

Foldseek: fast and accurate protein structure search

Michel van Kempen,^{1,*} Stephanie S. Kim,^{2,*} Charlotte Tumescheit,² Milot Mirdita,¹
Cameron L.M. Gilchrist,² Johannes Söding,^{1,3,†} and Martin Steinegger^{2,4,5,†}

Highly accurate structure prediction methods are generating an avalanche of publicly available protein structures. Searching through these structures is becoming the main bottleneck in their analysis. Foldseek enables fast and sensitive comparisons of large structure sets. It reaches sensitivities similar to state-of-the-art structural aligners while being four to five orders of magnitude faster. Foldseek is free open-source software available at foldseek.com and as a webserver at search.foldseek.com.

1 The recent breakthrough in *in-silico* protein structure pre-
2 diction at near-experimental quality [1, 2] is revolutionizing
3 structural biology and bioinformatics. The European Bioin-
4 formatics Institute already holds 1 106 829 protein structures
5 predicted by AlphaFold2 and plans to increase this to hun-
6 dreds of millions this year [3], with billions to be expected
7 soon [4]. The scale of this treasure trove poses challenges to
8 state-of-the-art analysis methods.

9 The most widely used approach to protein annotation and
10 analysis is based on sequence similarity search [5–8]. The goal
11 is to find homologous sequences from which properties of the
12 query sequence can be inferred, such as molecular and cellular
13 functions and structure. Despite the success of sequence-
14 based homology inference, many proteins cannot be annotated
15 because detecting distant evolutionary relationships from se-
16 quences alone remains challenging [9].

17 Detecting similarity between protein structures by 3D su-
18 perposition offers higher sensitivity for identifying homologous
19 proteins [10]. The imminent availability of high-quality struc-
20 tures for any protein of interest could allow us to use struc-
21 ture comparison to improve homology inference and struc-
22 tural, functional and evolutionary analyses. However, despite
23 decades of effort to improve speed and sensitivity of struc-
24 tural aligners, current tools are much too slow to cope with
25 the expected scale of structure databases.

26 Searching with a single query structure through a database
27 with 100 M protein structures would take the popular TM-
28 align [11] tool a month on one CPU core, and an all-versus-all
29 comparison would take 10 millennia on a 1 000 core cluster.
30 Sequence searching is four to five orders of magnitude faster:
31 An all-versus-all comparison of 100 M sequences would take
32 MMseqs2 [6] only around a week on the same cluster.

33 Structural alignment tools (reviewed in [12]) are slower for
34 two reasons. First, whereas sequence search tools employ
35 fast and sensitive prefilter algorithms to gain orders of mag-
36 nitude in speed, no comparable prefilters exist for structure
37 alignment. Second, structural similarity scores are non-local:
38 changing the alignment in one part affects the similarity in
39 all other parts. Most structural aligners, such as the popu-

40 lar TM-align, Dali, and CE [11, 13, 14], solve the alignment
41 optimization problem by iterative or stochastic optimization.

42 To increase speed, a crucial idea is to describe the amino
43 acid backbone of proteins as sequences over a structural alpha-
44 bet and compare structures using sequence alignments [15].
45 Structural alphabets thus reduce structure comparisons to
46 much faster sequence alignments. Many ways to discretize
47 the local amino acid backbone have been proposed [16]. Most,
48 such as CLE, 3D-BLAST, and Protein Blocks, discretize the
49 conformations of short stretches of usually 3 to 5 C α atoms
50 [17–19]. 3D-BLAST and CLE trained a substitution matrix
51 for their structural alphabet and rely on an aligner like BLAST
52 [5] to perform the sequence searches.

53 For Foldseek, we developed a novel type of structural alpha-
54 bet that does not describe the backbone but rather tertiary
55 interactions. The 20 states of the 3D-interactions (3Di) al-
56 phabet describe for each residue i the geometric conformation
57 with its spatially closest residue j . Compared to the various
58 backbone structural alphabets, 3Di has three key advantages:
59 First, the dependency of consecutive 3Di letters on each other
60 is weaker than for backbone structural alphabets, where for
61 instance a helix state is followed by another helix state with
62 high probability. The dependency decreases information den-
63 sity and results in high-scoring false alignments. Second, the
64 frequencies of the 3Di states are more evenly distributed than
65 for backbone states, for which 60 % describe generic secondary
66 structure states. This further increases information density in
67 3Di sequences (**Supplementary Table 1**) and decreases false
68 positives. Third, in backbone structural alphabets, less infor-
69 mation is contained in the highly conserved protein cores (con-
70 sisting mostly of regular secondary structure elements) and
71 more in the predominantly non-conserved coil/loop regions.
72 In contrast, 3Di sequences have the highest information den-
73 sity in conserved cores and the lowest in loop regions.

74 Foldseek (**Fig. 1a**) (1) discretizes the query structures into
75 sequences over the 3Di alphabet and then searches through
76 the 3Di sequences of the target structures using the double-
77 diagonal k -mer-based prefilter and gapless alignment prefilter
78 modules from MMseqs2, our open-source sequence search soft-
79 ware [6]. (2) High scoring hits are aligned locally using 3Di
80 (default) or globally with TM-align. The local alignment stage
81 combines 3Di and amino acid substitution scores. The con-
82 struction of the 3Di alphabet is summarized in **Fig. 1b** and
83 **Supplemental Fig. 2-4**.

84 To minimize high-scoring false positives caused by struc-
85 turally disordered regions and to provide reliable E-values, for
86 each match we subtract the score of the reversed query se-

FIG. 1. Foldseek workflow. (a) Foldseek searches a set of query structures through a set of target structures. (1) Query and target structures are discretized into 3Di sequences (see b). To detect candidate structures, we apply the fast and sensitive k -mer and ungapped alignment prefilter of MMseqs2 to the 3Di sequences, (2) followed by vectorized Smith-Waterman local alignment combining 3Di and amino acid substitution scores. Alternatively, a global alignment is computed with a 1.7 times accelerated TM-align version (see **Supplementary Fig. 1**). (b) Learning the 3Di alphabet: (1) 3Di states describe tertiary interaction between a residue i and its nearest neighbor j . Nearest neighbors have the closest virtual center distance (yellow). Virtual center positions (**Supplementary Fig. 2**) were optimized for maximum search sensitivity. (2) To describe the interaction geometry of residues i and j , we extract seven angles, the Euclidean C_α distance, and two sequence distance features from the six C_α coordinates of the two backbone fragments (blue, red). (3) These 10 features are used to define 20 3Di states by training a vector-quantized variational autoencoder [20] modified to learn states that are maximally evolutionary conserved. For structure searches, the encoder predicts the best-matching 3Di state for each residue.

87 quence from the original score. Furthermore, a compositional
88 bias correction lowers the substitution scores of 3Di states en-
89 riched within a local 40 residue window (see “Pair-
90 wise local structural alignments”). E-values are calculated
91 based on an extreme-value score distribution whose param-
92 eters are predicted by a neural network from 3Di sequence
93 composition and query length (see “E-Values”).

94 We measured the sensitivity and speed of Foldseek, six
95 protein structure alignment tools, an alignment-free struc-
96 ture search tool (Geometricus [21]) and a sequence search
97 tool (MMseqs2 [6]) on the SCOPe dataset of manually clas-
98 sified single-domain structures [22]. Clustering SCOPe 2.01
99 at 40% sequence identity yielded 11 211 non-redundant pro-
100 tein sequences (“SCOPe40”). We performed an all-versus-all
101 search and compared the tools’ performance for finding mem-
102 bers of the same SCOPe family, superfamily, and fold (true
103 positive matches, TPs) by measuring for each query the frac-
104 tion of TPs out of all possible correct matches until the first
105 false positive (FP). FPs are matches to a different fold (see
106 “SCOPe Benchmark”). The sensitivity was measured by the
107 area under the curve (AUC) of the cumulative ROC curve up
108 to the first FP (**Fig. 2a**).

109 Foldseek reaches sensitivities at family and superfamily
110 level below Dali, higher than the structural aligner CE, and
111 similar to TM-align and TM-align-fast. Foldseek is much
112 more sensitive than structural alphabet-based search tools 3D-
113 BLAST and CLE-SW (**Fig. 2a-b**). Similarly, Foldseek has the
114 second highest area under the precision-recall curve on each
115 of the three levels (**Fig. 2c**, **Supplementary Fig. 5**). The
116 performance is comparable across all six secondary structure
117 classes in SCOPe (**Supplementary Fig. 6**). On this small
118 SCOPe40 benchmark set, Foldseek is more than 4,000 times
119 faster than TM-align and Dali, and over 21,000 times faster

120 than CE (**Fig. 2b**). On the much larger AlphaFoldDB version
121 1 (v1), where Foldseek approaches its full speed, it is around
122 184,600 and 23,000 faster than Dali and TM-align, respec-
123 tively (see below). Its E-values are accurate, which is critical
124 for homology detection (**Fig. 2d**)

125 We devised a reference-free benchmark to assess search
126 sensitivity and alignment quality of structural aligners (see
127 **Fig. 2e,f**) on a more realistic set of full-length, multi-domain
128 proteins. We clustered the AlphaFoldDB (v1) to 34,270 struc-
129 tures using BLAST and SPICi [23]. We selected randomly 100
130 query structures from this set and aligned them against the
131 remaining structures. TP matches are those with a Local Dis-
132 tance Difference Test (LDDT) score [24] of at least 0.6 and FPs
133 below 0.25, ignoring matches in-between. (For other thresh-
134 olds and top-hit LDDT distributions, see **Supplementary**
135 **Figs. 7,8**). LDDT measures the agreement of local residue-
136 residue distances between two aligned structures. We set the
137 LDDT thresholds according to the median inter- and intra-
138 fold, -superfamily and -family LDDT scores of SCOPe40 align-
139 ments, see **Supplementary Fig. 9**. A domain-based sensitiv-
140 ity assessment would require a reference-based prediction of
141 domains. To avoid it, we evaluated the sensitivity per residue.
142 **Fig. 2e** shows the distribution of the fraction of query residues
143 that were part of alignments with at least x TP targets with
144 better scores than the first FP match. Again, Foldseek has
145 similar sensitivity as Dali, CE, and TM-align and much higher
146 than CLE-SW and MMseqs2.

147 We analyzed the quality of alignments produced by the top
148 five matches per query. We computed the alignment sensitiv-
149 ity as the number of TP residues divided by the query length
150 and the precision as the number of TP residues divided by
151 the alignment length. TP residues are those with residue-
152 specific LDDT score above 0.6, FP residues are below 0.25,

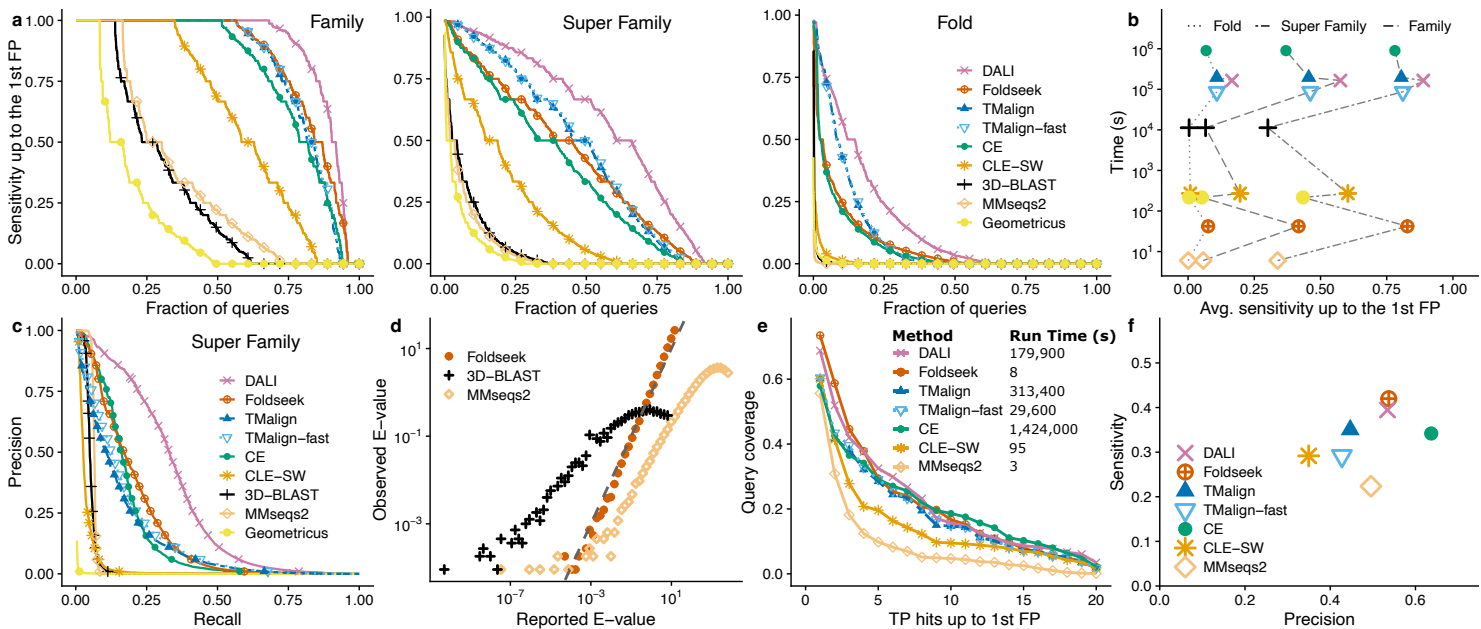

FIG. 2. Foldseek reaches similar sensitivities as structural aligners at thousands of times their speed (a) Cumulative distributions of sensitivity for homology detection on the SCOPe40 database of single-domain structures. True positives (TPs) are matches within the same SCOPe family, superfamily or fold, false positives (FPs) are matches between different folds. Sensitivity is the area under the ROC curve up to the first FP. (b) Avg. sensitivity up to the first FP for family, superfamily and fold versus total runtime on an AMD EPYC 7702P 64-core CPU for the all-versus-all searches of 11 211 structures of SCOPe40. (c) Precision-Recall curve of SCOPe40 superfamilies (see **Supplementary Fig. 5** for family and fold). (d) Accuracy of reported E-values: Mean number of FPs per query below the reported E-value threshold. (e) Search sensitivity on multi-domain, full-length AlphaFold2 protein models. 100 queries, randomly selected from AlfaFoldDB (v1), were searched against this database. Per-residue query coverage is the fraction of residues that are covered by at least x TP matches ranked before the first FP match. (f) Alignment quality for alignments of AlphaFoldDB (v1) protein models, averaged over the top five matches of each of the 100 queries. Sensitivity = TP residues in alignment / query length, precision = TP residues / alignment length.

153 residues with other scores are ignored. **Fig. 2f** shows the average sensitivity versus precision of the 100×5 structure alignments. Foldseek alignments are more accurate and sensitive than MMseqs2, CLE-SW, and TM-align, similarly accurate as Dali, and 16% less precise but 23% more sensitive than CE. In a reference-based alignment quality benchmark, Foldseek performs slightly below CE, Dali, and TM-align (**Supplementary Fig. 10**).

161 To find potentially problematic high-scoring Foldseek FPs, we searched the set of unfragmented models in AlphaFoldDB (v1) with average predicted LDDT [1] ≥ 80 against itself. We inspected the 1,675 (of 133 813) highscoring FPs (score per aligned column ≥ 1.0 , TM-score < 0.5), revealing queries with multiple segments correctly folded by AlphaFold2 but with incorrect relative orientations (**Supplementary Table 2, Supplementary Fig. 11**). The segments were correctly aligned by Foldseek. This illustrates that 3D aligners as TM-align may overlook homologous structures that are not globally superposable, whereas the 1D aligner Foldseek (as the 2D aligner Dali) is independent of relative domain orientations and excels at detecting homologous multi-domain structures [12].

174 We developed a webserver that can search through four structure databases, AlphaFoldDB (Uniprot50, Proteome, Swiss-Prot) and PDB100, using as alignment method standard Foldseek (default) or TM-align. The server takes PDB files as input and returns a list of

179 matched structures, sequence alignments, bit-scores, E-values or TM-scores, and 3D structural alignments.

180 We compared the Foldseek webserver with TM-align and Dali by searching with the SARS-CoV-2 RNA-dependent RNA polymerase (RdRp, PDB: 6M71_A [25]; 942 residues) through the AlphaFoldDB (Proteome+Swiss-Prot) containing 804 872 structures. On a single CPU core, the search took 10 days with Dali, 33h with TM-align, and 5s with Foldseek, 23 000 or 180 000 times faster. The 10 top hits of Foldseek, TM-align, and DALI are to reverse transcriptases and kinases, which are known homologs (**Supplementary Table 3**). We have included the new Uniprot/AlphaFold (version 3) database clustered to 50% sequence identity, with 52,327,413 million models, which Foldseek can search in 90 seconds per 300-residue query structure using a single core.

194 The availability of high-quality structures for nearly every folded protein is going to be transformative for biology and bioinformatics. Sequence-based analyses will soon be largely superseded by structure-based analyses. The main limitation in our view, the four orders of magnitude slower speed of structure comparisons, is removed by Foldseek.

METHODS

259

260 **Overview** Foldseek enables fast and sensitive comparison of
261 large structure sets. It encodes structures as sequences over
262 the 20-state 3Di alphabet and thereby reduces structural align-
263 ments to 3Di sequence alignments. The 3Di alphabet devel-
264 oped for Foldseek describes tertiary residue-residue interac-
265 tions instead of backbone conformations and proved critical
266 for reaching high sensitivities. Foldseek’s prefilter finds two
267 *similar*, spaced 3Di *k*-mer matches in the same diagonal of
268 the dynamic programming matrix. By not restricting itself to
269 exact matches, the prefilter achieves high sensitivity while re-
270 ducing the number of sequences for which full alignments are
271 computed by several orders of magnitude. Further speed-ups
272 are achieved by multi-threading and utilizing single instruction
273 multiple data (SIMD) vector units. Owing to the SIMDe li-
274 brary (github.com/simd-everywhere/simde), Foldseek runs on
275 a wide range of CPU architectures (x86_64, arm64, ppc64le)
276 and operating systems (Linux, macOS). The core modules of
277 Foldseek, which build on the MMseqs2 framework [26], are de-
278 scribed in the following paragraphs.

279 **Create database** The `createdb` module converts a set of
280 Protein Data Bank (PDB; [27]) or macromolecular Crystal-
281 lographic Information File (mmCIF) formatted files into an
282 internal Foldseek database format using the gemmi package
283 (project-gemmi.github.io). The format is compatible with
284 the MMseqs2 database format, which is optimized for paral-
285 lel access. We store each chain as a separate entry in the
286 database. The module follows the MMseqs2 `createdb` mod-
287 ule logic. However, in addition to the amino acid sequence it
288 computes the 3Di sequence from the 3D atom coordinates of
289 the backbone atom and C_β coordinates (see “Descriptors for
290 3Di structural alphabet” and “Optimize nearest-neighbor se-
291 lection”). Backbone atom and C_β coordinates are only needed
292 for the nearest-neighbor selection. For C_α -only structures,
293 Foldseek reconstructs backbone atom coordinates using PUL-
294 CHRA [28]. Missing C_β coordinates (e.g. in glycines) are
295 defined such that the four groups attached to the C_α are ar-
296 ranged at the vertices of a regular tetrahedron. The 3Di and
297 amino acid sequences and the C_α coordinates are stored in the
298 Foldseek database.

299 **Prefilter** The `prefilter` module detects double matches of
300 similar spaced words (k-mers) that occur on the same diag-
301 onal. The k-mer size is $k = 6$ by default. Similar k-mers are
302 those with a 3Di substitution matrix score above a certain
303 threshold, whereas MMseqs2 uses the Blosum62 substitution
304 matrix to compute the similarity. (see “3Di substitution score
305 matrix”). The gapless double-match criterion suppresses hits
306 to non-homologous structures effectively, as they are less likely
307 to have consecutive k-mer matches on the same diagonal by
308 chance. To avoid FP matches due to regions with biased 3Di
309 sequence composition, a compositional bias correction is ap-
310 plied in a way analogous to MMseqs2 [29]. For each hit we
311 perform an ungapped alignment over the diagonals with dou-
312 ble, consecutive, similar k-mer matches and sort those by the
313 maximum ungapped diagonal score. Alignments with a score
314 of at least 15 bits are passed on to the next stage.

315 **Pairwise local structural alignments** After the prefilter
316 has removed the vast majority of non-homologous sequences,
317 the `structurealign` module computes pairwise alignments
318 for the remaining sequences using a SIMD accelerated Smith-
319 Waterman algorithm [30, 31]. We extended this implementa-
320 tion to support amino acid and 3Di scoring, compositional bias
321 correction, and 256-bit-wide vectorization. The score linearly
322 combines amino acid and 3Di substitution scores with weights
323 1.4 and 2.1, respectively. We optimized these two weights and
324 the ratio of gap-extend to gap open-penalty on $\sim 1\%$ of align-
325 ments (all-versus-all on 10% of randomly selected SCOPe40
326 domains). A compositional bias correction is applied to the
327 amino acid and 3Di scores. To further suppress high-scoring
328 FP matches, for each match we align the reversed query se-
329 quence against the target and subtract the reverse score from
330 the forward score.

331 **E-Values** To estimate E-values for each match, we trained
332 a neural network to predict the mean μ and scale parameter
333 λ of the extreme value distribution for each query. Module
334 `computemulambda` takes a query and database structures as
335 input and aligns the query against a randomly shuffled ver-
336 sion of the database sequences. For each query sequence the
337 module produces N random alignments and fits to their scores
338 an extreme-value (Gumbel) distribution. The maximum like-
339 lihood fitting is done using the Gumbel fitting function taken
340 from HMMER3 (`hmmcalibrate`) [32]. To train the neural net-
341 work, it is critical to use query and target proteins that include
342 problematic regions such as structurally biased, disordered, or
343 badly modeled regions that occur ubiquitously in full-length
344 proteins or modeled structures. We therefore trained the net-
345 work on 100 000 structures sampled from the AlphaFoldDB
346 (v1). We trained a neural network to predict μ and λ from
347 the amino acid composition of the query and its length (so a
348 scrambled version of the query sequence would produce the
349 same μ and λ). The network has 22 input nodes, 2 fully-
350 connected layers with 32 nodes each (ReLU activation) and
351 two linear output nodes. The optimizer ADAM with learning
352 rate 0.001 was used for training. When testing the resulting
353 E-values on searches with scrambled sequences, the log of the
354 mean number of FPs per query turned out to have an accu-
355 rately linear dependence on the log of the reported E-values,
356 albeit with a slope of 0.32 instead of 1. We therefore correct
357 the E-values from the neural network by taking them to the
358 power of 0.32. We compared how well the mean number of
359 FPs at a given E-value agreed with the E-values reported by
360 Foldseek, MMseqs2, and 3D-Blast, (**Fig. 2d** for SCOPe40 and
361 **Supplementary Fig. 12** for AlphaFoldDB). We considered a
362 hit as FP if it was in a different fold and had a TM-score lower
363 than 0.3. Furthermore, we ignored all cross-fold hits within the
364 four- to eight-bladed β -propeller superfamilies (SCOPe b.66-
365 b.70) and within the Rossman-like folds (c.2-c.5, c.27, c.28,
366 c.30, and c.31) because of the extensive cross-fold homologies
367 within these groups [33].

368 **Pairwise global structural alignments using TM-align**
369 We also offer the option to use TM-align for pairwise struc-
370 ture alignment instead of the 3Di-based alignment. We im-
371 plemented TM-align based on the C_α atom coordinates and
372 made adjustments to improve the (1) speed and (2) memory

usage. (1) TM-align performs multiple floating-point based Needleman-Wunsch (NW) alignment steps, while applying different scoring functions (e.g., score secondary structure, Euclidean distance of superposed structures or fragments, etc.) TM-align’s NW code did not take advantage of SIMD instructions, therefore, we replaced it by parasail’s [34] SIMD-based NW implementation and extended it to support the different scoring functions. We also replaced the TM-score computation using fast_protein_cluster’s SIMD based implementation [35]. Our NW implementation does not compute exactly the same alignment since we apply affine gap costs while TM-align does not (**Supplementary Fig. 1**). (2) TM-align requires 17 bytes \times query length \times target length of memory, we reduce the constant overhead from 17 to 4 bytes. If Foldseek is used in TM-align mode (parameter `--alignment-type 1`), we replace the reported E-value column with TM-scores normalized by the query length. The results are ordered in descending order by TM-score.

Descriptors for 3Di structural alphabet The 3Di alphabet describes the tertiary contacts between residues and their nearest neighbors in 3D space. For each residue i the conformation of the local backbone around i together with the local backbone around its nearest neighbor j is approximated by 20 discrete states (see **Supplementary Fig. 4**). We chose the alphabet size $A=20$ as a trade-off between encoding as much information as possible (large A , see **Supplementary Fig. 13**) and limiting the number of similar 3Di k -mers that we need to generate in the k -mer based prefilter, which scales with A^k . The discrete single-letter states are formed from neighborhood descriptors containing ten features encoding the conformation of backbones around residues i and j represented by the C_α atoms ($C_{\alpha,i-1}, C_{\alpha,i}, C_{\alpha,i+1}$) and ($C_{\alpha,j-1}, C_{\alpha,j}, C_{\alpha,j+1}$). The descriptors use the five unit vectors along the following directions,

$$\begin{aligned} u_1 : C_{\alpha,i-1} &\rightarrow C_{\alpha,i} & u_4 : C_{\alpha,j} &\rightarrow C_{\alpha,j+1} \\ u_2 : C_{\alpha,i} &\rightarrow C_{\alpha,i+1} & u_5 : C_{\alpha,i} &\rightarrow C_{\alpha,j} \\ u_3 : C_{\alpha,j-1} &\rightarrow C_{\alpha,j} & & \end{aligned}$$

We define the angle between u_k and u_l as ϕ_{kl} , so $\cos \phi_{kl} = u_k^T u_l$. The seven features $\cos \phi_{12}, \cos \phi_{34}, \cos \phi_{15}, \cos \phi_{35}, \cos \phi_{14}, \cos \phi_{23}, \cos \phi_{13}$, and the distance $|C_{\alpha,i} - C_{\alpha,j}|$ describe the conformation between the backbone fragments. In addition, we encode the sequence distance with the two features $\text{sign}(i-j) \min(|i-j|, 4)$ and $\text{sign}(i-j) \log(|i-j| + 1)$.

Learning the 3Di states using a VQ-VAE The ten-dimensional descriptors were discretized into an alphabet of 20 states using a variational autoencoder with vector-quantized latent variables (VQ-VAE) [36]. In contrast to standard clustering approaches such as k-means, VQ-VAE is a nonlinear approach that can optimize decision surfaces for each of its states. In contrast to the standard VQ-VAE, we trained the VQ-VAE not as a simple generative model but rather to learn states that are maximally conserved in evolution. To that end, we trained it with pairs of descriptors $\mathbf{x}_n, \mathbf{y}_n \in \mathbb{R}^{10}$ from structurally aligned residues, to predict the distribution of \mathbf{y}_n from \mathbf{x}_n .

The VQ-VAE consists of an encoder and decoder network

with the discrete latent 3Di state as a bottleneck in-between. The encoder network embeds the 10-dimensional descriptor \mathbf{x}_n into a two-dimensional continuous latent space, where the embedding is then discretized by the nearest centroid, each centroid representing a 3Di state. Given the centroid, the decoder predicts the probability distribution of the descriptor \mathbf{y}_n of the aligned residue. After training, only encoder and centroids are used to discretize descriptors. Encoder and decoder networks are both fully connected with two hidden layers of dimension 10, a batch normalization after each hidden layer and ReLU as activation functions. The encoder, centroids, and decoder have 242, 40, and 352 parameters, respectively. The output layer of the decoder consists of 20 units predicting μ and σ^2 of the descriptors x of the aligned residue, such that the decoder predicts $\mathcal{N}(x|\mu, I\sigma^2)$ (with diagonal covariance).

We trained the VQ-VAE on the loss function defined in Equation (3) in [36] (with commitment loss = 0.25) using the deep-learning framework PyTorch (version 1.9.0), the ADAM optimizer, with a batch size of 512, and a learning rate of 10^{-3} over 4 epochs. Using Kerasify, we integrated the encoder network into Foldseek. The domains from SCOPe40 were split 80%/20% by fold into training and validation sets. For the training, we aligned the structures with TM-align, removed all alignments with a TM-score below 0.6, and removed all aligned residue pairs with a distance between their C_α atoms of more than 5 Å. We trained the VQ-VAE with 100 different initial parameters and chose the model that was performing best in the benchmark on the validation dataset (the highest sum of ratios between 3Di AUC and TM-align AUC for family, superfamily and fold level).

3Di substitution score matrix We trained a BLOSUM-like substitution matrix for 3Di sequences from pairs of structurally aligned residues used for the “VAE-VQ training”. First, we determined the 3Di states of all residues. Next, the substitution frequencies between 3Di states were calculated by counting how often two 3Di states were structurally aligned. (Note that the substitution frequencies from state A to B and the opposite direction are equal.) Finally, the score $S(x, y) = 2 \log_2 \frac{p(x, y)}{p(x)p(y)}$ for substituting state x through state y is the log-ratio between the substitution frequency $p(x, y)$ and the probability that the two states occur independently, scaled by the factor 2.

3Di alphabet cross-validation We trained the 3Di alphabet (the VQ-VAE weights) and the substitution matrix by four-fold cross-validation on SCOPe40. We split the SCOPe40 dataset into four parts, such that all domains of each fold ended up in the same part of the four parts. 3Di alphabets were trained on three parts and tested on the remaining part, selecting each of the four parts in turn as a test set. The 80:20 split between training and validation sets to select the best alphabet out of the 100 VQ-VAE runs happens within the 3/4 of the cross-validation training data. **Supplementary Fig. 14** shows the mean sensitivity (black) and the standard deviation (gray area) in comparison to the final 3Di alphabet, for which we trained the 3Di alphabet on the entire SCOPe40 (red). No overfitting was observed, despite training 492 parameters (282 neural network, 210 substitution matrix entries). In **Fig. 2** we therefore show the benchmark results for the final 3Di al-

phabet, trained on the entire SCOPe40.

Nearest-neighbor selection To select nearest-neighbor residues that maximize the performance of the resulting 3Di alphabet in finding and aligning homologous structures, we introduced the virtual center V of a residue. The virtual center position is defined by the angle θ ($V-C_\alpha-C_\beta$), the dihedral angle τ ($V-C_\alpha-C_\beta-N$), and the length l ($|V-C_\alpha|$) (**Supplementary Fig. 2**). For each residue i we selected the residue j with the smallest distance between their virtual centers. The virtual center was optimized on the training and validation structure sets used for the VQ-VAE training by creating alphabets for positions with $\theta \in [0, 2\pi]$, $\tau \in [-\pi, \pi]$ in 45° steps, and $l \in \{1.53\text{\AA} k : k \in \{1, 1.5, 2, 2.5, 3\}\}$ (1.53\AA is the distance between C_α and C_β). The virtual center defined by $\theta = 270^\circ$, $\tau = 0^\circ$ and $l = 2$ performed best in the SCOPe benchmark.

This virtual center preferably selects long-range, tertiary interactions and only falls back to selecting interactions to $i+1$ or $i-1$ when no other residues are nearby. In that case, the interaction captures only the backbone conformation.

SCOPe benchmark We downloaded SCOPe40 structures for the generation of 3Di states and for the performance evaluation of Foldseek.

The SCOPe benchmark set consists of single domains with an average length of 174 residues. In our benchmark, we compare the domains all-versus-all. Per domain, we measured the fraction of detected TPs up to the first FP. For family-, superfamily- and fold-level recognition, TPs were defined as same family, same superfamily and not same family, and same fold and not same superfamily, respectively. Hits from different folds are FPs.

Evaluation SCOPe benchmark In order to evaluate the sensitivity and precision of the structural alignment tools, we used a cumulative ROC curve analysis. After sorting the alignment result of each query (described in Tools and options for benchmark comparison section), we calculated the fraction of TPs in the list up to the first FP, all excluding self-hits. We quantitatively measured the sensitivity by comparing the AUC for family-, superfamily-, and fold-level classifications. We evaluated only SCOPe members with at least one other family, superfamily and fold member.

Additionally, we plotted precision-recall curves for each tool (**Fig. 2c, Supplementary Fig. 5**). After sorting the alignment results by the structural similarity scores (as described in Tools and options for benchmark comparison section) and excluding self-matches, we generated a weighted precision-recall curve for family-, superfamily-, and fold-level classifications (precision=TP/(TP+FP), recall=TP/(TP+FN)). All counts (TP, FP, FN) were weighted by the reciprocal of their family-, superfamily-, or fold size. In this way, folds, superfamilies, and families contribute linearly with their size instead of quadratically [33].

Runtime evaluations on SCOPe and AlphaFoldDB We measured the speed of structural aligners on a server with an AMD EPYC 7702P 64-core CPU and 1024 GB RAM memory. On SCOPe40, we measured or estimated the runtime for an all-versus-all comparison. To avoid excessive runtimes for TM-align, Dali, and CE, we estimated the runtime by randomly selecting 10% of the 11 211 SCOPe domains as queries.

We measured runtimes on AlphaFoldDB for searches with the same 100 randomly selected queries used for the sensitivity and alignment quality benchmarks (**Fig. 2e,f**). Tools with multi-threading support (MMseqs2 and Foldseek) were executed with 64 threads, tools without were parallelized by breaking the query set into 64 equally sized chunks and executing them in parallel.

Reference-free multi-domain benchmarks Benchmarking using domain annotation from SCOPe/CATH of multi-domain proteins is problematic. Labeling the domains requires a gold-standard, reference annotation tool. The issue is that the benchmark would be uncontrollably biased in favor of tools that optimize similar alignment metrics or even make similar mistakes as the reference tool used for annotation. False negatives of the annotation tool would give rise to numerous high-scoring FPs for more sensitive or dissimilar tools.

We therefore devised two reference-free benchmarks that do not rely on any reference structural alignments. We clustered the AlphaFoldDB (v1) [37] using SPiCi [38]. For this we first aligned all protein sequences all against all using an E-value threshold $< 10^{-3}$ using BLAST (2.5.0+) [39]. SPiCi produced 34,270 clusters from the search result. For each cluster we picked the longest protein as representative. We randomly selected 100 representatives as queries and searched the set of remaining structures. The top five alignments of all queries are listed at wwwuser.gwdg.de/~compbiol/foldseek/multi_domain_top5_alignments/.

For the evaluation, we needed to adjust the LDDT score function taken from AlphaFold2 [40]. LDDT calculates for each residue i in the query the fraction of residues in the 15\AA neighborhood which have a distance within 0.5, 1, 2, or 4\AA of the distance between the corresponding residues in the target [41]. The denominator of the fraction is the number of 15\AA -neighbors of i that are aligned to some residue in the target. This does not properly penalize non-compact models in which each residue has few neighbors within 15\AA . We therefore use as denominator the *total* number of neighboring residues within 15\AA of i .

For the alignment quality benchmark (**Fig. 2f**), we classified each aligned residue pair as TP or FP depending on its *residue-wise* LDDT score, that is, the fraction of distances to its 15\AA neighbors that are within 0.5, 1, 2, and 4\AA of the distance to the corresponding residues in the query, averaged over the four distance thresholds. TP residues are those with a residue-wise LDDT score of at least 0.6 and FPs below 0.25, ignoring matches in-between. For the sensitivity benchmark (**Fig. 2e**), TP residue-residue matches are those with an LDDT score of the query-target alignment of at least 0.6 and FPs below 0.25, ignoring matches in-between. (The LDDT score of the query-target alignment is the average of the residue-wise LDDT score over all aligned residue pairs.) The choice of thresholds is illustrated in **Supplementary Fig. 8**.

All-vs-all search of AlphaFoldDB with Foldseek We downloaded the AlphaFoldDB (v1) [37] containing 365,198 protein models and searched it all-versus-all using Foldseek `-s 9.5 --max-seqs 2000`. For our second best hit analysis we consider only models with: (1) an average C_α 's pLDDT

greater than or equal to 80, and (2) models of non-fragmented domains. We also computed the structural similarity for each pair using TM-align (default options).

Tools and options for benchmark comparison The following command lines were used in the SCOPE as well as the multi-domain benchmark:

Foldseek We used Foldseek commit 4de45 during this analysis. Foldseek was run with the following parameters: `--threads 64 -s 9.5 -e 10 --max-seqs 2000`

MMseqs2 We used the default MMseqs2 (release 13-45111) search algorithm to obtain the sequence-based alignment result. MMseqs2 sorts the results by e-value and score. We searched with: `--threads 64 -s 7.5 -e 10000 --max-seqs 2000`

CLE-Smith-Waterman We used PDB Tool v4.80 (github.com/realbigws/PDB_Tool) to convert the benchmark structure set to CLE sequences. After the conversion, we used SSW [31] (commit ad452e) to align CLE sequences all-versus-all. We sorted the results by alignment score. The following parameters were used to run SSW: (1) protein alignment mode (`-p`), (2) gap open penalty of 100 (`-o 100`), (3) gap extend penalty of 10 (`-e 10`), (4) CLE's optimized substitution matrix (`-a cle.shen.mat`), (5) returning alignment (`-c`). The gap open and extend values were inferred from DeepAlign [42]. The results are sorted by score in descending order.

```
ssw_test -p -o 100 -e 10 -a cle.shen.mat -c
```

3D-BLAST We used 3D-BLAST (beta102) with BLAST+ (2.2.26) and SSW [31] (version ad452e). We first converted the PDB structures to a 3D-BLAST database using `3d-blast -sq_write` and `3d-blast -sq_append`. We searched the structural sequences against the database using `blastp` with the following parameters: (1) we used 3D-BLAST's optimized substitution matrix (`-M 3DBLAST`), (2) number of hits and alignments shown of 12000 (`-v 12000 -b 12000`), (3) E-value threshold of 1000 (`-e 1000`) (4) disabling query sequence filter (`-F F`) (5) gap open of 8 (`-G 8`), and (6) gap extend of 2 (`-E 2`). 3D-BLAST's results are sorted by E-value in ascending order:

```
blastall -p blastp -M 3DBLAST -v 12000 -b 12000 -e 1000 -F F -G 8 -E 2
```

For Smith-Waterman we used (1) gap open of 8 (2) gap extend of 2 and (3) returning alignments (`-c`) (4) using the 3D-BLAST's optimized substitution matrix (`-a 3DBLAST`), (5) protein alignment mode (`-p`): `ssw_test -o 8 -e 2 -c -a 3DBLAST -p`. We noticed that the 3D-BLAST matrix with Smith-Waterman resulted in a similar performance to CLE: 0.717 0.230 0.011 for family-, superfamily- and fold-classification, respectively. We excluded 3D-BLAST's measurement from the multi-domain benchmark since it produced occasionally high-scores ($>10^7$) for single residue alignments.

TM-align We downloaded and compiled the `TMalign.cpp` source code (version 2019/08/22) from the Zhang group website. We ran the benchmark using default parameters and `-fast` for the fast version. TM-align reports two TM-scores: (1) normalized by the length of 1st chain (query) or (2)

normalized by the length of the 2nd chain (target). We used the TM-score normalized by the 1st chain (query) in all our analyses since, to be informative for searches with multi-domain proteins, we need to assess how well and how much of the query is aligned, not how well and how much of the target.

```
Default: TMalign query.pdb target.pdb
```

```
Fast: TMalign query.pdb target.pdb -fast
```

Dali We installed the standalone DaliLite.v5. For the SCOPE40 benchmark set, input files were formatted in DAT files with Dali's `import.pl`. The conversion to DAT format produced 11137 valid structures out of the 11211 initial structures for the SCOPE benchmark, and 34,252 structures out of 34,270 spici clusters. After formatting the input files, we calculated the protein alignment with Dali's structural alignment algorithm. The results were sorted by Dali's Z-score in descending order:

```
import.pl -pdbfile query.pdb -pdbname PDBid -dat DAT
dali.pl -cd1 queryDATid -db targetDB.list -TITLE
systematic -dat1 DAT -dat2 DAT -outfmt "summary"
-clean
```

CE We used BioJava's [43] (version 5.4.0) implementation of the combinatorial extension (CE) alignment algorithm. We modified one of the modules of BioJava under shape configuration to calculate the CE value. Our modified `CEalign.jar` file requires a list of query files, path to the target PDB files, and an output path as input parameters. This Java module runs an all-versus-all CE calculation, with unlimited gap size (`maxGapSize -1`) to improve alignment results [44]. The results were sorted by Z-score in descending order. For the multi-domain benchmark, we excluded 1 query that was running over 16 days. The Jar file of our implementation of CE calculation is provided.

```
java -jar CEalign.jar querylist.txt
TargetPDBDirectory OutputDirectory
```

Geometricus We included Geometricus [45] in the SCOPE benchmark as a representative of alignment-free tools. Geometricus discretizes fixed-length backbone fragments (shape-mers) using their 3D moment invariants and represents structures as a fixed-length count vector over the shape-mers. To calculate the shape-mer-based structural similarity of the benchmark set, we used Caretta-shape's Python implementation of multiple structure alignment (github.com/TurtleTools/caretta/caretta/multiple_alignment.py), which computes the BrayCurtis similarity between the Geometricus shape-mer vectors. Our modified version extracts structural information from the input files and generates all-versus-all pairwise structural similarity score as an output. The python code of our implementation of Geometricus is provided.

```
python runGeometricus_caretta.py -i querylist.txt
-o OutputDirectory
```

HOMSTRAD alignment benchmark The HOMSTRAD database contains expert-curated homologous structural alignments for 1032 protein families [46]. We downloaded the latest HOMSTRAD version (mizuguchilab.org/homstrad/data/homstrad_with_PDB_2022_Aug_1.tar.gz) and picked

714 the pairwise alignments between the first and last members of
715 each family, which resulted in structures of a median length
716 of 182 residues. We used the same parameters as in the
717 SCOPe and multi-domain benchmark. We forced Foldseek,
718 MMseqs2, and CLE-Smith-Waterman to return an alignment
719 by switching off the prefilter and E-value threshold. With
720 the HOMSTRAD alignments as reference, we measured for
721 each pairwise alignment the sensitivity (fraction of residue
722 pairs of the HOMSTRAD alignment that were correctly
723 aligned) and the precision (fraction of correctly aligned
724 residue pairs in the predicted alignment). Dali, CE and
725 CLE-Smith-Waterman failed to produce an alignment for
726 35, 1 and 1 out of 1032 pairs respectively, which were rated
727 with a sensitivity of zero. The mean sensitivity and precision
728 are shown in **Supplementary Fig. 10** and all individual
729 alignments are listed in `homstrad_alignments.txt` at
730 wwwuser.gwdg.de/~compbiol/foldseek/.

731 **Webserver** The Foldseek webserver is based on the MM-
732 seqs2 webserver [47]. To allow for searches in seconds we
733 implemented MMseqs2's pre-computed database indexing
734 capabilities in Foldseek. Using these, the search databases
735 can be fully cached in system memory by the operating
736 system and instantly accessed by each Foldseek process,
737 thus avoiding expensive accesses to slow disk drives. A
738 similar mechanism was used to store and read the associated
739 taxonomic information. The AlphaFoldDB/Uniprot50 (v3),
740 AlphaFoldDB/Proteome (v2), AlphaFoldDB/Swiss-Prot (v2),
741 and PDB100 require 459GB, 7.7GB, 5.5GB, and 3.7GB
742 RAM, respectively. If C_{α} coordinates are omitted from the
743 AlphaFoldDB/Uniprot50 (v3) then the database can be used
744 with 304GB RAM. The databases are kept in memory using
745 `vmtouch` (github.com/hoytech/vmtouch). Databases are
746 only required to remain resident in RAM, if Foldseek is used
747 as a webserver. During batch searches, Foldseek adapts
748 its memory use to the available RAM of the machine. We
749 implemented a structural visualization using the NGL viewer
750 [48] to aid the investigation of pairwise hits. Since we only
751 store C_{α} traces of the database proteins, we use PULCHRA
752 [28] to complete the backbone of these sequences, and also
753 of the query if necessary, to enable a ribbon visualization
754 [49] of the proteins. For a high quality superposition we
755 use TM-align [50] to superpose the structures based on the
756 Foldseek alignment. Both PULCHRA and TM-align are
757 executed within the users' browser using WebAssembly. They
758 are available as `pulchra-wasm` and `tmalign-wasm` on the
759 npm package repository as free open-source software.

760 **Code availability** Foldseek is GPLv3-licensed free open
761 source software. The source code and binaries for Foldseek can
762 be downloaded at github.com/steineggerlab/foldseek.
763 The webserver code is available at github.com/soedinglab/mmseqs2-app.
764 The analysis scripts are available at:
765 github.com/steineggerlab/foldseek-analysis.

766 **Data availability** Benchmark data is available at:
767 wwwuser.gwdg.de/~compbiol/foldseek
