1   **Abstract:**

2   *Ostreococcus tauri* is an ancient phototrophic microalgae that possesses favorable

3   genetic and cellular characteristics for reductionist studies probing biosystem design and

4   dynamics. Here multimodal bioimaging and multi-omics techniques were combined to

5   interrogate *O. tauri* cellular changes in response to variations in bioavailable nitrogen and

6   carbon ratios. Confocal microscopy, stimulated Raman scattering, and cryo-soft x-ray

7   tomography revealed whole cell ultrastructural dynamics and composition while proteomic and

8   lipidomic profiling captured changes at the molecular and macromolecular scale.

9   Despite several energy dense long-chain triacylglycerol lipids showing more than 40-fold

10 higher abundance under N deprivation, only a few proteins directly associated with lipid

11 biogenesis showed significant expression changes. However, the entire pathway for starch

12 granule biosynthesis was highly upregulated suggesting much of the cellular energy is

13 preferentially directed towards starch over lipid accumulation. Additionally, three of the five most

14 downregulated and five of the ten most upregulated proteins during severe nitrogen depletion

15 were unnamed protein products that warrant additional biochemical analysis and functional

16 annotation to control carbon transformation dynamics in this smallest eukaryote.

22

23 **Introduction**

24 Microalgae are ubiquitous in oceans and maintain a major carbon sink in the complex

25 world-wide ecosystem. Spanning more than one-billion years of evolution, microalgae are

2

26   phylogenetically diverse and exhibit varying cellular phenotypes that naturally produce high

27   value metabolites, proteins, carbohydrates and energy dense lipids that can be exploited for a

28   wide array of industrial applications [1-3]. Due to their high photosynthetic efficiency for energy

29   conversion, and minimal growth requirements consisting of sustainable resources such as

30   marine or brackish media, light, CO_2 and trace vitamins, microalgae are prime bioproduction

31   platforms [4,5].

32   Triacylglycerol (TAG) lipids are significantly enhanced when microalgae are subjected to

33   cellular stressors such as light, temperature, and nutrient deprivation [6]. TAG lipids possess

34   nonpolar character and are stored in anhydrous, high-density organelles called lipid bodies,

35   which are desirable for industrial lipid feedstock applications [7]. For other oleaginous algae, TAG

36   production can be triggered by nutrient deprivation of iron, sulfur, nitrogen, phosphate, or silicon

37   [6]. In most eukaryotes, combinatorial reduction of these nutrients results in altered levels of

38   growth-associated structural lipids (phospholipids) and energy storage lipids (TAG) products [8,9].

39   Unfortunately, in most cases starvation or deprivation can be detrimental to cell viability and

40   overall growth capacity thereby limiting cell biomass yields needed for viable lipid feedstock

41   industrial applications [10]. While several reports have shown that supplementing additional C

42   sources when combined with N depletion for certain organisms can yield increased growth and

43   lipid accumulation rates compared to strict starvation[2,11,12,13], a detailed understanding of the

44   interplay between carbon and nitrogen bioavailability is needed to advance bioproduction

45   applications.

46   Studying phototrophic metabolism in primitive species, such as the prasinophyte

47   *Ostreococcus tauri* can provide convenient opportunities to define minimal and critical metabolic

48   pathways for C transformation[14,15,16]. *O. tauri* is the smallest known free-living eukaryote

49   (~0.8μm in thickness), lacks a cell wall, and thrives in varying photic, toxic and thermal

50   ecosystems[17-19]. It also has a highly condensed genome with only ~8,000 genes[20] so most

3

51   reactions are governed by a single enzyme (rather than multiple duplicating function enzymes)

52   which simplifies engineering requirements and interpretation. For example, the canonical model

53   green alga *Chlamydomonas* has 4 copies of Acetyl-CoA Carboxylase (E.C. 6.4.1.2) whereas

54   *Ostreococcus* has only 1 enzyme of that class. In addition, a recent study[21] reported the genetic

55   diversity associated with large phenotypic differences between *Ostreococcus* strains

56   highlighting the uncharted abundance of genetic biodiversity. These characteristics make *O.*

57   *tauri* a potential candidate for future industrial applications. However, considerable biodesign

58   efforts will likely be needed to develop an efficient cell factory for controlled and cost-effective

59   bioproduction of lipid feedstocks or other high value metabolites. Here, an integrated analysis

60   of bioimaging, proteomic, and lipidomic characterization was used to investigate *O. tauri* cellular

61   response to varying C:N ratios. Our results provide additional understanding of C storage and

62   energy transformation pathways within the microalgae *O. tauri* and identify new proteins to

63   target for future engineering efforts.

64

65   **Results**

66   Other than the bioavailable C:N ratio, all other experimental parameters (e.g.,

67   temperature, duration, diurnal cycling, light fluence, etc.) were kept constant throughout this

68   study. The four different media conditions used herein are designated as K6CN, K2CN, K2C

69   and K6C which are listed in decreasing C:N ratio. The normal growth media for *O. tauri* is Keller

70   Media (referenced herein as K2CN media) and contains ~2.5mM bicarbonate and 0.9mM total

71   nitrogen. To streamline interpretation, bicarbonate was kept as the sole media carbon source.

72   For K6CN media the nitrogen content was kept equivalent, but the bicarbonate increased to

73   6mM providing elevated carbon but normal nitrogen conditions. The use of 6mM bicarbonate as

74   the elevated carbon set point was chosen following an initial growth screen of *O. tauri* in K

75   media supplemented with various levels of bicarbonate from 0-10mM where 6mM showed

76 highest growth response with healthy chlorophyll ratios per cell. The final two media conditions

77 K2C and K6C share the same composition as K2CN and K6CN but are depleted of all nitrogen

78 sources. Thus all subsequent experiments consisted of 4 conditions of decreasing C:N

79 bioavailable ratios from elevated carbon with normal nitrogen (K6CN), to normal carbon with

80 normal nitrogen (K2CN), to normal carbon with no nitrogen (K2C), and elevated carbon with no

81 nitrogen (K6C).

82   Diurnal cycling with 12:12 hour light:dark cycles was used to synchronize cellular

83 division and growth, and samples were harvested 3 hours after light to dark transition. Cell

84 growth was monitored by absorbance at 750nm (measure of particulates) and 680nm (measure

85 of chlorophyll a) for up to 144 hours (Fig. 1B). Decreases in absorbance at 680nm were typical

86 of K2C and K6C cell cultures relative to K2CN and K6CN. Absorbance at 750nm exhibited

87 similar decreases for N deprived cultures versus N replete. However, when comparing normal C

88 to excess C for either N replete or N deprived conditions, cultures with excess C consistently

89 displayed higher A680 and A750 values. Confocal fluorescence microscopy was used to

90 compare phenotypes for a couple dozen cells from each condition whereas fluorescence

91 activated cell sorting (FACS) allowed quantitative analysis of larger population dynamics every

92 24 hours. In both case, dramatic increases of neutral lipid (NL) content were detected for K2C

93 and K6C conditions (Fig. 1 C–F). Interestingly K6CN (Fig. 1C) cell cultures only exhibited subtle

94 differences between NL and some increases in phospholipid (PL) intensity indicating some

95 photosynthetic lipid metabolism difference to K2CN (Fig. 1D). Since confocal microscopy can

96 only track dynamics for fluorescently labelled components, label-free cell ultrastructure and

97 composition changes were also evaluated.

98   Cryogenic soft x-ray nanotomography (CSXT) was performed on 72-hour cell cultures to

99 increase resolution and highlight native cellular features of intracellular lipid accumulation (Fig.

100 1E). Dark subcellular features, assigned as vacuoles due to their linear absorption coefficient

101   (LAC), were observed in the intracellular cytosolic space of cells in K6CN and K2CN culture

102   conditions, but no vacuoles were observed for K2C and K6C cultured cells. The vacuoles were

103   much larger in K6CN compared to K2CN conditions. Based on studies conducted in other algae

104   and plants starch is likely present in the chloroplast[20]. However, intracellular starch was

105   undetected in *O. tauri* cells via X-ray nanotomography likely due to the density appearing similar

106   to or masked by the surrounding tissues with a similar LAC - possibly due to its small cell size or

107   chloroplast packing density. Therefore, stimulated Raman scattering (SRS) microscopy was

108   used as a second label-free imaging method to identify relative abundance of intracellular starch

109   accumulation. Interestingly, starch was detected in the chloroplast for all tested conditions.

110   However, the starch seen for K2C was minimal (Supplemental Figure 1). Considering that K6C

111   represents an even more deprived nitrogen to carbon ratio compared to K2C, it was anticipated

112   that K6C would show the lowest levels of starch since both conditions also show significant lipid

113   accumulation. However, the increase in starch content for K6C suggests that these cells still

114   have abundant carbon available for transformation into carbohydrates, and potential future

115   engineering efforts could focus on knocking out genes associated with starch accumulation to

116   divert this excess energy toward lipid feedstock production instead.

117   The confocal imaging also happened to capture a possible lipid droplet secretion event.

118   During live-cell imaging, a single cell was captured over a few minutes showing the formation of

119   a cellular bleb containing a single lipid droplet that was released in subsequent scans

120   (Supplemental Figure 2). We have previously reported that this organism does not appear to

121   have any canonical proteins associated with lipid droplet secretion from other organisms[22]. That

122   study also captured static images showing what was described as blebbing intermediates. The

123   current image series reported here is the first case in which the process was observed live

124   thereby lending additional support to the theory that *O. tauri* is capable of lipid droplet secretion

125   although the detailed mechanism remains elusive.

126   Dramatic changes observed for lipid staining profiles prompted the exploration of

127   underlying global proteomic expression profiles for each experimental culture condition.

128   Cultures were harvested at 24- and 48-hour time points for LC-MS/MS proteomics to obtain a

129   measure of global proteomic expression. These time-points were chosen for comparison since

130   they showed the biggest relative 24-hour changes via FACS and confocal analysis. The

131   proteomics data was mapped into individual metabolic groups (synthesis, degradation, energy,

132   other and non-metabolic pathways) to interpret relative changes of cells cultured in K6CN,

133   K2CN, K2C and K6C conditions for each metabolic pathway (Fig. 2). Of particular note was the

134   increased changes in abundance for both K2C and K6C in the carbohydrate synthesis pathway

135   compared to K2CN and K6CN. However, very few proteins within the fatty acid (FA)/lipid

136   synthesis pathways showed significant, if any, change in abundance despite bioimaging

137   observations of cellular lipid increases up to 60% the volume of cells. For example, while DGAT,

138   the canonical enzyme representing the last committed step of TAG synthesis was detected with

139   global proteomics, it's abundance remained effectively equivalent across all 4 sample

140   conditions.

141   High C to N ratio of K6C displayed consistently higher proteomic responses compared to

142   K2C for upregulated proteins related to C storage. The complete starch pathway was detected

143   with ascending upregulation from alpha amylase to granule-bound starch synthetase (GBSSI)

144   for N depletion conditions. GBSSI was the third highest upregulated protein overall highlighting

145   the reliance on carbon storage under these conditions. Previous studies have found similar

146   results for GBSSI[23]. N deprivation also caused downregulation of proteins involved in N

147   acquisition, such as nitrate transporters, nitrate reductase with concomitant upregulation of N

148   scavenging proteins for glutamine, asparagine, and urea. Much of the downregulated proteins

149   detected were ribosome based or were proteins localized to the chloroplast.

150   Overall 471 unnamed protein products were found to be upregulated or downregulated

151   with several exhibiting some of the most extreme abundance changes (Fig. 4). N deplete

152   conditions K2C and K6C had similar distributions of upregulated and downregulated protein

153   trends, with more increased upregulation of proteins for excess carbon cultures. For K6C, 5 of

154   the 10 most upregulated and 3 of the 10 most downregulated were UPP (Fig. 3). Interestingly,

155   several of these proteins show inversion of abundance for replete versus depleted N conditions.

156   XP_003075209 (ostta02g03680), XP_003081059 (ostta09g00670), XP_003078347

157   (ostta03g04500) all exhibit significant upregulation under K6CN and K2CN conditions at 48

158   hours compared to K2CN at 24 hours, however, these proteins show significant downregulation

159   for K2C and K6C conditions at 48 hours. The biggest change was seen for XP_003078347

160   (ostta03g04500) which was had a log2 value change of -0.54 for K6CN but a value of 1.96 for

161   K6C. Similarly, other unnamed proteins XP_003084215 (ostta18g01710), XP_003082140

162   (ostta11g03180) and XP_003082699 (ostta13g02170) were all downregulated for K6CN and

163   K2CN at 48 hours but upregulated for K2C and K6C. Clearly these unnamed proteins are

164   dramatically affected by the bioavailable ratio of C and N and represent interesting targets for

165   future in-depth functional annotation.

166   Conducting a BLAST alignment analysis on the UPP identified in these runs resolved a

167   predicted membrane protein (XP_003080099 (ostta06g04530)) upregulated for N depleted

168   conditions K2C and K6C, which was identified as having a domain with homology to TMEM14,

169   an uncharacterized superfamily believed to be involved in membrane transport of lipids in higher

170   eukaryotes. This protein could possibly play a role in the lipid droplet secretion from *O. tauri*.

171   Other potentially interesting unknown protein products were also uncovered during BLAST

172   alignments with two notable probable identifications: A putative Acyl-CoA N-acyltransferase

173   (XP_003084085.1 (ostta18g00460)) slightly upregulated for K2CN and K2C but not K6CN or

174   K6C; and a putative Zinc finger (XP_003080741.1 (ostta08g01730)) slightly downregulated for

175   K6CN, K6C, and K2C conditions, which have been known to participate in a number of

176   eukaryotic cellular mechanisms including lipid binding. Additional proteins such as sarcosine-

177   dimethyltransferase (SDMT), an enzyme found in the betaine biosynthesis pathway in other

178   algae and higher plants related to osmoprotection during cellular stress[24,25], were found to be

179   elevated only for K2C and K6C conditions, which may reinforce cellular stability during N stress

180   and lipid accumulation.

181   Despite observing limited changes in the proteome related to lipid metabolism, the visual

182   confocal and FACS analysis provided ample evidence of significant lipid accumulation that

183   warranted further characterization to understand cellular lipid composition and relative

184   abundance. Thus, the same K6CN, K2CN, K2C, and K6C cultures were surveyed at the same

185   24- and 48-hour time-points using LC-MS/MS global lipidomics analysis. Quantitative lipid

186   profiles were collected for more than 280 lipids (Supplemental Figures 3 – 9). The N depletion

187   conditions (K2C and K6C) resulted in significant increases of energy dense TAG lipids with

188   more than 10 TAGs showing >40-fold increase in abundance already at 48-hours. The FACS

189   and confocal analysis showed that the NL content continues to accumulate well beyond 48

190   hours. In comparison, TAG lipid abundance was flat or decreased for K6CN and K2CN

191   conditioned cells, indicating that cells were not diverting C into lipid energy storage during

192   nutrient rich conditions although they were still accumulating starch as seen from SRS

193   (Supplemental Figure 1). The observed FA profiles provide additional support for recently

194   reported[26] unique long chain FAs despite lacking annotated enzymes known to synthesize

195   them, indicating that *O. tauri* is at the very least an intriguing oleaginous organism for lipid

196   feedstock development. In addition, the number of long chain FAs in TAGs were significantly

197   enhanced during K6C conditions, demonstrating this organism's capacity to uptake and

198   transform excess C into long chain energy dense lipids without genetic modification

199   (Supplemental Figures 7–9).

9

200   Changes in structural lipids were also detected (Supplemental Figures 3 – 6).

201   Thylakoidal membranes are composed of monogalactosyldiacylglycerol (MGDG) and

202   digalactosyldiacylglycerol (DGDG), which stabilize the thylakoid for maximal photosynthetic

203   efficiency [27]. In addition, algal thylakoid membranes contain abundant amounts of

204   sulphoquinovosyldiacylglycerol (SQDG) which contributes to increased stability in the

205   photosynthetic harvesting complexes and accommodates membrane protein associations

206   unique to microalgae [28]. Increased abundances for MGDG and 3- to 7-fold increases in DGDG

207   were detected for K2C and K6C conditions, with C16 chain lengths exhibiting the most

208   abundant and dramatic changes during N depletion. C16 chain length SQDG lipids were also

209   slightly upregulated for K6C, suggesting they may be adding stability to light harvesting

210   complexes or membrane protein expression unique to excess C exposure and N depletion.

211

Discussion

213   Linkages between N and C metabolism related to lipid biogenesis were interrogated for

214   the microalgae *Ostreococcus tauri*. Single cell and population imaging experiments combined

215   with global proteomic and lipidomic experiments on the same cultures demonstrated that even

216   the simplified cell architecture and genome of *O. tauri* displays complicated regulatory linkages

217   as a function of bioavailable carbon to nitrogen ratios. Cryogenic soft x-ray nanotomography

218   revealed distinct lipid droplet distributions of varying sizes confirming initial fluorescence

219   microscopy results. K2C conditioned cells had uniform sized lipid droplets whereas cells in K6C

220   conditions had lipid droplets of varying size including very large lipid droplets that swelled and

221   deformed the cells.

222   Numerous photosynthetic, structural, and energy storage fatty acid (FA)/lipids were

223   verified through LC–MS/MS lipidomic analysis that included detection of long chain TAGs, ideal

224   for lipid feedstocks. Proteomic data combined with physiological cell responses to varying C and

10

225 N revealed that although FA/lipid synthesis pathways had little proteomic changes,

226 carbohydrate synthesis proteomics was independently upregulated. Both ribulose 1,5-

227 biphosphate carboxylase/oxygenase large and small subunits (Rubisco) were slightly

228 downregulated for K2C and K6C relative to K2CN suggesting Rubisco expression in

229 *Ostreococcus* contains minimum concentrations of Rubisco to support normal growth as

230 reported for other organisms[29]. Restricting protein identifications to subsets related to

231 carbohydrate conversion, N scavenging, and energy regulation allowed for the simplification of

232 biological interpretations related to lipid feedstock optimization targets. The most upregulated

233 protein was a protein kinase involved in serine/threonine phosphorylation and was equally

234 upregulated for K2C, K6C, and K6CN conditions, which could possibly play a role in regulating

235 diurnal cycling or stress response since K6CN could also be seen as another N deprived state

236 relative to available C. GBSSI was the third most upregulated protein in all and was more

237 upregulated in K6C than K2C. Knock-down of GBSSI could potentially provide a redirection of

238 *O. tauri* metabolism to less starch accumulation and more lipid accumulation under K6C

239 conditions.

240 In addition to the proteins related to energy storage, increased abundances of proteins

241 related to lipid viability, lipid production, and osmotic shock were detected to varying degrees.

242 Finally, a surprising number of proteins of unknown function and identity were revealed to be

243 part of the 10 most significant proteomic increases and decreases overall and each is a

244 potential target for future engineering efforts. A recent study focused on circadian protein

245 regulation[30] identified ostta03g04500, ostta09g00670, and ostta02g03680 proteins of unknown

246 function that happen to overlap with the findings reported here. This suggests that the proteins

247 found in both studies may have a co-relational effect between carbon and nitrogen

248 bioavailability and the circadian cycle. Delving further into the function of these individual

249 proteins will be important for understanding their real role in overall cellular regulation and

250   metabolic processes. Furthermore, the wealth of undefined proteins emphasizes the extent of

251   unexplored opportunities related to N, C, and energy storage pathways, and highlights the

252   peculiar genetic diversity within natural populations of *Ostreococcus* and possibly other primitive

253   marine species.

254

255   **Methods:**

256   **Strain maintenance, culture growth media, and nutrient starvation conditions**

257   *O. tauri* cell cultures were obtained from the Roscoff Culture Collection (RCC745); strain name:

258   OTTH0595, which has been fully sequenced [20]. Cultures of RCC745 were grown in defined

259   Keller (K) media[31] with normal or depleted N and HCO_3^-: K2CN contained normal N and C,

260   K6CN with normal N and 6mM HCO_3^-, K2C with depleted N and 2.5mM HCO_3^-, and K6C with

261   depleted N and 6mM HCO_3^-. All Keller media-based culture conditions were prepared in fresh

262   artificial seawater (ASW) with defined amounts of nutrients analytically prepared fresh and

263   sterile filtered prior to each experiment. To monitor growth and lipid accumulation over time

264   absorbance at 680nm and 750nm was measured to obtain both values for chlorophyll content

265   and particulate matter, respectively, for each culture. Graphing the ratio of 750nm/680nm

266   provided a measure of chlorophyll functional efficiency as well as possible lipid particulates in

267   solution. Graphical analysis of each growth and starvation curve required minimal normalization

268   due to our consistent efforts in capturing cells during mid-log stages of growth. For growth and

269   lipid accumulation studies cells were grown initially in normal K media to approximately 0.03 at

270   OD680 then gently centrifuging cultures at 1200XG for 10 minutes in a swing bucket rotor,

271   washed with respective defined K media, and resuspending cells into defined K media at a

272   target 0.03 at OD680 and continued diurnal light entrainment for specified time courses in

273   sealable CytoOne non-treated cell culture flasks (USA Scientific, USA) with mixing of cultures

274   once per 24 hours. To prepare cell cultures for starvation surveys they were gently centrifuged

275   fresh cultures at 2200xG for 10 mins with swing bucket rotor centrifugation and washed cell

276   pellets once with defined K media of interest then suspended cells in defined media conditions

277   and continued diurnal light entrainment for specified time courses in sealable CytoOne non-

278   treated cell culture flasks (USA Scientific, USA) with mixing of cultures once per 24 hours.

279

280   **Fluorescence activated cell sorting analysis of intracellular lipid content**

281   *O. tauri* cells were cultured to mid log phase and gently centrifuged to concentration then

282   stained with Nile Red (4.8µg/mL) lipid stain for exactly 10 mins before each experimental

283   measurement on the BD INFLUX flow cytometer (BD Biosciences, San Jose, CA, USA). FSC

284   and SSC were used to gate out any non-specific cellular debris. Specific gating in the range of

285   known cell size of *O. tauri* was used to determine the fluorescence from stained neutral lipid

286   (488/542±13.5 nm), phospholipid (561/615±12 nm), and natural chlorophyll autofluorescence

287   (640/670±15 nm) for defined populations of cells. Each individual FACS experiment was

288   calibrated to 3.6 ide scatter 10 mins before running our sample measurements in defined media

289   cultures. The fluorescence intensity of neutral lipid and phospholipid fluorescence intensity at

290   specific time points was compared in scatter plots to demonstrate population dynamics for each

291   sample condition. K2CN at 24 hours was used as the baseline for normal conditions to detect

292   changes due to varying C:N bioavailability.

293

294   **Fluorescence and SRS confocal microscopy**

295   Confocal images were obtained on Zeiss LSM 710 (Carl Zeiss AG, Germany) confocal

296   microscope with a 100x oil immersion objective. An InTune Laser with 505nm and 535nm light

297   was used to maximize the separation of the triglyceride (585nm) and phospholipid (638nm)

298   emission peaks while diminishing crosstalk of the Nile Red stained cells. In addition, chlorophyll

299   autofluorescence was excited with 405nm light and monitored the emission profile at 680nm.

300   Nile Red stained cells were immobilized on glass slides with poly-L-lysine and imaged

301   immediately with z-scan slicing of 0.43μm to survey whole cell fluorescence labeling distribution.

302   All fluorescence channels were set with identical gain and laser power settings to provide

303   relative levels of fluorescent intensity and no adjustments of contrast or gain were applied to

304   fluorescence imaging during post processing. *O. tauri* cultures were grown in 15mL falcon tubes

305   in a 12:12 light:dark illumination (~20 μmol/m^2/s) at 25°C for 96 hours, harvested by gentle

306   centrifugation (1000xG, 5 mins) and concentrated equally to 10x original cell density for

307   imaging. Concentrated cell suspensions were then stained with Nile Red (4.8 μg/mL) for 10

308   minutes and then 3μL of the labeled culture were mounted on poly-lysine treated microscope

309   slides (Electron Microscopy Sciences, USA) for confocal fluorescence and SRS imaging.

310   Fluorescence and SRS confocal microscopy were conducted on the Nile Red stained *O. tauri*

311   cells using a Leica DMi8 (Leica Microsystems GmbH, Germany) inverted confocal microscope

312   (a 63x/1.20na water immersion objective) integrated with an APE picoEmerald laser consisting

313   of a 2.5 ps pulsed tunable pump and 1031nm stokes with the SRS detection module and an

314   EOM Modulator. Prior to the SRS detection, the stokes beam was blocked by a FESH1000 filter

315   (Thorlabs, USA). The SRS signal was detected on a 10x10mm photodiode connected to the

316   APE lock-in amplifier. For starch detection the SRS pump signal was tuned to 947nm at 152mW

317   with bandwidth of 0.7nm with the stokes power at 150mW modulated by the integrated EOM,

318   and a delay of 3500fs to detect the 860cm^{-1} peak of starch [32]. Cellular chlorophyll was excited

319   with a 638nm laser with 1% power and fluorescence signal collected with emission range of

320   677–689nm. Neutral lipid fluorescence from Nile Red staining was excited with 552nm with 1%

321   laser power and emission 575–583nm. Sequential acquisition of different channels was

322   acquired at 1024x1024 format, with slower 400 scan speeds, and 4x zoom. Maximum

323   thresholds were changed consistently for all SRS starch images to obtain equal post processing

324   values across all samples; no post processing was conducted on either chlorophyll or neutral

14

325   lipid channels.

326

327   **Cryogenic Soft X-ray Tomography for Intracellular Distribution of Organelles**

328   Cell cultures were grown on-site at the Advanced Light Source (ALS) at Lawrence

329   Berkeley National Laboratory with a homemade 470nm light source with a measured intensity of

330   20μE. Cell cultures were incubated with 12-hour diurnal light at RT and harvested by

331   centrifugation at 48, 72 and 96-hour time points. Cells were gently centrifuged at 1000xG for

332   10mins to pellet. Pelleted cells had all but ~5μL of supernatant removed to remove a viscous

333   cell biomass. Wet cell biomass was inserted into 5μm micro capillaries and plunge frozen in cold

334   liquid propane. In some cases, 6μm polystyrene beads were added to cell suspensions prior to

335   centrifugation to minimize the impact of freezing on large lipid containing cells. Frozen

336   capillaries were stored in liquid nitrogen until imaging by the soft x-ray light source. Soft x-ray

337   data acquisition was carried out on beamline 2.1, a soft x-ray microscope in the National Center

338   for X-Ray Tomography (NCXT) located at the Advanced Light Source in Berkeley, California[33].

339   The microscope soft x-ray illumination was generated by a bend-magnet in the synchrotron

340   lattice and focused onto the specimen by a Fresnel Zone Plate (FZP) condenser. Specimen

341   illumination was order-sorted by a pinhole positioned just in front of the specimen. A second

342   zone plate, located downstream of the specimen, magnified and focused an image of the

343   specimen on a CCD detector. During data collection, the cells were maintained in a stream of

344   helium gas that had been cooled to liquid nitrogen temperatures. Each tomographic dataset

345   (i.e., 90 projection images spanning a range of 180°) was collected using Fresnel zone plate

346   based objective lens with a resolution of 50 nm. Exposure times for each projection image

347   ranged from 150 to 300 msec. The software suite AREC3D was used to align the projection

348   images calculate tomographic reconstructions[34].

349

15

350 **Lipid Extraction and Lipidomics Using Liquid Chromatography Tandem Mass**

351 **Spectrometry**

352   Each *O. tauri* culture was harvested at specific time points and ultimately spun down at

353 3000 x g for 10 min to form a pellet in chloroform compatible 2 mL Safe Seal microfuge tubes

354 (Sorenson Bioscience, Inc, Salt Lake City, UT). The supernatant was removed, and the wet

355 pellet was weighed for an estimate of biomass, then a mixture of 1 mL of methanol, 0.5 mL of

356 chloroform and 0.4 mL of nanopure water was added to each pellet. The pellets were vortexed

357 and sonicated for about 10 sec in a bath sonicator and the mixture was allowed to stand at room

358 temperature for 10 min. Then an additional 0.5 mL of chloroform and 0.5 mL of water were

359 added, and the mixtures were shaken vigorously into an emulsion. Each sample was

360 centrifuged at 10,000 x g for 10 min. The bottom chloroform layer was carefully removed from

361 the separated solvent layers using a Pasteur pipette and taking care not to take up any of the

362 protein disc or the top polar layer and was placed in a pre-weighed glass auto sampler vial. The

363 bottom lipid layer was dried down overnight under nitrogen and the vials with the total lipid

364 extract (TLEs) were weighed to obtain the total mass. 5μL of chloroform was added to each

365 dried sample and then the sample diluted to 50 μg/μL with methanol. The samples were then

366 stored at –20 °C until ready for mass spectrometric analysis.

367   Extracted lipids were dried down then reconstituted in methanol. The TLEs were

368 analyzed by LC-MS/MS using a Waters NanoAquity UPLC system interfaced with a Velos

369 Orbitrap mass spectrometer (Thermo Scientific, San Jose, CA) as outlined in Dautel et al.

370 2017[35]. LC-MS/MS raw data files were imported into the in-house developed software LIQUID[36]

371 for identification of lipid molecular species. Manual validation of the lipid identifications were

372 determined by examining the tandem mass spectra for diagnostic ion fragments along with

373 associated chain fragment information. In addition, the isotopic profile, extracted ion

374 chromatogram (XIC), and mass error of measured precursor ion were examined for lipid

375

Cellular Protein Extraction and Digestion

377   To the remaining protein/debris pellet obtained from the lipid extraction, 1 mL of ice cold

378   methanol was added 3 x to wash the majority of residual metabolites away from the pellet. A

379   Filter-Aided Sample Prep (FASP) protein extraction and trypsin digestion was then performed

380   using the FASP protein digestion kit (Expedeon, San Diego CA) using manufacturer's

381   suggested protocol (Erde J et al, 2014, J Proteome Res 13(4):1885-1895). Briefly, methanol

382   washed pellets were air dried for 2 hrs and were resuspended in solubilization buffer of 12 mM

383   deoxycholate, 12 mM N-lauroyl sarcosine with 10 mM TCEP, and 200 mM ammonium

384   bicarbonate, pH 8.0 at an approximate concentration of 13 μg/μL. 30 μL of this protein solution

385   was then mixed with 200 μL of urea sample solution (kit provided), the sample was centrifuged

386   on the kit provided spin filter at 14,000 x g for 15 min. Washes with urea and ammonium

387   bicarbonate along with trypsin digestion and alkylation with iodoacetamide were carried out as

388   the kit specifies. Peptides were then suspended in nanopure water and peptides were then

389   quantified using a BCA assay (Pierce, Rockford IL) with a bovine serum albumin standard.

390

iTRAQ Peptide Labeling

392   Peptides were labeled with 8-plex iTRAQ (AB Sciex, Redwood City, CA) reagents as

393   described below. 100 μg of each peptide sample was placed in a new tube and dried down.

394   Chanel designations are as follows: 43 μg of dissolution buffer (iTRAQ buffer kit) was added to

395   each sample, these being vortexed into solution and centrifuged briefly to draw sample to the

396   bottom of each tube. The iTRAQ reagent (30 μL) was diluted further with isopropanol (115 μL)

397   and this was then added to each sample. Each reaction was carried out at RT for 2 hrs, with 50

398   mM ammonium bicarbonate (200 μL) added to quench each reaction tube. After 1 hr, the

399   contents from all iTRAQ channel reactions were added to one tube and then the sample was

400   vortexed and dried down in a speed vac. The labeled peptides were cleaned up using C-18

401   SPE columns (SUPELCO Discovery) were then employed to remove the salts, using a 0.1%

402   TFA in nanopure water to wash the peptides and 80% acetonitrile, 0.1% TFA in water to elute

403   the peptides.

404

405   <u>Offline Fractionation of Peptides and Preparation of Proteome Samples</u>

406   400 μg of iTRAQ labeled peptides were separated using an off-line high pH (pH 10) reversed-

407   phase (RP) separation with a Waters XBridge C18 column (250 mm x 4.6 mm column

408   containing 5 μm particles and a 4.6 mm x 20 mm guard column) using an Agilent 1200 HPLC

409   System. The sample loaded onto the C18 column was washed for 15 min with Solvent A (10

410   mM ammonium formate, adjusted to pH 10 with ammonium hydroxide). The LC gradient started

411   with a linear increase of Solvent B (10 mM ammonium formate, pH 10, 90% acetonitrile in

412   water) to: 5% over 10 min, 45% Solvent B over 65 min, and then a linear increase to 100%

413   Solvent B over 15 min. Solvent B was held at 100% for 10 min, and then was changed to 100%

414   Solvent A, this being held for 20 min to recondition the column. The flow rate was 0.5 mL/min.

415   A total of 96 fractions were collected into a 96 well plate throughout the LC gradient. The high

416   pH RP fractions were then combined into 12 fractions using the concatenation strategy

417   previously reported[37]. Peptide fractions were dried down and re-suspended in nanopure water

418   at a concentration of 0.075 μg/ μL for mass spectrometry analysis using a Q Exactive HF Hybrid

419   Quadrupole-Orbitrap MS (Thermo Scientific) system as described below.

420

421   **<u>Mass-Spectrometry Based Analysis of Samples</u>**

422   All peptide samples were analyzed using an automated home-built constant flow nano

423   LC system (Agilent) coupled to an Q Exactive HF Hybrid Quadrupole-Orbitrap MS (Thermo

424   Fisher Scientific). Electrospray emitters were custom made using 150 μm o.d. x 20 μm o.d. x

18

425   20 μm i.d. chemically etched fused silica. An on-line 4-cm x 360 μm o.d. x 150 μm i.d. fused-

426   silica capillary analytical column (3 μm Jupiter C18) was used. Mobile phases consisted of

427   0.1% formic acid in water (A) and 0.1% formic acid acetonitrile (B) operated at 300 nL/min with

428   a gradient profile as follows (min:%B); 0:5, 2:8, 20:12, 75:35, 97:60, 100:85.

429

430   **Peptide Identification, Quantification and Analysis**

431   For peptide identification, MS/MS spectra were searched against a decoy O. tauri

432   database using the algorithm SEQUEST. An approach to correlate tandem mass spectral data

433   of peptides with amino acid sequences in a protein database[38]. Search parameters included: no

434   enzyme specificity for proteome data and trypsin enzyme specificity with a maximum of two

435   missed cleaves, ± 50 ppm precursor mass tolerance, ± 0.05 Da product mass tolerance, and

436   carbamidomethylation of cysteines and iTRAQ labeling of lysines and peptide N-termini as fixed

437   modifications. Allowed variable modifications were oxidation of methionine. MSGF+ spectra

438   probability values were also calculated for peptides identified from SEQUEST searches[39].

439   Measured mass accuracy and MSGF spectra probability were used to filter identified peptides to

440   <0.4% false discovery rate (FDR) at spectrum level and <1% FDR at the peptide level using the

441   decoy approach. iTRAQ reporter ions were extracted using the MASIC software[40] for fast

442   quantitation and flexible visualization of chromatographic profiles from detected LC-MS(/MS)

443   features with a 10-ppm mass tolerance for each expected iTRAQ reporter ion as determined

444   from each MS/MS spectrum.

445   Relative abundances of peptides were determined using iTRAQ reporter ion intensity

446   ratios from each MS/MS spectrum. Individual peptide intensity values were determined by

447   dividing the base peak intensity by the relative ratio associated with each reporter ion. All

448   peptide values were then transformed into log2 values for comparison between conditions.

19

Competing Interests: We declare no competing interests.

Contributions

JEE devised and managed all experiments with input from CRS. CRS conducted confocal and Raman imaging experiments and coordinated integrated omics analysis. KKH and CDN performed lipid and proteomics sample prep. RM collected proteomics data that SP analyzed, and NK and WRC worked into the cell model. JEK performed lipidomic data collection and lipidomic analysis. Cryogenic soft X-ray sample preparation was conducted by JHC, RB and CRS with JHC and GM acquiring tilt series for subsequent reconstruction by AE. FACS analysis was conducted by WC. JEE and CRS wrote initial manuscript and all authors edited and approved final text.

Main Figures
Figure 1 Single cell and population imaging and growth under varying C:N ratios

(A) Confocal microscopy of K6CN, K2CN, K2C, and K6C cultures to observe chlorophyll autofluorescence (magenta), nucleic acid fluorescent staining (blue), neutral lipid fluorescent staining (green) over time. Scale bar represents 1μm scale. (B) Corresponding growth plots for the same cultures monitored over time (error bars represent a replicate of 5) at 750nm and 680nm, and the ratio of the 750/680 as a measure of photosynthetic efficiency. (C) FACS time course study of same cultures comparing SSC (side-scattering) versus FSC (forward scattering) and chlorophyll autofluorescence in 3D plots at 0 hours and 120 hours, then 2D plot of SSC versus FSC at 120 hours, and histogram of FSC at 120 hours. (D) FACS time course study of same

cultures comparing phospholipid versus neutral lipid and chlorophyll autofluorescence in 3D plots at 0 hours and 120 hours, then 2D plot of phospholipid versus neutral lipid at 120 hours, and histogram of neutral lipid at 120 hours. (E) Label-free cryogenic soft x-ray nanotomography images of cells cryogenically frozen in microcapillaries. Central slices (1µm scale bar) display intracellular structures common to each culture condition. Chloroplasts and cytoplasm seen in all images. Vacuoles in K6CN and K2CN appear as dark objects indicated with white arrow. Lipid droplets appear as bright white circular objects indicated by white arrowhead.

25
Figure 2 Metabolic pathway mapping of global proteomics
O. tauri cells cultured in K6CN (black), K2CN (red), K2C (green), K6C (blue) at 48 hours relative to cultures from K2CN at 24 hours were grouped and mapped by metabolic pathway(A), subpathway (B), and individual proteins (C). Each large circle represents an average level of abundance on a log2 scale where negative values are increases in abundance relative to cell conditions K2CN at 24 hours. Smaller circles represent individual proteins in the respective metabolic pathway.
Figure 3 Selection differentially expressed proteins from global proteomics of varying N and C conditions
Abundance profiles for 10 most downregulated (positive values) and upregulated (negative values) proteins comparing K2CN at 24 hours versus K6CN at 48 hours (black), K2CN at 48 hours (red), K2C at 48 hours (green), and K6C at 48 hours (blue) cell cultures.

26
Figure 4 Time resolved differential expression of global lipids

Selection of lipids (out of 287) detected via LC-MS/MS for cell cultures at 24 (X symbols) and 48 hours (O symbols) for varying C:N ratio conditions K6CN (black), K2CN (red), K2C (green) and K6C (blue). *Cer: Ceramide; PC: phosphatidylcholine; MGDG: monogalactosyldiacylglycerol; DG: diacylglycerol; DGDG: digalactosyldiacylglycerol; DGTSA: diacylglyceryl trimethylhomoserine or diacylglyceryl trimethyl-beta-alanine; SQDG: sulfoquinovosyldiacylglycerol; and TG: triacylglycerols*

Supplemental Figures
Supplemental Figure 1 Fluorescence and SRS verification of neutral lipid and starch accumulation
Fluorescence and SRS microscopy were conducted on *O. tauri* cells stained with Nile Red from various C:N conditions after 96 hours of starvation. Chlorophyll autofluorescence (pink) was observed in all cells with neutral lipid (yellow) and SRS starch signal (green). Elevated neutral lipid was observed in K2C and K6C cells localized outside the chloroplast. Starch was detected and localized to the chloroplast for K6CN, K2CN, and to a lesser extent K6C, with little to no starch signal found in K2C cells. Scale bar represents 1μm.
Supplemental Figure 2 Time course of lipid release from cells into intercellular space

O. tauri cells cultured in K6C media for 72 hours were harvested and stained with Nile Red and then imaged by confocal fluorescence microscopy. Chlorophyll autofluorescence (pink) and neutral lipid (yellow) revealed many large lipid bodies during z-slice imaging and a single lipid body release was tracked over time (t) in intercellular milieu while other lipids remained inside the intracellular space.

Supplemental Figure 3 Time-resolved lipidomics of diacylglycerol lipids

Diacylglycerol (DG) lipids detected via LC-MS/MS for cell cultures at 24 (X symbols) and 48 hours (O symbols) for varying C:N ratio conditions K6CN (black), K2CN (red), K2C (green) and K6C (blue) relative to K2CN at 24 hours (y-axis).
Supplemental Figure 4 Time resolved differential expression of digalactosyldiacylglycerol lipids
Digalactosyldiacylglycerol (DGDG) lipids detected for cell cultures at 24 (X symbols) and 48 hours (O symbols) for varying C:N ratio conditions K6CN (black), K2CN (red), K2C (green) and K6C (blue) relative to K2CN at 24 hours (y-axis).

Supplemental Figure 5 Time resolved differential expression of monoacylglycerol and monogalactosyldiacylglycerol lipids
Monoacylglycerol (MG) and monogalactosyldiacylglycerol (MGDG) lipids detected via LC-MS/MS for cell cultures at 24 (X symbols) and 48 hours (O symbols) for varying C:N ratio conditions K6CN (black), K2CN (red), K2C (green) and K6C (blue) relative to K2CN at 24 hours (y-axis).

Supplemental Figure 6 Time resolved differential expression of lipids
Sulfoquinovosyldiacylglycerol (SQDG) lipids detected via LC-MS/MS for cell cultures at 24 (X symbols) and 48 hours (O symbols) for varying C:N ratio conditions K6CN (black), K2CN (red), K2C (green) and K6C (blue) relative to K2CN at 24 hours (y-axis).
32

Supplemental Figure 7 Time resolved differential abundance of triacylglycerol lipids set 1
Triacylglycerol (TG) lipidomics for cell cultures at 24 (X symbols) and 48 hours (O symbols) for varying C:N ratio conditions K6CN (black), K2CN (red), K2C (green) and K6C (blue) relative to K2CN at 24 hours (y-axis).

Supplemental Figure 8 Time resolved differential abundance of triacylglycerol lipids, set 2

Triacylglycerol (TG) lipidomics detected via LC-MS/MS for cell cultures at 24 (X symbols) and 48 hours (O symbols) for varying C:N ratio conditions K6CN (black), K2CN (red), K2C (green) and K6C (blue) relative to K2CN at 24 hours (y-axis).

Supplemental Figure 9 Time resolved differential abundance of long chain triacylglycerol lipids, scale 10
Long chain triacylglycerol (TG) lipidomics for cell cultures at 24 (X symbols) and 48 hours (O symbols) for varying C:N ratio conditions K6CN (black), K2CN (red), K2C (green) and K6C (blue) relative to K2CN at 24 hours (y-axis).
