Running title: Translation during the cell cycle

Abstract

It is generally accepted that global translation varies during the cell cycle and is low in mitosis. However, addressing this issue is challenging because it involves cell synchronization, which evokes stress responses which, in turn, affect translation rates. Here we have used two approaches to measure global translation rates in different cell-cycle phases. First, synchrony in different cell-cycle phases was obtained involving the same stress, by using temperature-sensitive mutants. Second, translation and DNA content were measured by flow cytometry in exponentially growing, single cells. We found no major variation in global translation rates through the cell cycle in either fission-yeast or mammalian cells. We also measured phosphorylation of eukaryotic initiation factor- 2α , an event thought to downregulate global translation in mitosis. In contrast with the prevailing view, eIF 2α phosphorylation correlated poorly with downregulation of general translation and ectopically induced eIF 2α phosphorylation inhibited general translation only at high levels.

1 Introduction

2 It is one of the basic principles of cell proliferation that there is a link between general 3 cell growth (protein synthesis) and cell-cycle regulation. Such a link is logical and has 4 been hypothesized to exist, but its nature has been elusive. Protein synthesis is one of 5 the most energy-demanding cellular processes and is therefore carefully regulated. It 6 is a generally accepted view that global translation is considerably reduced in mitosis 7 (reviewed in 1). The reduction is thought to result from altered phosphorylation state 8 of translation initiation factors. In particular, phosphorylation of the translation 9 initiation factor eIF2 α is induced after a number of different stresses and is thought to 10 be the main reason for repressed translation. Cell-cycle-dependent downregulation of 11 translation in G2/M phase was also attributed to increased eIF2 α phosphorylation (2-12 5).

13 Early translation measurements in synchronized mammalian cells revealed a 70% 14 reduction of the global translation rate in mitosis (6). More recent studies using 15 different synchronization methods suggested that the magnitude of the translation 16 reduction depends on the method of synchronization (7,8). Also, studies in budding 17 yeast indicated that the rate of protein synthesis is constant during the cell cycle 18 (9,10). More recent studies (in mammalian cells) have reported conflicting results 19 regarding the level of translational reduction in mitosis (11-13), and the question of 20 whether and to what extent global translation is downregulated in mitosis remains 21 unanswered.

22	Measurement	of translation	n in different	cell-cvcle	phases is	challenging	because it
	measurement	or transfactor			pliabeb 15	onunonging	occuuse .

- 23 often involves cell-cycle synchronization, which in itself can evoke stress responses
- 24 which, in turn, will affect translation rates. Thus, the exact contribution of the
- 25 synchronization method versus cell-cycle progression to any observed change in
- 26 translation rates or the phosphorylation state of translation initiation factors is difficult
- 27 to assess. Here we use novel approaches to measure global translation rates during the
- 28 cell cycle and whether it depends on $eIF2\alpha$ phosphorylation.

29

31 **Results**

32 Global translation in synchronized cells

33 First, we utilized temperature-sensitive fission yeast mutants that arrest at different 34 phases of the cell cycle. We synchronized the cells by shifting to the restrictive 35 temperature before release into the cell cycle, achieving synchrony at different cell-36 cycle phases by the same treatment (ie temperature shift). Samples for analysis of 37 DNA content, translation rate, and eIF2a phosphorylation were taken every 20 min 38 for 160 or 220 minutes after release from the cell-cycle arrest. DNA content and 39 translation rate were measured in single cells, by flow cytometry. Translation was assaved by pulse-labelling with the methionine analogue L-Homopropargylglycine 40 41 (HPG) (15), which is incorporated into growing polypeptide chains. It should be noted 42 that our assay addresses the regulation of global translation rather than the well-43 established translational regulation of individual proteins. To reveal small differences 44 in signal intensity, the samples were barcoded and processed together in the very 45 same solution. Phosphorylation of eIF2 α was assessed by immunoblot analysis. The 46 cdc10-M17 mutant was used to synchronize cells in G1, cdc25-22 was used to 47 synchronize cells in G2 and *nda3-KM311* was used to arrest the cells in mitosis.

The rate of translation changed as the cells progressed from the block and through the cell cycle, apparently consistent with cell-cycle-dependent translation. However, the changes in translation rate followed the same pattern after release from the cell-cycle arrest regardless of when in the cell cycle the cells were synchronized (Fig 1A-D and

52	Fig S1). At early time points the translation rate was low and after release it gradually
53	increased to a rate above that measured before the shift. At late timepoints translation
54	rates became similar to that measured in exponentially growing cells. There was no
55	correlation between any particular cell-cycle phase and an increase or decrease in
56	translation rates. These results strongly suggest that global translation is not regulated
57	in a cell-cycle-dependent manner and that the variations observed are caused by the
58	synchronization.

Figure 1. Global translation in cells synchronized in the cell cycle

Cells of the indicated strains were grown exponentially at 25oC (**A**, **B**, **E**-**G**) or 30 oC (**C**, **D**, **H**, **I**), incubated at 36oC or 20oC for one generation time and then shifted back to 25 and 30 oC, respectively. Samples were taken at the indicated times after the shift. **A**, **C** median intensities of the AF647 (HGP) signal normalized to that of exponentially growing cells. Average of three biological repeats and standard errors (SE) are shown. **B**, **D** illustrate cell-cycle progression in the respective mutants. Fig S1 shows the cell-cycle distributions **E** - **I** Quantification of eIF2α phosphorylation normalized to tubulin in the indicated strains. Average and SE of three independent experiments are shown. Representative immunoblots are shown in Fig S2.

- 60 To test the effects of a temperature shift, wild-type fission yeast cells were subjected
- 61 to the same shifts as employed to synchronize the cell-cycle mutants. Interestingly,

62	translation rates followed the same pattern in the wild-type cells as in the cell-cycle
63	mutants described above (Fig 1A, C), demonstrating that the observed changes are
64	due to the temperature shift rather than to the cell-cycle stage where the particular
65	mutant arrests. Furthermore, the temperature shift from 25 to 36 back to 25 $^{\rm o}{\rm C}$ in itself
66	induced a transient G2 delay (Fig S1G), which is probably due to the previously
67	described Rad3 ^{ATR} -Rad9-dependent mechanism (14). Curiously, also a shift from 30
68	to 20 to 30°C induced a cell-cycle delay, but in G1/S (Fig S1H).
69	Phosphorylation of eIF2 α was high at the early time points in the heat-sensitive
70	mutants, then gradually diminished (Fig 1 E, F), regardless of where in the cell cycle
71	the particular mutant was arrested. There was no correlation between $eIF2\alpha$
72	phosphorylation and any particular cell-cycle phase. As a control to assess synchrony
73	achieved in the above experiments, we followed expression of the G1 cyclin Cig2 by
74	immunoblotting. The previously reported cell-cycle-dependent regulation was
75	obvious in all three strains (Fig S1), showing that the synchrony achieved in the above
76	experiments allows us to detect cell-cycle-dependent changes in protein levels.
77	Furthermore, the temperature shift resulted in increased $eIF2\alpha$ phosphorylation also in
78	the wild-type cells (Fig 1G), confirming that such temperature shifts routinely
79	employed in cell-cycle synchronization experiments invoke a stress response.
80	When cells were shifted from 20 to 30 °C, changes in eIF2 α phosphorylation were
81	much less pronounced, be it wild-type cells or the cold-sensitive nda3 mutant (Fig 1H,
82	I). Notably, the <i>nda3</i> mutant arrests in metaphase, the very cell-cycle phase where
83	$eIF2\alpha$ phosphorylation is thought to increase and contribute to a downregulation of

translation. Furthermore, the biggest change in translation rate was observed in the cells shifted from 20 to 30 °C, both for wild-type cells and the *nda3* mutant(Fig 1C), although this treatment resulted in the smallest change in eIF2 α phosphorylation (Fig 1 H, I). These results are in direct contradiction to the prevailing view that eIF2 α phosphorylation correlates with and is the reason for downregulation of global translation.

90 To assess the contribution of $eIF2\alpha$ phosphorylation to the observed changes in

91 translation rates, strains carrying non-phosphorylatable $eIF2\alpha$ -S52A were used. Cell-

92 cycle synchronization experiments and translation measurements were performed as

above. Surprisingly, translation rates followed exactly the same pattern in the absence

94 of $eIF2\alpha$ phosphorylation as in its presence; low immediately after the temperature

95 shift, then recovering (Fig 1A, C). Furthermore, in the heat-sensitive mutants

96 translation was much more downregulated when $eIF2\alpha$ could not be phosphorylated

97 (Fig 1A).

98 We conclude that the changes in translation rates during the cell-cycle

99 synchronization experiments were not due to cell-cycle-specific regulation of

100 translation, but to the temperature shift itself. Furthermore, phosphorylation of $eIF2\alpha$

101 is not cell-cycle regulated and is not required for the downregulation of global

102 translation after temperature shift.

103

104 Global translation in exponentially growing cells

105	Having seen no evidence of cell-cycle dependent regulation of translation in
106	synchronized cells, we set out to measure translation rates in different cell-cycle
107	phases in unsynchronized cells. To this end, we measured HPG incorporation and
108	DNA content in exponentially growing cells by flow cytometry. Cells in each cell-
109	cycle phase were gated on two-parametric DNA cytograms (15) and HPG
110	incorporation per cell was quantified in each cell-cycle phase. There were no
111	significant differences in the rate of translation in the different cell-cycle phases (Fig
112	2A,C). It should be noted that this method does not allow us to distinguish cells in
113	mitosis from those in G1. Thus, a high translation rate in G1 cells might compensate
114	for a reduced translation rate in the mitotic cells so that the relative translation rate for
115	the mixed M-G1 population appears to be unchanged. However, in such a scenario the
116	distribution of the HPG intensities in the M-G1 population would be broad, but this is
117	not the case (Fig 2A, C), arguing against this explanation. Another concern is that a
118	low number of mitotic cells in the population would conceal a low translation rate in
119	mitotic cells. To address this issue, cells of the M-G1 population were sorted onto
120	microscopy slides and the microtubuli were stained. At least 20 % of the cells clearly
121	contained a mitotic spindle (data not shown), demonstrating that the translation rates
122	measured in the M-G1 population reliably represent those of mitotic cells. In addition,
123	we analyzed exponentially growing fission yeast cells grown in a medium with
124	isoleucine as sole nitrogen source. Under these conditions G1 is longer and
125	cytokinesis occurs in G1 (16), which allows us to distinguish a G1 population
126	containing 1C DNA from mitotic cells. Also under these conditions, translation rates

- 127 were similar in the different cell-cycle phases (Fig 2B, D). These results obtained in
- 128 unsyncronized, exponentially growing cells confirm that global translation does not
- 129 vary significantly through the cell cycle.

Figure 2. Global translation in exponentially growing cells A,B Two-parametric flow cytometry plots of fission yeast cells grown in (A) EMM or (B) in isoleucine-minimal medium. **C, D** Average of median intensity of the AF647 signal normalized to G2 (C) or G1 (D) from at least three biological repeats with SE. Gating is shown on Fig S2.

131	Basic cellular processes such as regulation of translation through the cell cycle are
132	expected to be conserved in evolution, but the extent of such regulation might vary
133	from organism to organism. Therefore, we investigated whether the level of global
134	translation varies during the cell cycle in human cells. To this end, we measured
135	translation rates in different cell-cycle phases in three different human cell lines. To
136	measure translation, unsynchronized cells were pulse-labelled with the puromycin

137	analogue O-propargyl-puromycin (OPP) and analyzed by flow cytometry. Cells in
138	G1, S and G2 were identified based on their DNA content and mitotic cells were
139	identified using the mitotic marker phospho-S10-histone H3. The cell lines
140	investigated were normal epithelial RPE cells immortalized by telomerase expression,
141	the osteosarcoma-derived U2OS cells and cervix carcinoma-derived HeLa cells.
142	There is a wide distribution of the intensity of the OPP signal in the G1 population,
143	indicating that there are significant differences in translation rates among G1 cells.
144	This feature is particularly obvious in the normal epithelial RPE cells, less
145	pronounced in the two cancer cell lines (Fig 3). The G1 cells with lower translation
146	rates might represent cells that have not yet passed the restriction point. There is a
147	gradual increase in translation from G1 phase through S to G2 in all three cell lines,
148	and a somewhat lower rate in mitotic cells. However, the rate of protein synthesis in
149	mitotic cells is higher or similar to that in G1 cells and the extent of reduction from
150	G2 to M ranges from 40% (RPE) to 15 % (U2OS).

Figure 3. Global translation through the cell cycle in human cells

A-C Two-parametric flow cytometry plots of the indicated cell lines. Yellow lines represent the mean intensity of AF647 (OPP) for each cell-cycle phase. Bar graphs showing mean intensities and standard deviation are shown in Fig S3. **D-F** Bar graphs representing mean AF647 (OPP) intensity with standard deviation. **G** Quantification of eIF2 α phosphorylation normalized to eIF2 α in the indicated cell-cycle phases. Exponentially growing HeLa cells were fixed and stained for H3-P and DNA content to identify cells in each cell-cycle phase and then 50 000 cells from each phase were sorted to measure eIF2 α phosphorylation. Average and SE of three independent experiments are shown. Representative immunoblots are shown in Fig S3. **H**. Two-parametric flow cytometry plots of asynchronously growing and nocodazole-arrested cells and cells 4 h after release from the nocodazole block. **I** Bar graphs representing mean AF647 (OPP) intensity with standard deviation after nocodazole block and release. eIF2 α phosphorylation is shown in Fig S3.

- 152 Phosphorylation of $eIF2\alpha$ was investigated in HeLa cells. Unsynchronized cells were
- 153 fixed, analysed as above and collected by fluorescence-activated cell sorting (FACS).

154	Phosphorylation	of eIF2α was	investigated i	in the different	populations b	v
			0			~

immunoblotting. There were no significant changes in $eIF2\alpha$ phosphorylation during

156 the cell cycle (Fig 3G).

157 The above results strongly suggest that the previously observed apparent cell-cycle-

158 dependent variation in translation rates was a result of synchronization. In order to

159 directly address this, we synchronized HeLa cells using nocodazole and mitotic shake-

160 off and measured the translation rates. Consistent with previous studies, translation

161 rates changed dramatically in the nocodazole-tretated cells (Fig 3H, I) and eIF2 α

162 phosphorylation increased upon nocodazole arrest (Fig S3).

163 These findings strongly suggest that global translation rates are not dramatically

164 downregulated in mitotic cells and that earlier studies overestimated the extent of

165 variation through the cell cycle.

166 eIF2α phosphorylation and general translation

167 Surprisingly poor correlation was observed between the levels of $eIF2\alpha$

168 phosphorylation and global translation in the temperature-shift experiments,

169 prompting us to directly address the importance of $eIF2\alpha$ phosphorylation on global

170 translation rates.

171 To this end, we expressed PKR, one of the four human eIF2 α kinases, in fission yeast 172 and measured eIF2 α phosphorylation and the global translation rates. PKR expression 173 was controlled by the regulatable *nmt1* promoter, which is induced when thiamine is 174 removed from the medium (17,18). We used two different versions of the promoter, 175 providing two different expression levels of PKR. Cells were grown exponentially 176 with the promoter repressed before PKR expression was induced and global 177 translation rates as well as eIF2 α phosphorylation were measured during the first 24 hours (6 generations) after induction. PKR expressionwas detected at 13 hous after 178 179 induction and eIF2 α phosphorylation reached maximal values at 16 - 19 hours (Fig. 180 4A, B and S4). The extent of eIF2 α phosphorylation induced by PKR driven by the 181 weaker promoter was comparable to that induced by milder stresses (Fig 4C and S4). 182 Curiously, we did not see any significant decrease in global translation rates when 183 PKR was expressed from the weaker of the promoters, the rate of translation remained 184 similar to that before induction of PKR expression. (Fig 4D). However, in the cells 185 expressing PKR from the full-strength nmt promoter translation was strongly reduced 186 and, consistently, these cells could not form colonies when the promoter was 187 derepressed (not shown). These results are consistent with previous findings, 188 suggesting that extreme and lasting eIF2 α phosphorylation can inhibit global

- 189 translation and is lethal (19,20). We conclude that the extent of $eIF2\alpha$ phosphorylation
- 190 is crucial for the effect on downregulation of general translation. A very high level of
- 191 eIF2α phosphorylation blocks translation, but an intermediate level might have little
- 192 influence on global translation.

Figure 4. elF2a phosphorylation and general translation

Cells carrying the indicated plasmids were grown exponentially with the promoter repressed and one sample was taken to measure translation. The promoter was induced for the indicated times. **A**, **B** Quantification of eIF2α phosphorylation normalized to α-tubulin at the indicated time points when PKR is expressed from the two different promoters. Note the different scales on the y axes. Representative immunoblots are shown in Fig S4. **C** Quantification of eIF2α phosphorylation normalized to tubulin after the indicated stresses. Average and SE of three independent experiments are shown.

D Median intensities of the AF647 (HGP) signal normalized to that of exponentially growing cells (promoter repressed). Average of three biological repeats and SE are shown.

194 **Discussion**

195 Global translation rate changes little during the cell cycle

196 Many recent studies dispute the generally accepted view that global translation 197 varies in a cell-cycle-dependent manner and is low in mitosis. Our results suggest that 198 the discrepancies arise from experimental challenges. Studies of cell-cycle-related 199 events often involve synchronization of cell cultures. In this work, we employed 200 temperature-sensitive yeast mutants. It should be noted that studies on heat stress 201 generally employ higher temperatures (>40 $^{\circ}$ C) and the temperatures we used are 202 close to those in the natural environment of fission yeast cells. However, here we 203 show that even the temperature shifts routinely used to synchronize the temperature-204 sensitive S. pombe mutants invoke a cellular stress response by themselves and 205 influence global translation rates, supporting the idea that previously reported cell-206 cycle-dependent changes in translation rates are caused by the method of 207 synchronization. Using the same stress to synchronize cells in different cell-cycle 208 phases allowed us to separate the effects of cell-cycle progression from temperature 209 shift on global translation rates. It is possible that, in our experiments, modest cell-210 cycle-dependent variations in global translation rates could be concealed by imperfect 211 synchrony. However, the synchrony achieved in the block-and-release experiments 212 (Fig S1) should have allowed us to observe the dramatic changes described 213 previously. Furthermore, using flow cytometry to measure translation in exponentially 214 growing cells allowed us to investigate global translation rates in different cell-cycle 215 phases in unstressed cells.

216 One caveat of analyzing the cell cycle of fission yeast by flow cytometry is that 217 mitotic cells can only be identified after separation of the daughter nuclei, but cells in 218 the early phases of mitosis cannot be distinguished from cells in G2. Thus, a reduction 219 of global translation rates in metaphase would not be detected using asynchronously 220 growing cells and flow cytometry alone, although it would have been detected in the 221 block-and-release experiments. Collectively, these data demonstrate that global 222 translation is not significantly different between any of the cell-cycle phases in fission 223 yeast cells.

In the human cell lines we also saw only small changes in the translation rate,

225 consistent with recent studies reporting only minor variations. Mitotic cells were

identified based on histone H3 phosphorylation, a mitotic marker that is present both

in metaphase and anaphase. Notably, our approach did not involve any

228 synchronization method, exposure to chemicals or changes in the cellular

229 environment, which makes our results less subject to artifacts and methodical

230 problems. Furthermore, when we synchronized the cells we also observed the

231 previously reported variations, confirming the notion that the changes in translation

are due to the synchronization-induced stress rather then cell-cycle progression.

233 **Phosphorylated eIF2α does not significantly repress global**

234 translation

235 Under stressful conditions cells reduce the rate of global translation to conserve

resources (21). At the same time, synthesis of proteins necessary to survive the stress

237 is maintained or even increased. Many different forms of stress results in

238	phosphorylation of eIF2 α in eukaryotic cells (22,23) and it is thought to be required
239	for both responses; downregulation of general translation and upregulation of
240	translation of selected mRNAs. In addition, it is also implicated in the cell-cycle-
241	dependent regulation of translation. Here we find that increased $eIF2\alpha$
242	phosphorylation does not correlate with any particular cell-cycle phase, but rather
243	with the stress involved in synchronization, be it temperature shift or exposure to
244	nocodazole. We conclude that $eIF2\alpha$ phosphorylation is not regulated in a cell-cycle-
245	dependent manner.

246 There is compelling evidence that $eIF2\alpha$ phosphorylation can attenuate the translation 247 of mRNAs (24,25). The regulation of eIF2 α phosphorylation is relevant for a number 248 of diseases, such as neurodegenerative disorders, cancer and autoimmune diseases 249 (26-31). In all these fields, increased levels of phosphorylated $eIF2\alpha$ has commonly 250 been taken to be a readout of reduced general translation. However, the two 251 parameters have rarely been measured in the same experiment. Our results 252 demonstrate that there is poor correlation between $eIF2\alpha$ phosphorylation and 253 repressed general translation. First, $eIF2\alpha$ phosphorylation is clearly not required for 254 the temperature-shift-induced downregulation of translation (Fig 1), consistent with 255 previous findings after UVC irradiation, oxidative stress and ER stress (32-34). 256 Second, in the absence of $eIF2\alpha$ phosphorylation translation is repressed more 257 dramatically after temperature shift (Fig 1). Third, ectopically induced $eIF2\alpha$ 258 phosphorylation did not noticeably downregulate global translation in unstressed 259 fission yeast cells, unless it was induced to high levels (Fig 4). We suggest that the 260 impact of phosphorylated eIF2 α on global translation has been overestimated in the

- 261 literature and that eIF2α phosphorylation can not be used as a marker of
- 262 downregulated translation. Our results demonstrate that the extent of $eIF2\alpha$
- 263 phosphorylation is crucial to determine whether it impacts on general translation and
- it has only a minor effect on the global translation at levels observed after mild
- 265 stresses. This implies that the main consequence of eIF2 α phosphorylation is not
- 266 downregulation of general translation but most likely translation of selected mRNAs,
- as also suggested previously (35).

268 Materials and Methods

269 Cells and cell handling

- 270 All fission yeast strains used in this study are derivatives of S. pombe L972 h- wild-
- type strain (Leupold, 1950) and are listed in Table 1.

272 Table 1 Fission yeast strains used in this study

_	38	ura4-D18 leu1-32 h-		
273	Cells were main	tained and cultured as previously described (Moreno 1991). The cells		
274	were grown in li	quid Edinburgh minimal medium (EMM) with appropriate		
275	supplements at 2	25 °C (or at 30 °C for <i>nda3-KM311</i> cells) to a cell concentration of 2-		
276	4×10^6 /ml. The c	cells were synchronised in G1 or G2 phase by incubating <i>cdc10-M17</i>		
277	or <i>cdc25-22</i> cells, respectively, at 36 °C for 4 h (or 5 h for <i>cdc10-M17 eIF2alphaS52A</i>			
278	strain) before release into the cell cycle at 25 °C; in M phase by incubating <i>nda3</i> -			
279	<i>KM311</i> cells at 20 °C for 4 h before release into the cell cycle at 30 °C. To obtain a			
280	population of mo	ononuclear G1 cells, cultures were maintained at 30 °C in minimal		
281	medium where NH ₄ Cl was replaced with 20 mM L-isoleucine (Carlson et al., 1999).			

- grown to a cell concentration of 8×10^6 /ml (OD₅₉₅ = 0.4) in minimal medium where
- 284 NH₄Cl was replaced with 3.75 g/l L-glutamic acid, monosodium salt (Pombe
- 285 Glutamate medium, PMG). To induce human PKR expression, cells cultured in PMG
- 286 containing 5 µg/ml thiamine (Sigma-Aldrich) were harvested by centrifuging for
- 287 3 min at 3 000 rpm, washed three times with PMG without thiamine, and resuspended
- in PMG lacking thiamine for the induction of *nmt1* and *nmt41* promoters.
- Human HeLa and U2OS cells were cultivated in Dulbecco's modified Eagle's
- 290 Medium (DMEM) (Gibco) and Tert-RPE cells were cultivated in DMEM-F-12
- 291 (Gibco) supplemented with 10% fetal bovine serum and 1% Penicillin/Streptomycin
- at 37° C in a humidified environment with 5% CO2.

293 Cell-cycle analyses

Cell-cycle phases were identified in fission yeast by DNA staining (Sytox Green) as
described (15). In mammalian cells DNA staining (Hoechst or propidium iodie) and
phospho-histone H3 (Ser10) staining were employed.

297 Translation assays

- 298 To label newly synthesized proteins, 50 µM of L-homopropargylglycine (HPG,
- 299 Thermo Fisher Scientific) was added to 1 ml samples of the main yeast culture taken
- 300 out 10 min before the indicated time points. To stop translation, 0.1 mg/ml of
- 301 cycloheximide (CHX) was added after 10 min. Cells were fixed in ice-cold methanol
- 302 or 70 % ethanol, washed in 0.5 ml TBS and barcoded using up to five different

303	concentration (4	50, 124.8,	31.2, 6.24,	and 0.78 ng/ml)	of Pacific Blue	(PB; Thermo
-----	------------------	------------	-------------	----------------------------	-----------------	-------------

- 304 Fisher Scientific) dye for 30 min in the dark at room temperature. Samples were then
- 305 washed three times in 0.5 ml TBS and pooled together. The samples were
- permeabilised with 0.5 ml 1 % Triton X-100 in TBS, and blocked with 1 % BSA in
- 307 TBS. To detect HPG, Alexa Fluor 647 was linked to the incorporated HPG in a
- 308 'click' reaction (Liang, Astruc, 2011) using the Click-iT cell reaction buffer kit
- 309 (Thermo Fisher Scientific C10269) following the manufacturer's protocol to ligate the
- 310 HPG alkyne with a fluorescent azide. Incorporation was quantified by using flow
- 311 cytometry (LSR II flow cytometer, BD Biosciences). SYTOX Green dye (Thermo
- 312 Fisher Scientific) was used to stain the DNA. Cell doublets were excluded from the
- analysis as described previously (Knutsen, 2011). Samples without HPG were used as
- anegative controls.

315 O-propargyl-puromycin (OPP), (Thermo Fisher Scientific) was added to 6 μM for 20 min, the cells were then trypsinized and fixed in 70% ethanol. To detect 316 317 incorporated OPP, the fixed cells were washed once in PBS with 1 % FBS. OPP 318 was ligated with Alexa Fluor 647 in a 'click' reaction following the 319 manufacturer's instructions. The samples were incubated for 5 min in detergent 320 buffer (0.1 % Igepal CA-630, 6.5 mM Na₂HPO₄, 1.5 mM KH₂PO₄, 2.7 mM KCl, 321 137 mM NaCl, 0.5 mM EDTA (pH 7.5)) containing 4 % non-fat milk to block nonspecific binding. The cells were incubated for 1 h with anti-phospho-histone H3 322 323 (Ser10) primary antibody (1:500, Millipore 06-570) in detergent buffer containing 2 % non-fat milk, washed once in PBS with 1 % FBS, and incubated for 324 325 30 min with Alexa Flour 488-linked secondary antibody (1:500, Thermo Fisher 326 Scientific A-11034) in detergent buffer. All incubations were carried out in the 327 dark at room temperature. The cells were washed once in PBS with 1 % FBS and 328 stained with 1.5 µg/ml of Hoechst 33258 (Sigma) in PBS. The samples were analysed using flow cytometry (LSR II flow cytometer, BD Bioscience, San Jose, 329 CA, USA). Samples without OPP and without the primary antibody were used as 330 331 negative controls.

332 Fluorescence activated cell sorting

Exponentially growing cells were fixed with 70% EtOH and stained for anti-phosphohistone H3 as described above and detected using Alexa-fluor 647-coupled secondary
antibody. DNA was stained with 8 µg/ml propidium iodide. 50 000 cells from each
cell-cycle phase were harvested using a FACS Aria II cell sorter.

337

338 UVC irradiation

- 339 Fission yeast cells were irradiated with 254 nm UV light (UVC) in a suspension in
- 340 EMM (or PMG) medium under continuous stirring to ensure equal irradiation dose
- 341 (Nilssen, 2003). The incident dose was measured with a radiometer (UV Products). A
- 342 surface dose of 1100 J/m^2 (at a dose rate of approximately 250 J/m²/min) induces a
- 343 checkpoint response, but results in over 90 % cell survival. Samples for protein
- analysis were taken immediately after irradiation.

345 H_2O_2 treatment

- 346 Cells grown in PMG medium were treated with H₂O₂ at the indicated concentrations
- 347 for 15 minutes before samples were taken.

348 Leucine starvation

- 349 An auxotroph strain was grown in PMG medium supplemented with leucine. The
- 350 cells were washed with PMG medium three times and incubated in medium not
- 351 containing leucine for the indicated times.

352 Immunoblotting

- 353 Total protein extracts of yeast cells were obtained using a low salt buffer (25 mM
- MOPS (pH 7.1), 60 mM β-glycerophosphate, 15 mM p-nitrophenylphosphate, 15 mM
- 355 MgCl₂, 15 mM EGTA (pH 8.0), 1 mM DTT, 0.1 mM Na₃VO₄, 1 % Triton X-100)
- 356 supplemented with protease inhibitors (Roche). Cell debris was removed by

- 357 centrifugation at 14 000 g for 15 min at 4 °C. The extracts were mixed with $4 \times LDS$
- 358 Sample Buffer (Thermo Fisher Scientific) and 50 mM DTT.
- 359 Human cells were lysed in Laemmli sample buffer.
- 360 Extracts were run on polyacrylamide gels, transferred onto PVDF membranes, and
- 361 probed with antibodies against phospho-eIF2 α (1:750, CST 3398), eIF2 α (1:1000,
- 362 Santa Cruz sc-11386) PKR (1:3000, Abcam 32052), α-tubulin (1:30 000, Sigma-
- 363 Aldrich T5168) and γ -tubulin (1:30 000,). The signal intensities were quantified
- 364 using ImageJ software.

365 Acknowledgements

- 366 We are grateful to the Norwegian Cancer Society, the Norwegian South-Eastern
- 367 Health Authority and Radiumhospitalets Legater for funding and thank L.
- 368 Lindbergsengen and M. O. Haugli for excellent technical assistance. The funders had
- 369 no role in study design, data collection and interpretation, or the decision to submit
- the work for publication.

505 **Figure 1. Global translation in cells synchronized in the cell cycle**

Cells of the indicated strains were grown exponentially at 25°C (A, B, E-G) or 30 °C 506 507 (C, D, H, I), incubated at 36°C or 20°C for one generation time and then shifted back 508 to 25 and 30 °C, respectively. Samples were taken at the indicated times after the 509 shift. A, C median intensities of the AF647 (HGP) signal normalized to that of 510 exponentially growing cells. Average of three biological repeats and standard errors 511 (SE) are shown. **B**, **D** illustrate cell-cycle progression in the respective mutants. Fig. 512 S1 shows the cell-cycle distributions $\mathbf{E} - \mathbf{I}$ Quantification of eIF2 α phosphorylation 513 normalized to tubulin in the indicated strains. Average and SE of three independent 514 experiments are shown. Representative immunoblots are shown in Fig S2.

515 **Figure 2. Global translation in exponentially growing cells**

- 516 A,B Two-parametric flow cytometry plots of fission yeast cells grown in (A) EMM or
- 517 (B) in isoleucine-minimal medium. C, D Average of median intensity of the AF647
- 518 signal normalized to G2 (C) or G1 (D) from at least three biological repeats with SE.
- 519 Gating is shown on Fig S2.

520 Figure 3. Global translation through the cell cycle in human cells

- 521 A-C Two-parametric flow cytometry plots of the indicated cell lines. Yellow lines
- 522 represent the mean intensity of AF647 (OPP) for each cell-cycle phase. **D-F** Bar
- 523 graphs representing mean AF647 (OPP) intensity with standard deviation. G
- 524 Quantification of eIF2α phosphorylation normalized to eIF2α in the indicated cell-
- 525 cycle phases. Exponentially growing HeLa cells were fixed and stained for H3-P and

DNA content to identify cells in each cell-cycle phase and then 50 000 cells from each
phase were sorted to measure eIF2α phosphorylation. Average and SE of three
independent experiments are shown. Representative immunoblots are shown in Fig
S3. H. Two-parametric flow cytometry plots of asynchronously growing and
nocodazole-arrested cells and cells 4 h after release from the nocodazole block. I Bar
graphs representing mean AF647 (OPP) intensity with standard deviation after
nocodazole block and release. eIF2α phosphorylation is shown in Fig S3.

533 **Figure 4. eIF2α phosphorylation and general translation**

534 Cells carrying the indicated plasmids were grown exponentially with the promoter

repressed and one sample was taken to measure translation. The promoter was

536 induced for the indicated times. **A**, **B** Quantification of $eIF2\alpha$ phosphorylation

537 normalized to α -tubulin at the indicated time points when PKR is expressed from the

two different promoters. Note the different scales on the y axes. Representative

539 immunoblots are shown in Fig S4. C Quantification of eIF2α phosphorylation

540 normalized to tubulin after the indicated stresses. Average and SE of three

541 independent experiments are shown. Representative immunoblots are shown in Fig

542 S4. **D** Median intensities of the AF647 (HGP) signal normalized to that of

statistic exponentially growing cells (promoter repressed). Average of three biological repeatsand SE are shown.

545

Fig S1, related to Fig 1.

A-H Cell-cycle progression in the cell-cycle synchronization experiments. **I-K** Representative immunoblots of the cell-cycle-regulated Cig2 cyclin in the indicated mutants. α-tubulin is shown as loading control.

Fig S2, related to Fig 1 and Fig2.

A - **H** Representative immunoblots showing $eIF2\alpha$ phosphorylation and tubulin loading control in the indicated strains.

I-J Two-parametric DNA histograms showing gating used for the plot shown in Fig. 2A, B.

Fig S3 related to Fig. 3. A eIF2 α phosphorylation in the different cell-cycle phases. **B** eIF2 α phosphorylation in asynchronous (AS) and nocodazole-arrested cells (N) and 4h after release from a nocodazole arrest (4h).

Fig S4 related to Fig 4.

A Representative immunoblots showing PKR expression, eIF2 α phosphorylation and loading controls in the indicated strains. **B** Representative immunoblot showing eIF2 α phosphorylation and loading control in a wild-type strain after treatment with the indicated stresses.

546 Supplementary figure legends

- 547 Fig S1, related to Fig 1. A-H Cell-cycle progression in the cell-cycle
- 548 synchronization experiments. I-K Representative immunoblots of the cell-cycle-
- 549 regulated Cig2 cyclin in the indicated mutants. α-tubulin is shown as loading control.

550 Fig S2, related to Fig 1 and Fig2. A - H Representative immunoblots showing

- 551 eIF2α phosphorylation and tubulinloading control in the indicated strains. I-J Two-
- parametric DNA histograms showing gating used for the plot shown in Fig. 2A, B.
- **Fig S3 related to Fig. 3**. A eIF2α phosphorylation in the different cell-cycle
- 554 phases. **B** eIF2α phosphorylation in asynchronous (AS) and nocodazole-arrested cells
- 555 (N) and 4h after release from a nocodazole arrest (4h).

556 Fig S4 related to Fig 4. A Representative immunoblots showing PKR expression,

- 557 eIF2α phosphorylation andloading controls in the indicated strains. **B** Representative
- 558 immunoblot showing eIF2αphosphorylation and loading control in a wild-type strain
- after treatment with the indicated stresses.
