacity, which reflects the rate of decrease of Calcium Green-5N fluorescence and plotted as extramitochondrial calcium (Extra mitoCa) for the third pulse of added calcium, as described in figure legend.

Additional methods

See the Supplementary material for more comprehensive description of the mentioned methods and details on genotyping, measurement of glutathione levels and glutathione peroxidase and glutathione reductase activities.

Statistical analyses

Statistical computations were performed using GraphPad Prism version 7.0, GraphPad Software, La Jolla, CA, USA, and SPSS version 21.0 (IBM SPSS Statistics for Windows, IBM Corp). Statistical analysis was performed for individual subjects and among groups (controls, premanifest and manifest patients). For fibroblasts experiments at least three independent assays were performed for each experimental condition. Statistical significance was analyzed using parametric test, two-way ANOVA, followed by Bonferroni post-hoc test and non-parametric test Kruskal Wallis followed by Dunn's multiple comparison test. Correlations were done using the Spearman rank correlation coefficient (ρ). The power analysis approach to sample size determination was done using G power software on effect size (mean/standard deviation within groups) for $1-\beta = 0.8$ and $\alpha = 0.05$. The results obtained from the animal's experiments are expressed as the mean \pm SEM of the number of replicates, considering the number of animals indicated in the figure legends. Comparisons among multiple groups were performed by two-way ANOVA followed by Tukey's post-hoc test. Comparison between two populations, as described in figure legends was performed by nonparametric Mann Whitney U test. Significance was defined as $p < 0.05$.

RESULTS

Clinical data

From the selected nine participants for this study, six were *HTT* gene mutation carriers, classified in premanifest and prodromal (three) and in manifest stages (**Table 1**). Premanifest or presymptomatic HD carriers had no clinical motor signs or symptoms, based on standardized total motor score of Unified Huntington Disease Rating Scale (UHDRS)³⁵. HD carriers had CAG repeats ranging from 42-52; the early-stage/prodromal patient exhibited the longest repeat expansion and an anticipated phenotypic onset, compared to age-matched HD carriers. Manifest HD patients showed later symptom disease onset than premanifest and prodromal patients. Furthermore, symptoms at onset varied from psychiatric (manifest HD patients) and cognitive (prodromal HD patient) symptoms.

Increased accumulation of [⁶⁴Cu]-ATSM in premanifest HD carriers

Whole brain and regional PET [⁶⁴Cu]-ATSM retention in the SUV images was compared between groups using statistical parametric mapping and ROI analysis. Despite the reduced number of patients, the values obtained in the analysed areas of HD patients and controls were similar. Nonetheless, an apparent increased accumulation of [⁶⁴Cu]-ATSM was observed in the premanifest/early-stage HD carriers, when compared to the control group. The exception was the caudate as the SUV decreased with disease severity, suggesting neuronal degeneration (**Figure 1A-C**). Spearman correlation analyses showed that [⁶⁴Cu]-ATSM brain accumulation in whole brain and subthalamic nucleus (STN) directly correlates with CAG repeat number ($\rho=0.709$; $p=0.074$; $\rho=0.746$, $p=0.05$, respectively) (**Figure 1D,E**).

Enhanced [⁶⁴Cu]-ATSM complex entrapment in an intracellular overreductive state observed in the majority of brain areas in premanifest/early-stage HD carriers can be caused by altered mitochondrial respiratory chain in patient's brains.

Altered mitochondrial function and redox deregulation in premanifest/prodromal HD carriers

Because [⁶⁴Cu]-ATSM PET labelling has been attributed to overreduced intracellular state due to altered mitochondrial function and enhanced production of ROS^{24,25,27}, we assessed

changes in mitochondrial function and ROS levels in human skin-derived fibroblasts obtained from the controls and HD carriers detailed in **Table 1**.

Comparisons of oxygen consumption rates (OCR) between groups showed that basal and maximal respiration were enhanced in premanifest HD carriers *versus* controls accompanied of increased H⁺ leak ($p < 0.05$) (**Figure 2A-D**). Contrarily, manifest HD patients demonstrated a general decrease in mitochondrial bioenergetic profile in basal (*vs* controls), maximal, spare respiration and H⁺ leak (*vs* premanifest), $p < 0.05$ (**Figure 2A-D**). No significant differences in ATP production (**Figure 2A-D**), ATP/ADP ratio or energy charge (**Figure S1**) were found in HD carriers, when compared to the control group. The observed increase in H⁺ leak in premanifest/early-stage HD carriers can be responsible for the increase in oxygen consumption without ATP synthesis.

Interesting, we observed an inverse correlation between individual disease duration, age of diagnosis and onset and chronological age with basal oxygen consumption rates and a trend towards statistical significance. Longer disease duration ($\rho = -0.949$, $p = 0.051$), more advanced age at symptom onset ($\rho = -0.678$, $p = 0.05$) and at clinical diagnosis ($\rho = -0.771$, $p = 0.072$) were accompanied by lower absolute values of basal respiration. Furthermore, older patients had significantly lower values of basal respiration ($\rho = -0.678$, $p = 0.05$) (**Figure 2E**).

We also analysed glycolytic parameters by assessing extracellular acidification rates (ECAR) in human skin fibroblasts derived from the same individuals. Data showed no significant differences between groups, except for the glycolytic capacity of manifest HD patients that had lower absolute values, compared to controls ($p < 0.05$) and premanifest HD carriers ($p < 0.01$) (**Figure S2**).

The levels of ROS are largely determined by mitochondrial dysfunction, triggering an overreduction state that may lead to oxidative stress, involved in [⁶⁴Cu]-ATSM accumulation. Thus, the relative levels of mitochondrial and extracellular hydrogen peroxide (H₂O₂) were measured in human skin fibroblasts using MitoPY1 and Amplex Red, respectively (**Figure 3**). We found significantly higher levels of extracellular H₂O₂ in fibroblasts derived from premanifest/early-stage HD carriers, which remained constant along disease progression (**Figure 3A**). Interestingly, a significant rise in basal levels of mitochondrial H₂O₂ (mito-H₂O₂) were observed in more advanced stages of HD only (**Figure 3B**). Following complex III inhibition with myxothiazol (3 μ M), the levels of mito-H₂O₂ increased along disease severity, being significantly higher in cells derived from manifest HD patients *versus* controls ($p < 0.05$)

(**Figure 3C**). Correlation analysis showed augmented extracellular levels of H₂O₂ in HD carriers with longer CAG repeat number ($\rho=0.769$, $p=0.05$), and a lower uptake of [⁶⁴Cu]-ATSM in the caudate was associated with increased extracellular H₂O₂ levels ($\rho= -0.714$, $p=0.071$) (**Figure 3D,E**).

These data indicate early increased mitochondrial respiration linked to H⁺ leak and redox deregulation that is heightened in manifest HD.

HD carriers at premanifest/prodromal stage show decreased roundness and increased mitochondrial DNA levels correlated to higher [⁶⁴Cu]-ATSM uptake

Because mitochondrial dysfunction has been linked to changes in mitochondrial morphology, we analysed the morphometric parameters of mitochondria that were individually traced from TEM images obtained in human skin fibroblasts (**Figure 4A**). We measured the major mitochondrial shape factors: area, circularity, Feret's diameter, perimeter, form factor, and aspect ratio (**Figure 4B**). Mitochondria from premanifest/early HD carriers showed decreased circularity, are more elongated (higher Feret's diameter), have more complex and branched networks and larger aspect ratio (length/width ratio) when compared with the control or manifest HD patients (**Figure 4A,B; Suppl. Table 1**) ($p<0.05$). However, increased circularity can be observed in manifest HD patient's fibroblasts, when compared to the controls ($p<0.05$). These results indicate that mitochondria from fibroblasts of premanifest/early-stage HD carriers are less fragmented.

Fibroblasts from premanifest/early-stage HD carriers show a trend for increased number of mitochondrial DNA copies, whilst manifest HD patients have reduced mitochondrial DNA copy number when compared to cells from premanifest carriers ($p<0.05$) (**Figure 4C**). Furthermore, we observed that human skin fibroblasts with higher number of mitochondrial DNA copies have significantly greater spare ($\rho=0.867$, $p=0.01$) and maximal respiratory capacity ($\rho=0.783$, $p=0.05$). In accordance, patients with longer disease duration present a lower number of mitochondrial DNA copies ($\rho=-0.949$, $p=0.041$). Interestingly, enhanced mitochondrial DNA copies was observed in patients with augmented [⁶⁴Cu]-ATSM uptake in whole brain ($\rho=0.786$, $p=0.036$), cerebellum ($\rho=0.679$, $p=0.094$), basal ganglia ($\rho=0.75$, $p=0.052$) and putamen ($\rho=0.857$, $p=0.014$). These data suggest that premanifest HD carriers showing higher number of mitochondrial DNA copies in peripheral cells also have higher accumulation of [⁶⁴Cu]-ATSM in selected brain areas, which may reflect a mitochondrial overreduced state.

Enhanced [⁶⁴Cu]-ATSM brain accumulation in YAC128 mouse brain

In order to verify whether changes in [⁶⁴Cu]-ATSM brain accumulation correlate with mitochondrial changes in HD brain affected areas, we further analysed *in vivo* [⁶⁴Cu]-ATSM accumulation by PET and studied mitochondrial fractions isolated from the striatum and cortex of YAC128 mice along aging. YAC128 mice showed an age-dependent gain of body weight (**Figure S1A**), as described previously^{36,37}.

In vivo age-dependent analysis of intracellular overreductive status was evaluated in YAC128 versus wild-type mice over the progression of the disease, at 3 (pre/early symptomatic), 6 and 9 and 12 (symptomatic) months of age (mo), through the analysis of [⁶⁴Cu]-ATSM accumulation in the striatum (**Figure 5A,B**) and frontal cortex (**Figure 5A,C**). Statistical analysis by two-way ANOVA revealed a significant genotype and age-dependent effect of [⁶⁴Cu]-ATSM accumulation in striatum ($F(1,35)=12.07$; $p=0.0014$) and ($F(3,35)=36.67$; $p<0.0001$), respectively, evidencing a higher total accumulation of the radioligand in YAC128 compared to WT striatum (**Figure 5Bi**). *In vivo* data obtained from the cortex also demonstrated an age-dependent effect ($F(3,38)=12.61$; $p<0.0001$) and a slight, but significant, genotype effect in [⁶⁴Cu]-ATSM accumulation ($F(1,18)=4.192$; $p=0.0476$) (**Figure 5Ci**). Accordingly, when all ages were merged for both YAC128 and WT striatum and cortex, a significant increase in overall radioligand accumulation was observed, indicating increased overreductive status in these two YAC128 mouse brain areas. In addition, when [⁶⁴Cu]-ATSM accumulation at YAC128 mouse striatum or cortex were replotted in relation to WT mice, a significant increase in the radioligand accumulation was observed in the striatum of 6 mo ($p < 0.05$) and a trend at 12 mo ($p = 0.0571$) (**Figure 5Bii**), but not in the cortex (**Figure 5Cii**).

Increased oxygen consumption rate, complexes II and III activities and oxidative status in striatal mitochondria derived from pre/early-symptomatic YAC128 mice

The respiratory activity of striatal and cortical isolated mitochondrial-enriched fractions derived from YAC128 and WT mouse brain striatum and cortex was analyzed by determining the oxygen consumption rate (OCR) and complexes activities (**Figures 6 and S4**). Notably, both wild-type HTT and mHTT were shown to associate with cortical- and striatal-enriched isolated mitochondria derived from WT and YAC128 mice, respectively (**Figure S3C**).

Coupling experiments performed under Cx II feeding (in the presence of succinate) and Cx I inhibition (with rotenone) in striatal mitochondria obtained from 3 mo (early symptomatic) YAC128 mice showed increased basal and maximal respiration and ATP production, but unchanged H⁺ leak, (**Figure 6Ai**), when compared to WT mice. In order to further explain these changes in oxygen consumption rates, we analyzed the electron flow through mitochondrial respiratory chain, to evaluate Cx I-IV activities under conditions of direct mitochondrial feeding (pyruvate, to generate acetyl-CoA) plus malate (to activate the TCA cycle) in FCCP-induced uncoupled state. In agreement with results obtained in **Figure 6Ai**, striatal mitochondria obtained from 3 mo YAC128 mice exhibited a significant increase in Cx II and III activities, but unaltered activities in Cx I and IV (**Figure 6Aii**), when compared with WT mouse mitochondria. No significant changes in mitochondrial-coupled respiration parameters or Cx I-IV activities were observed in cortical mitochondria (at 3, 6, 9 and 12 mo) (**Figure 6 Bi and Bii; Figure S4Bi and S4Bii**) or striatal mitochondria obtained from older YAC128 mice (at 6, 9 and 12 mo) (**Figure S4Ai and S4Aii**). Data suggest a striatum-specific increase in mitochondrial respiratory chain activity and Cx II and III activity in mitochondria from pre/early symptomatic YAC128 mice.

As in human fibroblasts, we further analyzed the levels of mitochondrial H₂O₂ produced by *ex vivo* striatal- and cortical mitochondrial-enriched fractions isolated from early symptomatic (3 mo) and symptomatic (6, 9 and 12 mo) YAC128 mice and age-matched WT mice (**Figure 7Ai and 7Aii**). Results evidenced a significant increase in H₂O₂ production by striatal mitochondria from both early (3 mo; p<0.05) and late symptomatic (12 mo; p<0.01) mice (**Figure 7Ai**) and by cortical mitochondria from late symptomatic YAC128 mice, at 12 mo (p<0.05) (**Figure 7Aii**) without significant changes in intermediate ages (6 and 9 mo) for both brain areas.

Elevated mito-H₂O₂ levels were not accompanied by compromised antioxidant defenses in YAC128 mice at 3 and 9 mo, since no significant changes were observed on mitochondrial acetyl(K68)SOD2/SOD2 or SOD2 protein levels in both striatum (**Figure S5Ai**) and cortex (**Figure S5Bi**), reduced (GSH) and oxidized (GSSG) glutathione total levels in striatum (**Figure S5Aii and S5Aiii**, respectively) or cortex (**Figure S5Bii and S5Biii**, respectively), nor glutathione peroxidase and reductase activities in both striatum (**Figure S5Aiv and S5Av**, respectively) and cortex (**Figure S5Biv and S5Bv**, respectively), despite significant decreased glutathione reductase protein levels in mitochondria from 3 mo YAC128 mouse striatum (p<0.05) (**Figure**

S5Avi), but not in cortex (**Figure S5Bvi**). Similarly, data evidenced no differences in antioxidants at 12 mo in striatum or cortex (data not shown).

Early Ca²⁺ deregulation and altered ultrastructure in YAC128 mouse striatal mitochondria

Because altered mitochondrial Ca²⁺ retention may serve as an indicator of mitochondrial impairment, we next evaluated Ca²⁺ handling in striatal and cortical mitochondria-enriched fractions isolated from 3 mo YAC128 and WT mice. Mitochondrial Ca²⁺ uptake was monitored after sequential additions of 10 μM Ca²⁺ to raise intramitochondrial Ca²⁺ concentration in 3 mo striatal (**Figure 7Bi, upper panel**) and cortical (**Figure 7Bi, lower panel**) mitochondria. Under these conditions, Ca²⁺ was sequentially taken up by both striatal and cortical mitochondria (**Figure 7Bi**), however the response to the 3rd pulse of Ca²⁺ produced a decrease in Ca²⁺ retention in striatal ($p < 0.05$; **Figure 7Bi, upper panel, detailed in dashed green window**), but not in cortical (**Figure 7Bi, lower panel, detailed in dashed green window**) YAC128 mitochondria, when compared to WT mitochondria, as evaluated by extramitochondrial Ca²⁺ (Extra mitoCa) quantification; the following pulse of Ca²⁺ in striatal (**Figure 7Bi, upper panel**), but not in cortical (**Figure 7Bi, lower panel**) mitochondria exceeded the mitochondrial Ca²⁺ retention capacity, with a subsequent abrogation of Ca²⁺ uptake as represented by upward deflection of the trace, indicating the opening of the mitochondrial permeability transition pore (mPTP). Our data highlight defects in Ca²⁺ handling in striatal mitochondria derived from early symptomatic YAC128 mice, exhibiting lower Ca²⁺ thresholds for mPTP opening after repeated Ca²⁺ loads. Ca²⁺ taken up by WT and YAC128 striatal-derived mitochondria was shown to be released through a FCCP-induced “releasable pool” (**Figure 7Bii**) and prevented by pre-incubation with the mitochondrial Ca²⁺ uniporter (MCU) inhibitor, Ru360 (**Figure 7Bii**), indicating that Ca²⁺ retention occurred through the MCU in polarized mitochondria. Similar results were observed in cortical mitochondria (data not shown).

In order to investigate YAC128 mouse striatal mitochondrial morphology, electron micrographs obtained by TEM of 3 mo YAC128 and WT mice striatum were assessed using quantitative measures for mitochondrial morphology (**Figure 7C**). Over 154 individual mitochondria were assessed for area, perimeter, aspect ratio and roundness (**Figure 7D**). YAC128 mouse striatal mitochondria presented increased area and perimeter along with decreased aspect ratio and a more roundness appearance, whereas WT mitochondria appeared ellipsoidal. These observations are consistent with the loss of normal mitochondrial

appearance *in situ*, suggesting increased mitochondrial fragmentation despite higher area, when compared to WT mitochondria (**Figure 7 D**), further supporting dysfunctional YAC128 striatal mitochondria.

DISCUSSION

This work is the first to demonstrate evidence of higher accumulation of [⁶⁴Cu]-ATSM in premanifest HD patients and in an early-stage HD animal model in different brain regions. The exception was the caudate, a region reported to be affected in the prodromal phase and showing progressive atrophy along the advance of the disease due to neuronal loss³⁸⁻⁴⁰. High levels of [⁶⁴Cu]-ATSM retention appear to be indicative of an overreduction state²⁷. In accordance, our results show that fibroblasts from premanifest HD patients and striatal mitochondria derived from pre/early symptomatic stages YAC128 mice exhibit increased mitochondrial hydrogen peroxide levels, which is unrelated with decreased antioxidant levels or activity, but rather with an apparently compensatory enhanced activity of mitochondrial respiratory chain and altered morphology.

Classically, disease burden is defined based on CAG repeat length and age. In this study we show a correlation between imaging of the whole brain and particularly the STN and the extent of CAG repeats. The STN is a key component of the basal ganglia and several reports in animal models argue that STN dysfunction and neuronal loss precede cortico-striatal abnormalities in HD, which might contribute to motor impairment, and explain the greater accumulation of [⁶⁴Cu]-ATSM in presymptomatic patients^{41,42}.

The excessively overreduced microenvironment found in premanifest HD patients was coupled to an overall increase in mitochondrial bioenergetics, including higher values of basal OCR and maximal respiration in skin fibroblasts. Nevertheless, adenine nucleotide levels remained unaffected, probably due an increase in basal OCR uncoupled from ATP synthesis, measured as H⁺ leak. In skin fibroblasts, we also found lower values of basal OCR in HD patients correlating with earlier age of clinical diagnosis and age of onset, with longer disease duration and higher calendar age. Additionally, a lower mitochondrial network fragmentation occurred concomitantly with a tendency for upregulation in mtDNA copy number in peripheral cells from premanifest HD patients. Importantly, mtDNA levels are increased in younger premanifest patients with shorter disease duration and correlate with enhanced mitochondrial bioenergetics and increased accumulation of [⁶⁴Cu]-ATSM, probably as a reflex of the redox state already documented at this stage.

In YAC128 mice, increased [⁶⁴Cu]-ATSM retention was mostly evident in striatum of 6 and 12 mo and less manifested in the cortex. Interestingly, striatal isolated mitochondria (but not cortical mitochondria) derived from early symptomatic (3 mo) YAC128 mice exhibited not

only increased levels of hydrogen peroxide, but also enhanced activity of complexes II and III, linked to increased basal, maximal OCR and ATP production. Enhanced complexes activity and hydrogen peroxide levels were recently observed by us in isolated YAC128 mouse striatal mitochondria at 3 mo¹². The increase in mitochondrial ATP generation in striatal mitochondria contrasts with human fibroblasts showing unchanged ATP levels due to H⁺ leakage. Striatal mitochondria from pre/early symptomatic YAC128 mice showed defects in Ca²⁺ handling and altered mitochondrial morphology, suggesting deregulated mitochondrial function despite the increase in mitochondrial respiratory activity, which precedes the increase in [⁶⁴Cu]-ATSM retention, at 6 mo. Altered striatal mitochondrial function observed in this study implicates enhanced susceptibility of this brain region, consistently with previous reports showing a highly susceptibility of the striatum to impaired mitochondrial oxidative phosphorylation⁴³ and age-dependent striatal volumetric changes defined by us through longitudinal structural imaging in the YAC128 mouse model⁴⁴. Unchanged OCR in YAC128 mouse mitochondria at 6-12 mo may be accounted for by alternative metabolic profile and/or decreased striatal energy demand, as demonstrated by enhanced levels of creatine and phosphocreatine, determined by spectroscopy (1H-MRS)⁴⁴.

Several studies have established a link between [⁶⁴Cu]-ATSM accumulation, mitochondrial dysfunction, impairment of mitochondrial respiratory chain, due e.g. hypoxia, and related oxidative stress^{26,27,45}. Dysfunctional mitochondrial electron transport chain causes an overreduced state due to ROS generation. Furthermore, in a patient with MELAS (mitochondrial encephalopathy, lactic acidosis, and stroke-like episode), caused by a mitochondrial mutation, [⁶²Cu]-ATSM accumulation reflected changes in regional oxidative stress²⁶. Increased ROS production and mitochondrial dysfunction were also described in Parkinson's disease (PD) and amyotrophic lateral sclerosis (ALS) patients, as evaluated by PET using [⁶²Cu]-ATSM and further associated with disease severity in both diseases^{24,25,46}.

In HD, mHTT is widely expressed in all body cells turning energy metabolism studies in peripheral cells important in the search for disease biomarkers. A previous study stressed that fibroblasts from healthy donor and HD patients have different profiles if stratified according to motor function, psychiatric and functional capacity. Fibroblasts obtained from manifest HD patients displayed compromised cell growth, reduced ATP production, accompanied by decreased mitochondrial activity, which was indicative of respiratory chain defects¹⁵. Of interest, the age at onset seems to be a crucial element alongside the CAG expansion to define

the bioenergetic profile of fibroblasts of HD patients¹⁴. Concordantly, our data suggest that HD patients suffering for longer periods of time have highly compromised mitochondrial function. In these cells, a slight increase in mitochondrial ROS was reported, despite a significant elevation in antioxidant enzymes (SOD2 and GR)¹⁵. Other authors described a decrease in catalase activity in HD fibroblasts²². Impaired antioxidant defenses, namely a decrease in GPx and SOD1 activities, were also observed in erythrocytes from HD patients⁴⁷. Previous studies performed in our lab showed increased mitochondrial-driven ROS in HD human cybrids¹⁸ and mouse striatal cells expressing full-length mHTT^{20,21,48,49}. An increase in ROS was also found in the brain striatum and cortex of symptomatic R6/1⁵⁰, R6/2 HD mouse models^{51,52}, and in YAC128 embryonic fibroblasts and fibroblasts derived from HD patients⁵³. Despite enhanced mitochondrial production of hydrogen peroxide, our data showed unchanged antioxidant activity in cortical and striatal mitochondria at all ages, implicating that decreased antioxidant profile does contribute for altered redox changes in HD mouse brain.

Mitochondrial function has a high impact on organelle morphology, defined by a regulated balance between fission and fusion events, since loss of bioenergetic capacity results in an inability to maintain the mitochondrial network organization³³. In our study, skin fibroblast mitochondria from premanifest HD carriers, compared to healthy controls and manifest patients, became larger as assessed by several parameters, whereas circularity decreased. These ultrastructural characteristics suggest a promotion of mitochondrial fusion events that might be required to maximize oxidative phosphorylation. Conversely, striatal mitochondria from early symptomatic YAC128 mice, retaining mHTT interaction, exhibited increased roundness, as revealed by ultrastructure analysis. Such opposing results might be determined by cell type-specific vulnerability of human peripheral cells or isolated organelle derived from mouse brain cells (neurons and glia) in the most affected brain area in HD. Fragmented mitochondria was previously reported in many HD cell models, including peripheral cells (e.g.⁵⁴). Mitochondrial fragmentation was observed in rat cortical neurons expressing mHTT and in fibroblasts from manifest HD patients and in YAC128 HD mouse model, before the presence of neurological deficits and mHTT aggregates⁵⁵; in striatum of YAC128 mice, an increase in the number of small mitochondria and decreased cristae surface area were also detected⁵⁵.

Decreased ability to take up Ca^{2+} through the MCU was further observed in striatal mitochondrial-enriched fractions from pre/early-symptomatic YAC128 mice, when compared to cortical mitochondria, again underlying a highly dysfunctional organelle derived from the striatum. Defects on mitochondrial Ca^{2+} handling were previously demonstrated in lymphoblast mitochondria from HD patients and brain mitochondria from YAC128 mice⁵⁶, isolated mitochondria from transgenic HD rats with 51 CAG repeats⁵⁷ and in mutant mouse striatal cell line^{58,59}. Concordantly, in striatal mitochondria obtained from rat brain, lower calcium levels consistently evoked a permeability transition easily than in cortical mitochondria (Brustovetsky et al. 2003). Conversely, an increase in Ca^{2+} loading capacity in forebrain (brain minus the cerebellum)-derived mitochondria from R6/2 and YAC128 mice, but not in organelle isolated from Hdh150 knock-in mice, was observed¹⁶. More recently, Pellman and cols evidenced a large Ca^{2+} uptake capacity in synaptic and nonsynaptic mitochondria isolated from 2 and 12 mo YAC128 mice brain, when compared with YAC18 or FVB/NJ mice³⁴. Indeed, changes in mitochondrial Ca^{2+} handling have not been consistent in HD models, particularly when studying isolated brain mitochondria, which might be related with different methodologies of isolating the organelle and/or assessing ion changes, as well as the isolated brain tissue.

The number of mtDNA copies has a crucial role in cellular metabolism and bioenergetics. The mechanisms responsible for regulation of mtDNA copy number in HD pathology are still under discussion. Our study has revealed that premanifest patients harbor more copies; interestingly, a strong and significant correlation was observed with enhanced mitochondrial bioenergetics and ^{64}Cu -ATSM uptake. Contradictory conclusions may be dependent on the cell type as shown by the mtDNA/nDNA copy number significantly higher in leukocytes, but lower in fibroblasts, of manifest HD patients⁶⁰. Moreover, mtDNA copy number was increased before disease onset in leukocytes of HD mutation carriers and declined after disease onset⁶¹. Of relevance, this study provides novel and important data suggesting a compensatory mechanism in premanifest HD patients and pre/early symptomatic HD mice model to overcome the early insults, particularly the underlying oxidative stress. Compensatory mechanisms at early stages of age-related diseases, as determined in human and mouse, have been described elsewhere^{62,63}. Reports of upregulation in the expression of mitochondrial-encoded genes in blood samples of mild cognitively impaired patients, compared to AD

patients and healthy controls, suggested a compensatory-like mechanism at the early stages of disease^{64,65}.

Overall, this study provides novel data regarding major redox changes and mitochondrial deregulation at early symptomatic stages in HD, as revealed by *in vivo* PET analysis showing accumulation of [⁶⁴Cu]-ATSM; this is a powerful tool to improve our insights into oxidative stress linked to mitochondrial dysfunction, sustaining an early oxidant status. The major limitation of this study includes the small number of participants. Further studies with a larger number of participants and at different disease timepoints are necessary to validate human data. Nonetheless, the overlapping results obtained in mitochondrial function and oxidative stress in pre/early symptomatic stages in YAC128 mice supports the changes reported in patients. Moreover, data in mouse striatum reinforces an increased susceptibility of this brain region in HD. Thus, potential benefits of early therapeutic interventions based on mitochondrial-targeted compounds aiming to regularize mitochondrial function and reduce ROS generation, particularly in the striatum, are anticipated to help to slowdown HD progression.

Author Disclosure Statement - The authors have no competing or financial conflicts of interest to disclose.

List of abbreviations

ADP - Adenosine diphosphate

ATP - Adenosine triphosphate

BSA - Bovine serum albumin

CAG - Cytosine-Adenine-Guanine

EGTA – Ethylene glycol tetra-acetic acid

ETC – Electron transport chain

FCCP – Carbonyl cyanide p-trifluoromethoxyphenylhydrazone

GPx – Glutathione peroxidase

GRed – Glutathione reductase

GSH – Glutathione, reduced form

GSSG – Glutathione, oxidized form

HD - Huntington's disease

H₂O₂ - Hydrogen peroxide

HTT – Huntingtin

MCU - Mitochondrial Ca²⁺ uniporter

mHTT - Mutant huntingtin

MIM – Mitochondrial inner membrane

mmp – Mitochondrial transmembrane potential

mPTP - Mitochondrial permeability transition pore

NaF – Sodium fluoride

NEM – N-ethylmaleimide

OCR – Oxygen consumption rate

PET - Positron emission tomography

ROS - Reactive oxygen species

SDS - Sodium dodecyl sulphate

SDS-PAGE - SDS polyacrylamide gel electrophoresis

SOD - Superoxide dismutase

STN - Subthalamic nucleus

YAC - Yeast artificial chromosome

Table and Figure Legends

TABLE 1: Clinical data of Huntington's disease carriers and patient's and control groups.

	Code	CAG repeat number	Sex	Calendar age, y	Disease duration, y	Age at clinical diagnosis, y	Age at symptom onset, y	Symptom at onset	Symptoms UHDR
Control	C1	23	F	25	n.a.	n.a.	n.a.	n.a.	n.a.
	C2	25	M	46	n.a.	n.a.	n.a.	n.a.	n.a.
	C3	23	M	47	n.a.	n.a.	n.a.	n.a.	n.a.
Premanifest & Prodromal HD	Pre-M1	46	M	25	n.a.	22	n.a.	n.a.	2
	Pre-M2	42	M	30	n.a.	29	n.a.	n.a.	n.a.
	Pre-M3	52	F	29	7	28	22	cognitive	24
Manifest HD	HD1	43	M	62	22	47	40	psychiatric	30
	HD2	42	F	66	19	54	47	psychiatric	Motor: 33
	HD3	46	F	43	7	39	36	psychiatric	72

Abbreviations: F- female; M- male; n.a.- not applied; C- controls; pre-M- premanifest HD carriers; HD- Manifest HD patients.

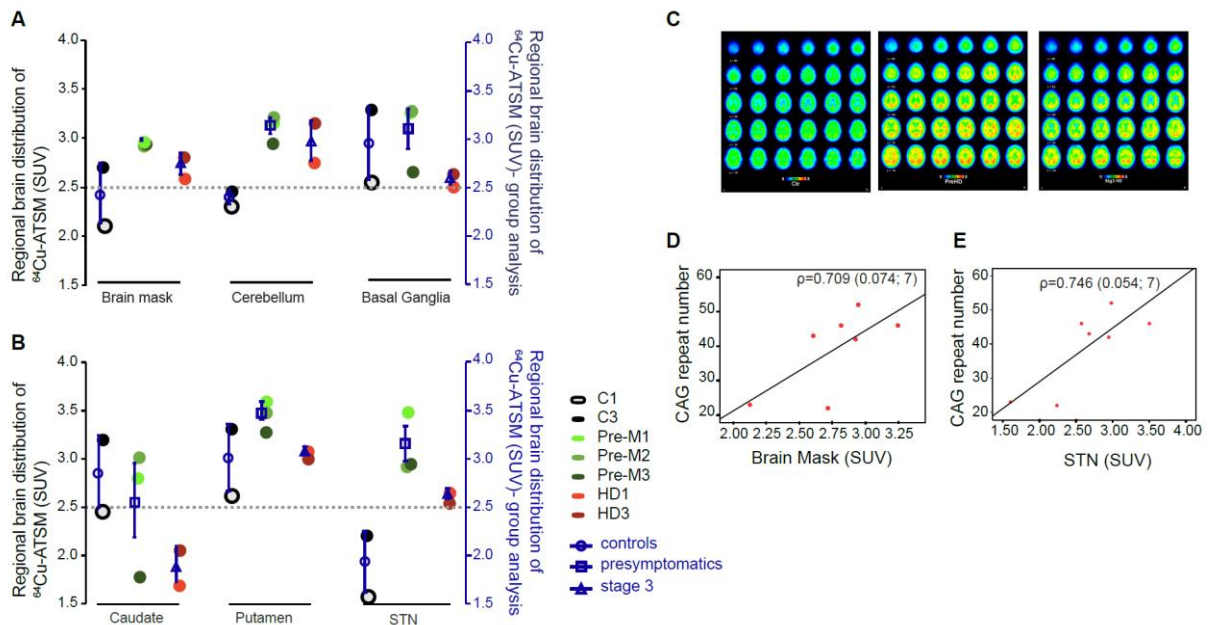

Figure 1: ^{64}Cu -ATSM brain accumulation in premanifest and manifest HD patients and correlation with CAG repeats. ^{64}Cu -ATSM brain PET imaging of HD patients and controls was evaluated in cerebellum and basal ganglia (A) and basal ganglia subregions: caudate, putamen and subthalamic nucleus (STN) (B) of controls (C), premanifest (Pre-M) and manifest HD (HD)

patient's brains, as described in Methods section. **(C)** Representative PET imaging of the 3 groups analyzed: controls, premanifest and manifest HD patients; PET color scale indicates the uptake of the $[^{64}\text{Cu}]$ -ATSM normalized for cerebral blood vessels SUVs. Correlation between CAG repeat number and normalized SUV of $[^{64}\text{Cu}]$ -ATSM uptake from total brain **(D)** and uptake from putamen anterior **(E)**. Regional brain distribution of $[^{64}\text{Cu}]$ -ATSM **(A)(B)** was calculated as the sum of 3 time-points SUVs between 14 to 22 minutes acquisition time; mean \pm SEM values of the groups are plotted on the secondary Y axis (blue). **(D)(E)** Correlation was performed using the Spearman correlation coefficient ρ (sig; n). SUV - standardized uptake values.

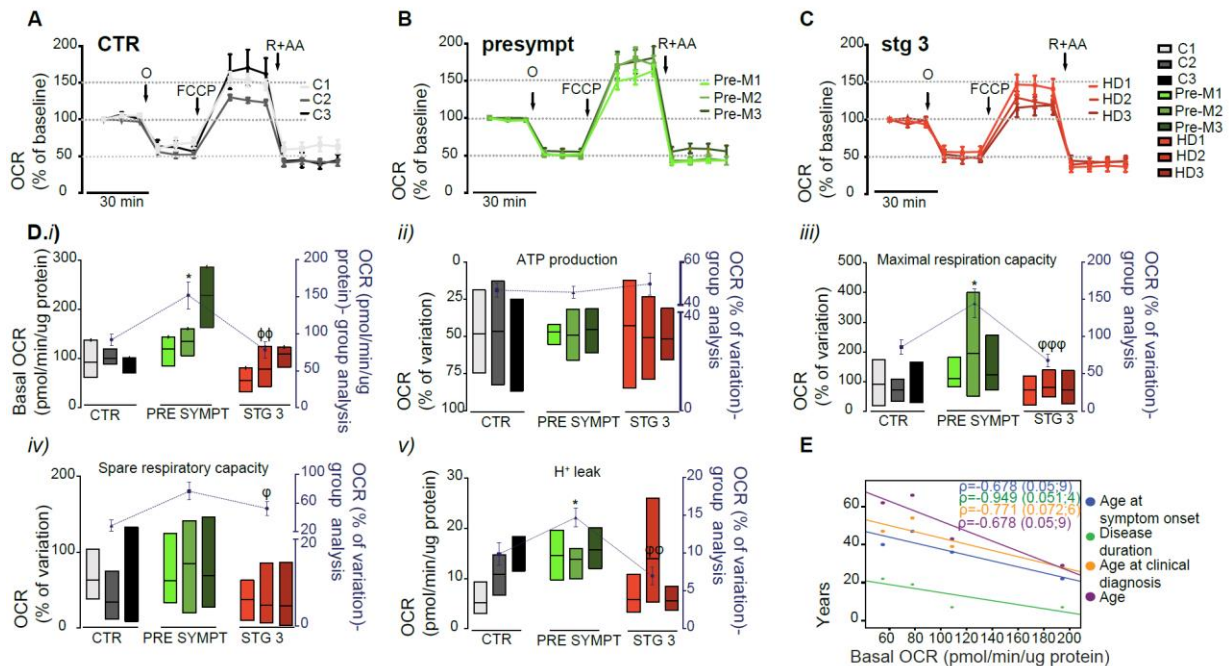

Figure 2: Oxygen consumption rate (OCR) in skin fibroblasts from premanifest and manifest HD carriers and controls. (A-C) OCR of cells treated with the different compounds. The mitochondrial inhibitors were sequentially injected into different ports of the Seahorse XF24 analyzer and the final concentrations of each were: 1 μM oligomycin (O), 0.3 μM FCCP (F), 1 μM rotenone and 1 μM antimycin A (R+A). **(D).**(i) Levels of basal OCR; (ii) oxygen consumed for ATP generation through the complex V; (iii) maximal respiration capacity; (iv) Spare respiratory capacity; (v) component of OCR representing passive H⁺ leakage across the mitochondrial inner membrane were calculated as described in Methods section; Individual data are presented as floating bars (min, max) with mean lines shown at least 3 independent

experiments; group analysis represents the mean \pm SEM values (controls (CTR), premanifest (Pre-M) and manifest HD patients) and are plotted on the secondary Y axis (blue). **(E)** Correlation was performed using the Spearman correlation coefficient ρ (sig; n). Statistical analysis: One-Way ANOVA – post hoc Bonferroni's multiple comparisons test. * $p < 0.05$ (controls vs premanifest); $\phi\phi$ $p < 0.01$ (controls vs HD manifest) and ϕ $p < 0.05$, $\phi\phi$ $p < 0.01$, $\phi\phi\phi$ $p < 0.001$ (premanifest vs HD manifest).

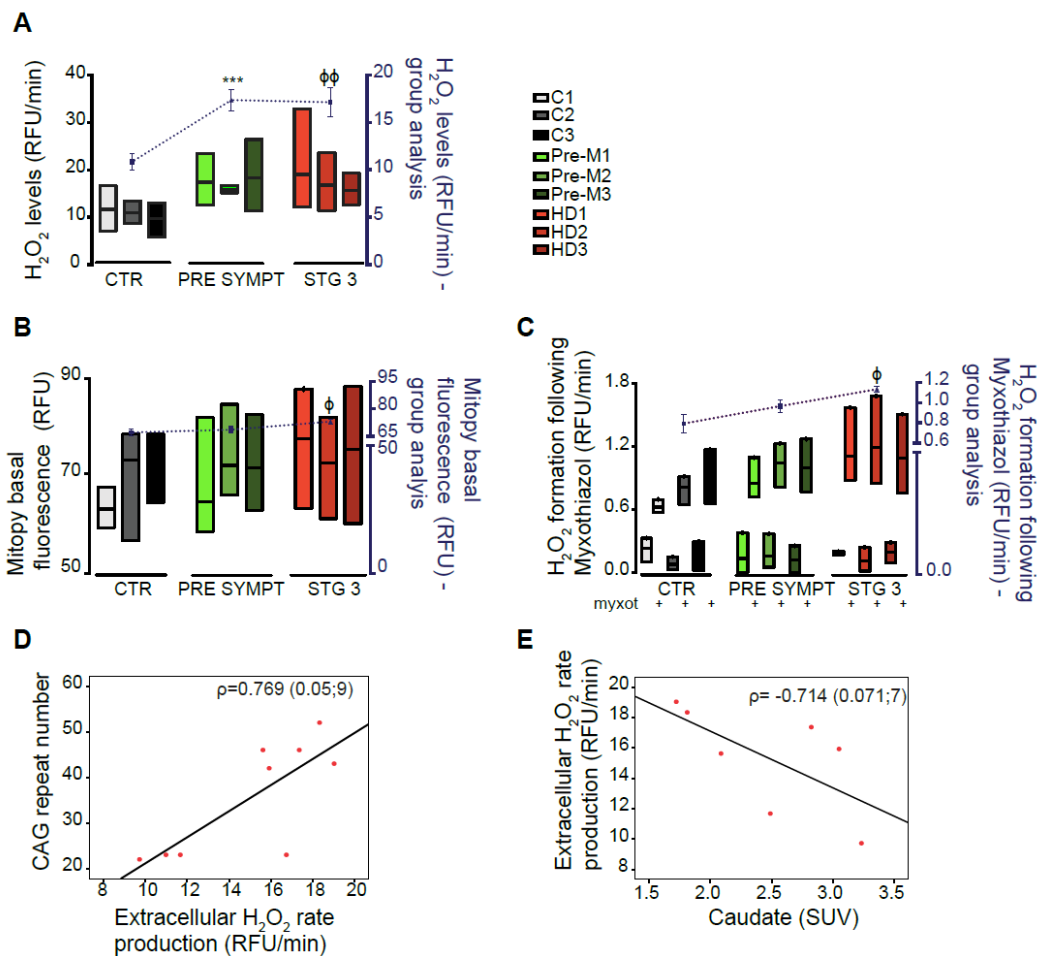

Figure 3: Cellular and mitochondrial ROS levels in skin fibroblasts from HD patient's and controls - correlation with CAG repeats and ⁶⁴Cu]ATSM uptake in caudate. Extracellular **(A)** and basal mitochondrial **(B)** H₂O₂ production were measured as described in Methods section and was plotted as bars graph. **(C)** Time-dependent H₂O₂ production in the mitochondria after stimulation with complex III inhibitor- myxothiazol (3 μ M). Individual data are presented as floating bars (min, max) with mean lines shown at least 3 independent experiments; group

analysis represents the mean±SEM values (controls (CTR), pre-symptomatic (Pre-M) and manifest HD patients) and are plotted on the secondary Y axis (blue). **(D)(E)** Correlation was performed using the Spearman correlation coefficient ρ (sig; n). Statistical analysis: non-parametric Kruskal-Wallis test followed by Dunn's Multiple Comparison Test. *** $p < 0.001$ (controls vs premanifest); and ϕ $p < 0.05$, $\phi\phi$ $p < 0.01$ (controls vs HDs).

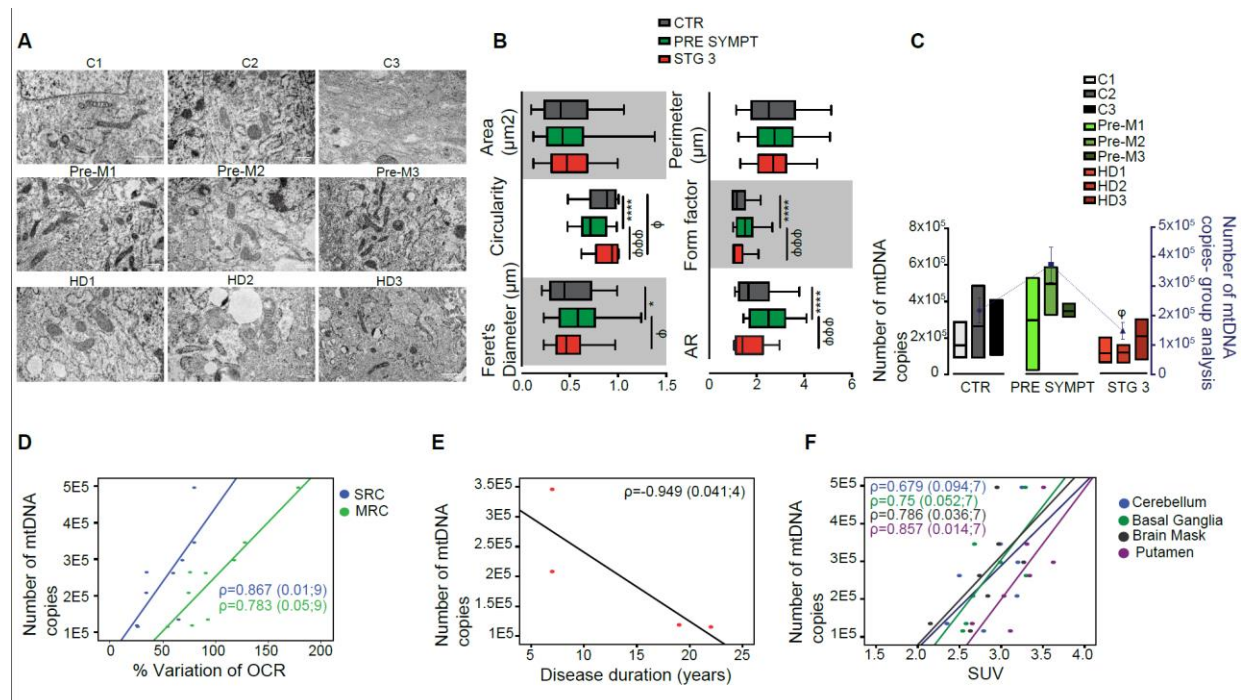

Figure 4: Mitochondrial morphological features and DNA copy number in fibroblasts derived from premanifest and manifest HD carriers and controls - correlation with $[^{64}\text{Cu}]$ -ATSM uptake, disease duration and OCR. (A) Transmission Electron Microscopy (TEM) representative images of mitochondrial ultrastructure. **(B)** Analysis of morphological parameters for mitochondria area, circularity, Feret's diameter, perimeter, form factor and aspect ratio made using ImageJ software. The results are expressed as the mean±SEM of mitochondria counted by images ($n=9-26$) from a total of $n=29-122$ mitochondria analysed. Bars represent the median and interquartile range [percentiles 5-95] for each parameter. Statistical analysis: ANOVA followed post-hoc Bonferroni test: **** $p < 0.0001$ (controls vs pre-symptomatic); ϕ $p < 0.05$, (controls vs HDs) and ϕ $p < 0.05$, $\phi\phi\phi$ $p < 0.001$ (premanifest vs HDs). **(C)** Number of mitochondrial DNA copies quantified as described in Methods section. Individual data are presented as floating bars (min, max) with mean lines shown at least 3

independent experiments; group analysis represents the mean \pm SEM values (controls (CTR), premanifest (Pre-M) and manifest HD carriers) and are plotted on the secondary Y axis (blue). Statistical analysis: non-parametric Kruskal-Wallis test followed by Dunn's Multiple Comparison Test. ϕ $p < 0.05$ (premanifest vs HDs) (**D-F**) Correlation was performed using the Spearman correlation coefficient ρ (sig; n). Scale bar: 2000 nm.

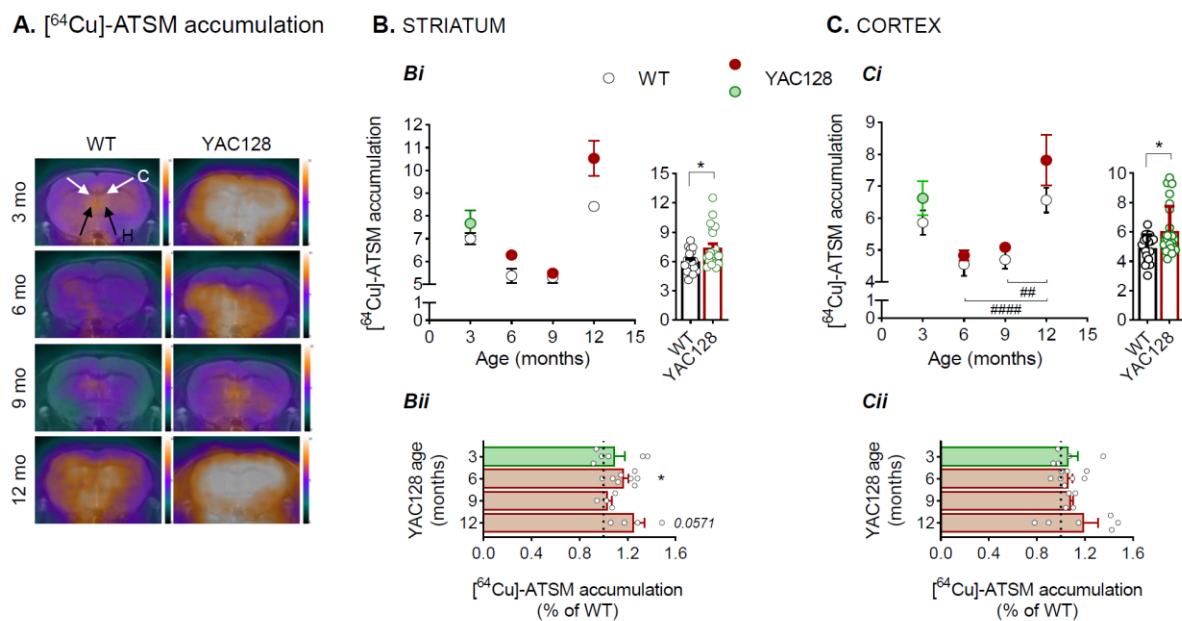

Figure 5: **Age-dependent $[^{64}\text{Cu}]$ -ATSM brain accumulation in YAC128 and WT mouse striatum and cortex.** $[^{64}\text{Cu}]$ -ATSM PET and MRI overlapped axial images of brain YAC128 and WT mice where PET color scale indicates the uptake (number of counts per mm^3) of the $[^{64}\text{Cu}]$ -ATSM normalized by the injected activity, mass of the mouse and sensibility of the PET equipment. White arrows point to frontal cortex and black arrows to striatum (**A**). $[^{64}\text{Cu}]$ -ATSM accumulation was plotted for striatum (**B**) and cortex (**C**) at 3, 6, 9 and 12 mo YAC128 vs WT mice, as described in Methods section and replotted as total radioligand accumulation for all ages of each genotype (insets **Bi** and **Ci** for striatum and cortex, respectively) and in percentage of WT for each age for striatum (**Bii**) and cortex (**Cii**). Statistical analysis: * $p < 0.05$ when compared with 6 mo WT mitochondria by nonparametric Mann-Whitney U test.

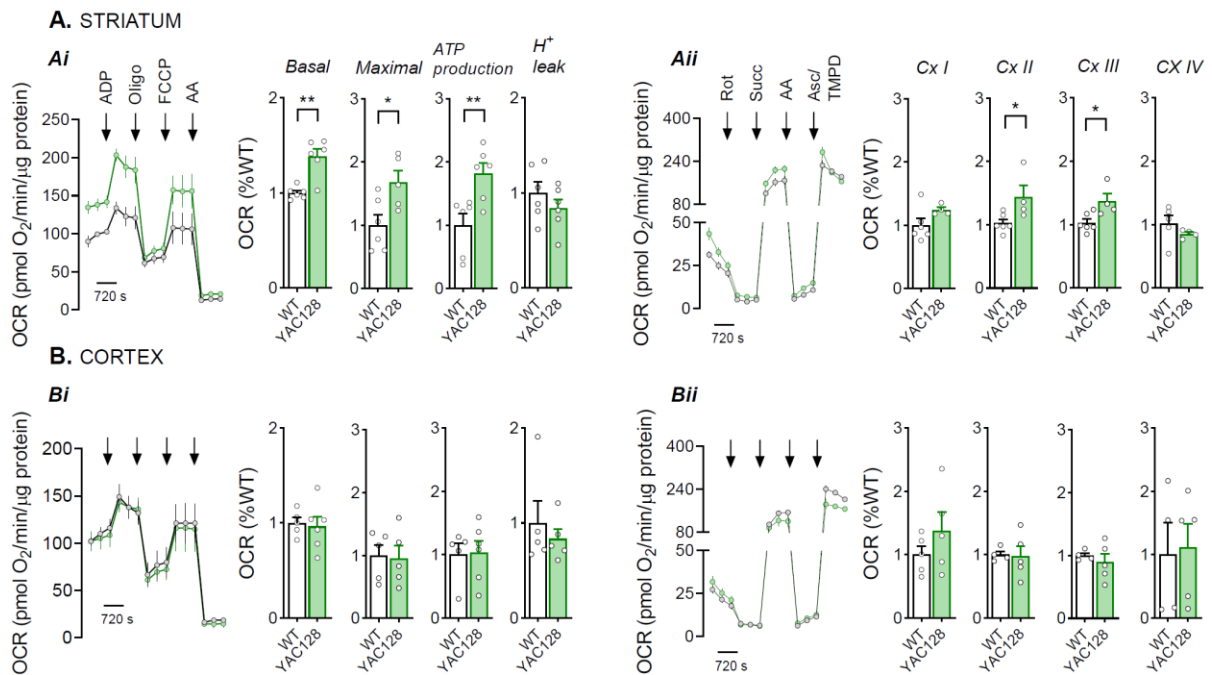

Figure 6: Oxygen consumption rates (OCR) in 3 mo YAC128 mouse striatal and cortical mitochondria. Mitochondrial respiration was measured using the Seahorse flux analyzer in 3 mo YAC128 and WT striatal (**A**) and cortical (**B**) isolated mitochondria. Levels of respiratory coupling (**Ai and Bi**; for striatal and cortical mitochondria, respectively) were analysed in MAS containing 10 mM succinate plus 2 μM rotenone under sequentially injection of mitochondrial inhibitors and substrates (final concentration: 4 mM ADP; 2.5 μg/mL oligomycin; 4 μM FCCP and 4 μM antimycin A) as shown in representative traces and basal respiration and maximal respiration, ATP production and H⁺ calculated as described in Methods section. The activity of mitochondrial respiratory chain complexes (**Aii and Bii**; for striatal and cortical mitochondria, respectively) was analyzed in uncoupling conditions performed in MAS containing 4 μM FCCP, 10 mM pyruvate and 2 mM malate. Mitochondrial inhibitors and substrates were sequentially injected (final concentration: 2 μM rotenone, 10 mM succinate, 4 μM antimycin A and 10 mM ascorbate/100 μM TMPD) as shown in the representative traces and Cx I-IV activities calculated as described in Methods section. Data are the mean ± SEM of experiments performed in independent mitochondrial preparations obtained from 3-7 mice from each genotype, run in duplicates or triplicates. Statistical analysis: *p<0.05, **p<0.01 when compared with WT mitochondria, by nonparametric Mann-Whitney U test.

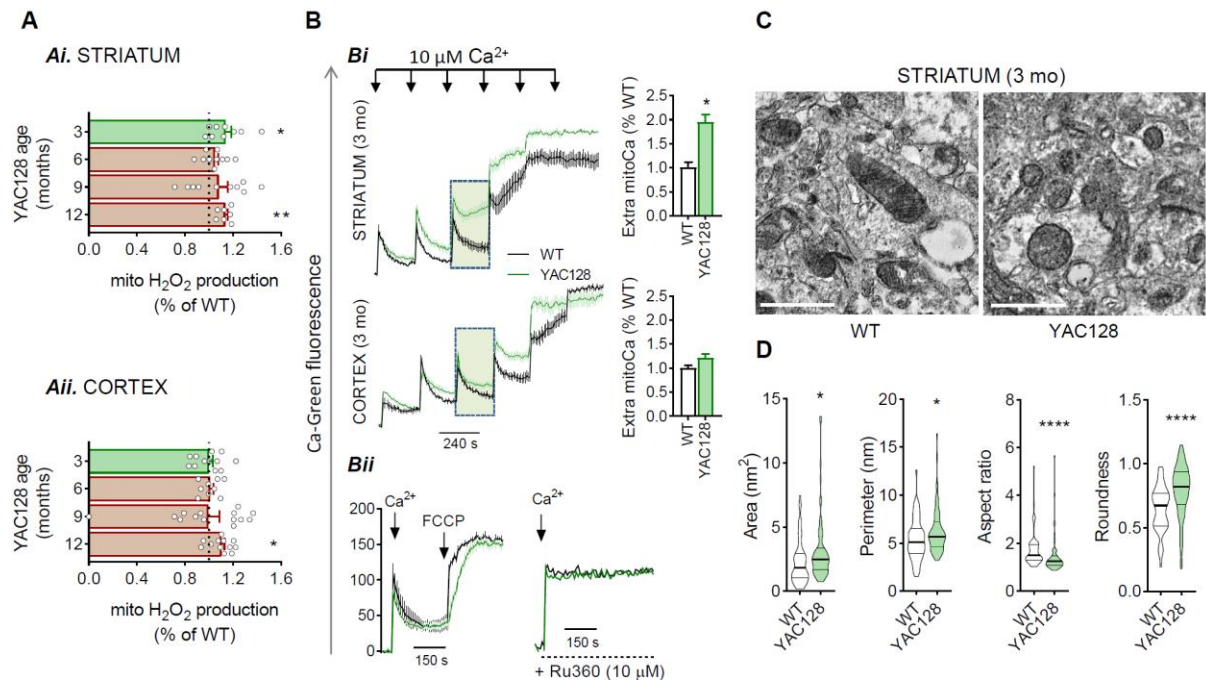

Figure 7: Mitochondrial ROS levels, Ca^{2+} handling, and mitochondrial ultrastructure in YAC128 mouse striatal and cortical mitochondria.

H_2O_2 production was measured in functional isolated mitochondria (**A**) derived from 3, 6, 9 and 12 mo YAC128 and WT mice striatum (**Ai**) and cortex (**Aii**) using the Amplex Red assay as described in Methods section. The capacity to handle Ca^{2+} was evaluated in striatal and cortical mitochondria obtained from 3 mo YAC128 and WT mice (**B**) by using Calcium Green-5N fluorescent probe. Pulses of 10 μM Ca^{2+} were applied to raise intramitochondrial Ca^{2+} concentrations until the Ca^{2+} retention capacity was reached as shown by the upward deflection of the traces (**Bi**). The Ca^{2+} handling capacity for striatal and cortical mitochondria at the third Ca^{2+} pulse is detailed in the dashed green window and presented as extra-mitochondrial Ca^{2+} (area under the curve) (**Bi, inset**). The effect of the mitochondrial uncoupler FCCP and the pharmacological inhibition of the mitochondrial calcium uniporter (MCU; Ru360) are also depicted (**Bii**). Electron micrographs were obtained from 3 mo YAC128 and WT mice striatum and mitochondrial morphology presented for area, perimeter, aspect ratio and roundness as evaluated by Fiji-imageJ software (**C**). Over 62 individual mitochondria were assessed in independent preparations from 6 independent TEM images from WT and YAC128 mice (scale bar: 1000 nm). Data are the mean \pm SEM of experiments performed in independent mitochondrial preparations obtained from 3-16 mice from each genotype run in triplicates to quadruplicates. Statistical analysis: * $p < 0.05$, ** $p < 0.01$, **** $p < 0.0001$ when compared with WT mitochondria, by nonparametric Mann-Whitney U test.

Graphical Abstract/Figure 8:

Overview of the mechanism responsible to $[^{64}\text{Cu}]\text{-ATSM}$ uptake and retention in cells from HD carriers, at premanifest and manifest stages. In premanifest/prodromal stages of HD an electron rich environment induced by increase ROS production and an impaired electron transport chain can result in an overreduced state. Under these conditions Cu(II)-ATSM is reduced to Cu(I)-ATSM after entering the cell, turning the complex unstable, and free copper-64 is trapped and accumulated in the intracellular space.
