# Abstract

RNA interference (RNAi) requires RNA-dependent RNA polymerases (RdRPs) in many eukaryotes, and RNAi amplification constitutes the only known function for eukaryotic RdRPs. Yet in animals, classical model organisms can elicit RNAi without possessing RdRPs, and only nematode RNAi was shown to require RdRPs. Here we show that RdRP genes are much more common in animals than previously thought, even in insects, where they had been assumed not to exist. RdRP genes were present in the ancestors of numerous clades, and they were subsequently lost at a high frequency. In order to probe the function of RdRPs in a deuterostome (the cephalochordate Branchiostoma lanceolatum), we performed high-throughput analyses of small RNAs from various *Branchiostoma* developmental stages. Our results show that Branchiostoma RdRPs do not appear to participate in RNAi: we did not detect any candidate small RNA population exhibiting classical siRNA length or sequence features. Our results show that RdRPs have been independently lost in dozens of animal clades, and even in a clade where they have been conserved (cephalochordates) their function in RNAi amplification is not preserved. Such a dramatic functional variability reveals an unexpected plasticity in RNA silencing pathways.

# Author summary

RNA interference (RNAi) is a conserved gene regulation system in eukaryotes. In non-animal eukaryotes, it necessitates RNA-dependent RNA polymerases ("RdRPs"). Among animals, only nematodes appear to require RdRPs for RNAi. Yet additional animal clades have RdRPs and it is assumed that they participate in RNAi. Here, we find that RdRPs are much more common in animals than previously thought, but their genes were independently lost in many lineages. Focusing on a species with RdRP genes (a cephalochordate), we found that it does not use them for RNAi. While RNAi is the only known function for eukaryotic RdRPs, our results suggest additional roles. Eukaryotic RdRPs thus have a complex evolutionary history in animals, with frequent independent losses and apparent functional diversification.

## Introduction

Small interfering RNAs (siRNAs) play a central role in the RNA interference (RNAi) response. Usually loaded on a protein of the AGO subfamily of the Argonaute family, they recognize specific target RNAs by sequence complementarity and typically trigger their degradation by the AGO protein [1]. In many eukaryotic species, normal siRNA accumulation requires an RNA-dependent RNA polymerase (RdRP). For example in plants, RdRPs are recruited to specific template RNAs and they generate long complementary RNAs [2–4]. The template RNA and the RdRP product are believed to hybridize, forming a long double-stranded RNA which is subsequently cleaved by Dicer nucleases into double-stranded siRNAs (reviewed in [5]). In fungi, RdRPs have also been implicated in RNAi and in RNA-directed heterochromatinization [6–9], but the exact nature of their products remains elusive: fungal RdRPs are frequently proposed to polymerize long RNAs which can form Dicer substrates after annealing to the RdRP template [10–12]. But the purified Neurospora crassa, Thielavia terrestris and Myceliophthora thermophila QDE-1 RdRPs tend to polymerize essentially short (9-21 nt) RNAs in vitro, suggesting that they may generate Dicer-independent small RNAs [13, 14]. In various unicellular eukaryotes, RdRPs have also been implicated in RNAi and related mechanisms (e.g., see [15, 16]). It is usually believed that their products are long RNAs that anneal with the template to generate a Dicer substrate, and that model has gained experimental support in one organism, *Tetrahymena* [17].

Among eukaryotes, animals are thought to constitute an exception: most classical animal model organisms (Drosophila and mammals) can elicit RNAi without the involvement of an RdRP [1]. Only one animal model organism was shown to require RdRPs for RNAi: the nematode *Cænorhabditis elegans* [18, 19]. In nematodes, siRNAs made by Dicer only constitute a minor fraction of the total siRNA pool: such "primary" siRNAs recruit an RdRP on target RNAs, triggering the production of short antisense RNAs named "secondary siRNAs" [20-22]. Secondary siRNAs outnumber primary siRNAs by  $\approx 100$ -fold [20] and the major class of secondary siRNAs (the so-called "22G RNAs") is loaded on proteins of the WAGO subfamily of the Argonaute family [22,23]. WAGO proteins appear to be unable to cleave RNA targets [23]. Yet WAGO/secondary siRNA/cofactor complexes appear to be much more efficient at repressing mRNA targets than AGO/primary siRNA/cofactor complexes [24], possibly by recruiting another, unknown, nuclease. In contrast to Dicer products (which bear a 5' monophosphate), direct RdRP products bear a 5' triphosphate. 22G RNAs are thus triphosphorylated on their 5' ends [20]. Another class of nematode RdRP products, the "26G RNAs", appears to bear a 5' monophosphate, and it is not clear whether they are matured from triphosphorylated precursors, or whether they are directly produced as monophosphorylated RNAs [25–27].

The enzymatic activity of RNA-dependent RNA polymerization can be mediated by several unrelated protein families [28]. Most of these families are specific to viruses (*e.g.*, PFAM ID #PF00680, PF04196 and PF00978). Viral RdRPs are involved in genome replication and transcription in RNA viruses, and they share common structural motifs [29]. On the other hand, RdRPs involved in RNAi in plants, fungi and nematodes belong to a family named "eukaryotic RdRPs" (PFAM ID #PF05183). While viral RdRPs are conceivably frequently acquired by virus-mediated horizontal transfer, members of the eukaryotic RdRP family are thought to be inherited vertically only [30]. The eukaryotic RdRP family can be further divided into three subfamilies, named  $\alpha$ ,  $\beta$  and  $\gamma$  based on sequence similarity. Phylogenetic analyses suggest these three subfamilies derive from three ancestral RdRPs that could have coexisted in the most recent common ancestor of animals, fungi and plants [31].

Besides eukaryotic RdRPs, other types of RdRP enzymes have been proposed to exist in various animals. It has been suggested that human cells express an atypical 1

RdRP, composed of the catalytic subunit of telomerase and a non-coding RNA [32]. While that complex exhibits RdRP activity *in vitro*, functional relevance of that activity is unclear, and other mammalian cells were shown to perform RNAi without RdRP activity [33]. More recently, bat species of the *Eptesicus* clade were shown to possess an RdRP of viral origin, probably acquired upon endogenization of a viral gene at least 11.8 million years ago [34].

Here we took advantage of the availability of hundreds of metazoan genomes to draw a detailed map of predicted RdRP genes in animals. We found RdRP genes in a large diversity of animal clades, even in insects, where they had escaped detection so far. Even though RdRP genes are found in diverse animal clades, they are lacking in many species, indicating that they were frequently and independently lost in many lineages. Furthermore, the presence of RdRP genes in non-nematode genomes raises the possibility that additional metazoan lineages possess an RdRP-based siRNA amplification mechanism. We sequenced small RNAs from various developmental stages in one such species with 6 candidate RdRP genes, the cephalochordate *Branchiostoma lanceolatum*, using experimental procedures that were designed to detect both 5<sup>'</sup> monoand tri-phosphorylated RNAs. Our analyses did not reveal any evidence of the existence of secondary siRNAs in that organism. While RNAi is the only known function for eukaryotic RdRPs, we thus propose that *Branchiostoma* RdRPs do not participate in RNAi.

## Materials and methods

### Bioinformatic analyses of protein sequences

Predicted animal proteome sequences were downloaded from the following databases: NCBI (ftp://ftp.ncbi.nlm.nih.gov/genomes/), VectorBase (https://www.vectorbase.org/download/), FlyBase (ftp://ftp.flybase.net/releases/FB2015\_03/), JGI (ftp://ftp.jgi-psf.org/pub/JGI\_data/), Ensembl (ftp://ftp.ensembl.org/pub/release-81/fasta/), WormBase (ftp://ftp.wormbase.org/pub/wormbase/species/) and Uniprot (http://www.uniprot.org/). The predicted Branchiostoma lanceolatum proteome was obtained from the *B. lanceolatum* genome consortium. RdRP HMMer profiles were downloaded from PFAM v. 31.0 (http://pfam.xfam.org/): 19 viral RdRP family profiles (PF00602, PF00603, PF00604, PF00680, PF00946, PF00972, PF00978, PF00998, PF02123, PF03035, PF03431, PF04196, PF04197, PF05788, PF05919, PF07925, PF08467, PF12426, PF17501) and 1 eukaryotic RdRP family profile (PF05183). Candidate RdRPs were selected by hmmsearch with an E-value cutoff of  $10^{-2}$ . Only those candidates with a complete RdRP domain according to NCBI's Conserved domain search tool (https://www.ncbi.nlm.nih.gov/Structure/bwrpsb/bwrpsb.cgi) were considered (tolerating up to 20% truncation on either end of the domain). One identified candidate, in the bat *Rhinolophus sinicus*, appears to be a plant contaminant (it is most similar to plant RdRPs, and its genomic scaffold [ACC# LVEH01002863.1] only contains that gene): it was not included in Figure 1 and in Supplementary Fig. S1. The Branchiostoma Hen1 candidate was identified using HMMer on the predicted

The Branchiostoma Hen1 candidate was identified using **HMMer** on the predicted B. lanceolatum proteome, with an HMMer profile built on an alignment of Drosophila melanogaster, Mus musculus, Danio rerio, Nematostella vectensis and Arabidopsis thaliana Hen1 sequences.

#### Phylogenetic tree reconstruction

Amino acid sequences of the eukaryotic RdRP domain (Pfam #PF05183) were retrieved 101 from PFAM [35], and supplemented with the RdRP domains of the proteins identified 102 in the 538 animal proteomes (cf above). Sequences were aligned using **hmmalign** [36] 103 using the HMM profile of the PF05183 RdRP domain. Sequences for which the domain 104 was incomplete were deteled from the alignment. Sites used to reconstruct the 105 phylogenetic tree were selected using **trimAl** [37] on the Phylemon 2.0 webserver [38]. 106 Bayesian inference (BI) tree was inferred using MrBayes 3.2.6 [39], with the model 107 recommended by **ProtTest 1.4** [40] under the Akaike information criterion (LG+ $\Gamma$ ), at 108 the CIPRES Science Gateway portal [41]. Two independent runs were performed, each 109 with 4 chains and one million generations. A burn-in of 25% was used and a fifty 110 majority-rule consensus tree was calculated for the remaining trees. The obtained tree 111 was customized using **FigTree v.1.4.0**. 112

#### Sample collection

Mediterranean amphioxus (*Branchiostoma lanceolatum*) males and females were collected at le Racou (Argelès-sur-mer, France) and were induced to spawn as previously described [42]. Embryos were obtained after fertilization in Petri dishes filled with filtered sea water and cultivated at 19°C. Total RNA was extracted from 8, 15, 36 and 60 hours post fertilization (hpf) embryos (three independent batches for each stage, pooled before small RNA gel purification) as well as from males (6 pooled individuals) and females (4 pooled individuals) using the RNeasy mini kit (for embryonic samples) and the RNeasy midi kit (for adult samples) (Qiagen).

#### Sequencing analyses

The BL09945 locus was PCR-amplified from adult female DNA, cloned in the pGEM-T easy vector (cat. #A1360; Promega, Madison, WI, USA) and sequenced by MWG Eurofins Genomics (Ebersberg, Germany).

For Small RNA-Seq, 18–30 nt RNAs were gel-purified from total RNA (using between 92 and 228  $\mu$ g total RNA per sample). One quarter of the small RNA preparation was kept untreated before library preparation (for "Libraries #1"). One quarter was incubated for 10 min at room temperature in 100  $\mu$ L of freshly-prepared 60 mM sodium borate (pH=8.6), 25 mM sodium periodate, then the reaction was quenched with 10  $\mu$ L glycerol (for "Libraries #2"). One quarter was treated with 1.25 U Terminator exonuclease (Epicentre, Madison, WI, USA) in 25  $\mu$ L 1X Terminator reaction buffer A for 1h at 30°C, then the reaction was quenched with 1.25  $\mu$ L 500 mM EDTA (pH=8.0) and ethanol-precipitated. RNA was then treated with 5 U Antarctic phosphatase (New England Biolabs, Ipswich, MA, USA) in 20  $\mu$ L 1X Antarctic phosphatase buffer for 30 min at 37°C, the enzyme was heat-inactivated, then RNA was precipitated, then phosphorylated by 15 U T4 PNK (New England Biolabs) with 50 nmol ATP in 50  $\mu$ L 1X T4 PNK buffer for 30 min at 37°C, then the enzyme was heat-inactivated (for "Libraries #3"). One quarter was treated successively with Terminator exonuclease, Antarctic phosphatase, T4 PNK then boric acid and sodium periodate, with the same protocols (for "Libraries #4"). Small RNA-Seq libraries were then generated using the TruSeq Small RNA library preparation kit (Illumina, San Diego, CA, USA), following the manufacturer's instructions.

Libraries were sequenced by the MGX sequencing facility (CNRS, Montpellier, France). Read sequences were aligned on the *B. lanceolatum* genome assembly [43] using **bowtie2**. A database of abundant non-coding RNAs was assembled by a search for orthologs for human and murine rRNAs, tRNAs, snRNAs, snoRNAs and scaRNAs; 147

142

deep-sequencing libraries were also mapped on that database using **bowtie2**, and matching reads were flagged as "abundant ncRNA fragments". For pre-miRNA annotation, every *B. lanceolatum* locus with a Blast E-value  $\leq 10^{-6}$  to any of the annotated *B. floridae* or *B. belcheri* pre-miRNA hairpins in miRBase v.22 was selected. Reads matching these loci were identified using **bowtie2**. For the measurement of miRNA abundance during development, hairpins were further screened for their **RNAfold**-predicted secondary structure and their read coverage: Supplementary Table S1 only lists unbranched hairpins with at least 25 bp in their stem, with a predicted  $\Delta G_{folding} \leq -15 \ kcal.mol^{-1}$ , generating mostly 21- to 23-mer RNAs, and with at least 20 ppm read coverage on any nucleotide of the hairpin.

RNA-Seq data was taken in [43] for embryonic and juvenile samples. Adult sample libraries were prepared and sequenced by "Grand plateau technique régional de génotypage" (SupAgro-INRA, Montpellier). mRNA abundance data was extracted using **vast-tools** [44].

### Extragenomic contig assembly and annotation

Small RNA reads that fail to map on the *B. lanceolatum* genome or transcriptome according to **bowtie2** were collected and assembled using **velvet** [45], with k values ranging from 9 to 19 for better sensitivity [46].

Contigs at least 50 bp in length were then compared to the NCBI non-redundant nucleotide collection (as of October 31, 2018) by **megablast** on the NCBI server with default parameters. Contigs with a detected similarity to known sequences in the collection were annotated with phylogenetic information (see Table 2) using the NCBI "Taxonomy" database.

## Code availability

Source code, detailed instructions, and intermediary data files are accessible on GitHub (https://github.com/HKeyHKey/Pinzon\_et\_al\_2018) as well as on https://www.igh.cnrs.fr/en/research/departments/genetics-development/ systemic-impact-of-small-regulatory-rnas/165-computer-programs.

## Data availability

Deep-sequencing data has been deposited at NCBI's Short Read Archive under BioProject accession #PRJNA419760 (for Small RNA-Seq) and BioSample accession #SAMN09381006 and SAMN09381007 (for adult RNA-Seq). Sequences of the re-sequenced *B. lanceolatum* BL09945 locus have been deposited at GenBank under accession #MH261373 and #MH261374.

# Results

## A sporadic phylogenetic distribution of RdRP genes

Previous analyses showed that a few animal genomes contain candidate RdRP genes [28, 31, 34, 47]. Rapid development of sequencing methods recently made many animal genomes available, allowing a more complete coverage of the phylogenetic tree. A systematic search for RdRP candidates (including every known viral or eukaryotic RdRP family) in 538 predicted metazoan proteomes confirms that animal species possessing RdRPs are unevenly scattered in the phylogenetic tree, but they are much more abundant than previously thought: we identified 98 metazoan species with convincing eukaryotic RdRP genes (see Figure 1A). Most RdRPs identified in animal

predicted proteomes belong to the eukaryotic RdRP family, but 3 species (the Enoplea 192 Trichinella murrelli, the Crustacea Daphnia magna and the Mesozoa Intoshia linei) 193 possess RdRP genes belonging to various viral RdRP families (in green, dark blue and 194 light blue on Figure 1A), which were probably acquired by horizontal transfer from 195 viruses. Most sequenced nematode species appear to possess RdRP genes. But in 196 addition, many other animal species are equipped with eukaryotic RdRP genes, even 197 among insects (the Diptera *Clunio marinus* and *Rhagoletis zephyria*), where RdRPs 198 were believed to be absent [47, 48]. 199

Fig 1. Phylogenetic distribution of RdRP genes in metazoans. A. Proteome sequences from 538 metazoans were screened for potential RdRPs. For each clade indicated on the right edge, *n* is the number of species analyzed in the clade, and piecharts indicate the proportion of species possessing RdRP genes (with each RdRP family represented by one piechart, according to the color code given at the top left). B. An HMMer search identifies 6 candidate RdRPs in the predicted *Branchiostoma lanceolatum* proteome. Only 2 candidates have a complete RdRP domain (represented by a red bar with round ends; note that apparent domain truncations may be due to defective proteome prediction). A white star indicates that every catalytic amino acid is present. Candidate BL02069 also possesses an additional known domain, AAA\_12 (in yellow).

Our observation of eukaryotic family RdRPs in numerous animal clades therefore 200 prompted us to revisit the evolutionary history of animal RdRPs: eukaryotic RdRPs 201 were probably present in the last ancestors for many animal clades (including insects, 202 mollusks, deuterostomes) and they were subsequently lost independently in most insects, 203 mollusks and deuterostomes. It has been recently shown that the last ancestor of 204 arthropods possessed an RdRP, which was subsequently lost in some lineages [47]: that 205 result appears to be generalizable to a large diversity of animal clades. The apparent 206 absence of RdRPs in some species may be due to genome incompleteness, or to defective 207 proteome prediction. Excluding species with low numbers of long predicted proteins ( $\geq$ 208 500 or 1,000 amino acids) indeed eliminates a few dubious proteomes, but the resulting 209 distribution of RdRPs in the phylogenetic tree is only marginally affected, and still 210 suggests multiple recent RdRP losses in diverse lineages (see Supplementary Fig. S1). 211

Alternatively to multiple gene losses, such a sporadic phylogenetic distribution could 212 be due to frequent horizontal transfer of RdRP genes in animals. In order to assess 213 these two possibilities, it is important to better understand the evolution of metazoan 214 RdRPs in the context of the whole eukaryotic RdRP family. We therefore used 215 sequences found in all eukaryotic groups for phylogenetic tree reconstruction. The 216 supports for deep branching are low and do not allow us to propose a complete 217 evolutionary history scenario of the whole eukaryotic RdRP family (see Figure 2A). 218 However, metazoan sequences are forming three different groups, which were named 219 RdRP  $\alpha$ ,  $\beta$  and  $\gamma$  according to the pre-existing nomenclature [31], and their position in 220 relation to non-metazoan eukaryotic sequences does not support an origin through 221 horizontal gene transfer. The only data that would support horizontal gene transfer 222 pertains to the metazoan sequences of the RdRP  $\beta$  group (see Figure 2C). Indeed, 223 sequences of stramenopiles and a fungus belonging to parasitic species are embedded in 224 this clade. For the RdRP  $\alpha$  and  $\gamma$  groups, the phylogeny strongly suggests that they 225 derive from at least two genes already present in the common ancestor of cnidarians and 226 bilaterians and that the scarcity of RdRP presence in metazoans would be the result of 227 many secondary gene losses. Even the Strigamia maritima RdRP was probably not 228 acquired by a recent horizontal transfer from a fungus, as has been proposed [47]: when 229 assessed against a large number of eukaryotic RdRPs, the S. maritima sequence clearly 230 clusters within metazoan  $\gamma$  RdRP sequences. In summary, we conclude that RdRPs 231 were present in the last ancestors of many animal clades, and they were recently lost independently in diverse lineages.

Fig 2. Eukaryotic RdRP phylogeny supports the vertical transfer scenario. Bayesian phylogenetic tree of the eukaryotic RdRP family.  $\alpha$ ,  $\beta$  and  $\gamma$  clades of eukaryotic RdRPs have been defined by [31]. Sectors highlighted in grey are detailed in panels B, C and D for clarity. Scale bar: 0.4 amino acid substitution per position. Posterior probability values are indicated for each node in panels B–D.

### Experimental search for RdRP products in *Branchiostoma*

In an attempt to probe the functional conservation of RdRP-mediated RNAi amplification among metazoans, we decided to search for secondary siRNAs in an organism where RdRP candidates could be found, while being distantly related to C. elegans. We reasoned that endogenous RNAi may act as a gene regulator during development or as an anti-pathogen response. Thus siRNAs are more likely to be detected if several developmental stages are probed, and if the analyzed specimens are gathered in a natural ecosystem, where they are naturally challenged by pathogens. From these considerations it appears that the most appropriate organism is a cephalochordate species, Branchiostoma lanceolatum [49]. In good agreement with the known scarcity of gene loss in that lineage [50], cephalochordates also constitute the only bilaterian clade for which both RdRP  $\alpha$  and  $\gamma$  sequences can be found, thus increasing the chances of observing RNAi amplification despite the diversification of eukaryotic RdRPs into three groups. According to our HMMer-based search, the B. lanceolatum genome encodes 6 candidate RdRPs, three of which containing an intact active site DbDGD (with b representing a bulky amino acid; [51]) (see Figure 1B). The current B. lanceolatum genome assembly contains a direct 1,657 bp repeat in one of the 6 RdRP genes, named BL09945. This long duplication appears to be an assembly artifact: we cloned and re-sequenced that locus and identified two alleles (with a synonymous mutation on the 505th codon; deposited at GenBank under accession numbers MH261373 and MH261374), and none of them contained the repeat. In subsequent analyses, we thus used a corrected version of that locus, where the 1,657 bp duplication is removed.

In most metazoan species, siRNAs (as well as miRNAs) bear a 5' monophosphate and a 3' hydroxyl [52,53]. The only known exceptions are "22G" secondary siRNAs in nematodes (they bear a 5' triphosphate; [20]), which may be primary polymerization products by an RdRP; Ago2-loaded siRNAs and miRNA in *Drosophila*, which are 3'-methylated on their 2' oxygen after loading on Ago2 and unwinding [54,55]; and a subset of "26G" secondary siRNAs in nematodes (those which are loaded on the ERGO-1 Argonaute protein), which also bear a 2'-O-methyl on their 3' end [56–58].

In order to detect small RNAs with any number of 5' phosphates, bearing either an 264 unmodified or a methylated 3' end, we prepared multiple Small RNA-Seq libraries (see 265 Figure 3A). Total RNA was extracted from various embryonic stages: gastrula (8 hours 266 post-fertilization, hpf), early neurula (15 hpf), premouth neurula (36 hpf) and larvae 267 (60 hpf), as well as from adult male and female specimens collected from their natural 268 ecosystem. Small (18 to 30 nt long) RNAs were gel-purified, then Small RNA-Seq 269 libraries were prepared using either the standard Small RNA-Seq protocol (which 270 detects 5' monophosphorylated small RNAs, whether they bear a 3' methylation or not; 271 "Library #1"); or by oxidizing small RNAs with NaIO<sub>4</sub> in the presence of H<sub>3</sub>BO<sub>3</sub> prior 272 to library preparation (such treatment renders unmodified 3' RNAs non-ligatable, hence 273 undetectable by deep-sequencing; [59]; "Library #2"); or by treating small RNAs with 274 the Terminator exonuclease (which degrades 5' monophosphorylated RNAs) then with 275

phosphatase then T4 PNK (to convert 5' polyphosphorylated RNAs and 5' hydroxyl 276 RNAs into monophosphorylated RNAs, suitable for Small RNA-Seq library preparation; 277 "Library #3"); or by a combination of both treatments (to detect only small RNAs 278 bearing a 5' polyphosphate or a 5' hydroxyl, and a 3' modification; "Library #4"). If 279 the same experiments were performed in classical animal model organisms, such as 280 Drosophila, nematodes and vertebrates (where miRNAs are essentially 5' 281 monophosphorylated and 3'-unmodified, and piRNAs are 5' monophosphorylated and 282 3'-methylated), miRNAs would be expected to be detected in Libraries #1 and piRNAs, 283 in Libraries #1 and 2. Nematode "22G" siRNAs would be detected in Libraries #3. 284

Fig 3. Detection of *B. lanceolatum* small RNAs. Four libraries were prepared for each biological sample, to detect small RNAs bearing either a single 5' phosphate (Libraries #1 and 2) or any other number of phosphates (including zero; Libraries #3 and 4), and either a 2'-OH and 3'-OH 3' end (Libraries #1 and 3), or a protected (*e.g.*, 2'-O-methylated) 3' end (Libraries #2 and 4). hpf: hours post fertilization. B. Size distribution of genome-matching adult male small RNAs, excluding reads that match abundant non-coding RNAs (rRNAs, tRNAs, snRNAs, snoRNAs or scaRNAs). Read numbers are normalized by the total number of genome-matching reads (including <18 nt and >30 nt reads) that do not match abundant non-coding RNAs, and expressed as *parts per million* (ppm). C. Size distribution of adult male small RNAs matching pre-miRNA hairpins in the sense (blue) or antisense (red) orientation.

In the course of library preparation, it appeared that Libraries #4 contained very little ligated material, suggesting that small RNAs with a 3' modification as well as  $n \ge 0$  (with  $n \ne 1$ ) phosphates on their 5' end, are very rare in *Branchiostoma* regardless of developmental stage. This observation was confirmed by the annotation of the sequenced reads: most reads in Libraries #4 did not map on the *B. lanceolatum* genome, probably resulting from contaminating nucleic acids (see Supplementary Fig. S2).

In Libraries #1 in each developmental stage, most *Branchiostoma* small RNA reads fall in the 18–30 nt range as expected. Other libraries tend to be heavily contaminated with shorter or longer reads, and 18–30 nt reads only constitute a small fraction of the sequenced RNAs (see Figure 3B for adult male libraries; see Supplementary File S1 section 1 for other developmental stages). miRNA loci have been annotated in two other cephalochordate species, B. floridae and B. belcheri (156 pre-miRNA hairpins for B. floridae and 118 for B. belcheri in miRBase v. 22). We identified the B. lanceolatum orthologous loci for annotated pre-miRNA hairpins from B. floridae or B. belcheri. Mapping our libraries on that database allowed us to identify candidate *B. lanceolatum* miRNAs. These RNAs are essentially detected in our Libraries #1, implying that, like in most other metazoans, B. lanceolatum miRNAs are mostly 22 nt long, they bear a 5 monophosphate and no 3' methylation (see Figure 3C for adult male libraries; see Supplementary File S1 section 2 for other developmental stages). Among the B. lanceolatum loci homologous to known B. floridae or B. belcheri pre-miRNA loci, 56 exhibit the classical secondary structure and small RNA coverage pattern of pre-miRNAs (*i.e.*, a stable unbranched hairpin generating mostly 21–23 nt long RNAs from its arms). These 56 loci, the sequences of the miRNAs they produce, and their expression profile during development, are shown in Supplementary Table S1.

# No evidence of RdRP-based siRNA amplification in *Branchiostoma*.

In an attempt to detect siRNAs, we excluded every sense pre-miRNA-matching read and searched for distinctive siRNA features in the remaining small RNA populations.

> Whether RdRPs generate long antisense RNAs which anneal to sense RNAs to form a substrate for Dicer, or whether they polymerize directly short single-stranded RNAs which are loaded on an Argonaute protein, the involvement of RdRPs in RNAi should result in the accumulation of antisense small RNAs for specific target genes. These small RNAs should exhibit characteristic features:

- a narrow size distribution (imposed either by the geometry of the Dicer protein, or by the processivity of the RdRP [24,60]; the length of Argonaute-loaded RNAs can also be further refined by exonucleolytic trimming of 3<sup>'</sup> ends protruding from Argonaute [22,61–65]);
- and possibly a sequence bias on their 5' end; it is remarkable that the known classes of RdRP products in metazoans (nematode 22G and 26G RNAs) both display a strong bias for a guanidine at their 5' end. RNA polymerases in general tend to initiate polymerization on a purine nucleotide [66–72] and it can be expected that primary RdRP products bear either a 5'A or a 5'G. Of note: loading on an Argonaute may also impose a constraint on the identity of the 5' nucleotide, because of a sequence preference of either the Argonaute protein or its loading machinery [73–78].

The analysis of transcriptome-matching, non-pre-miRNA-matching small RNAs does 331 not indicate that such small RNAs exist in *Branchiostoma* (see Figure 4 for adult males, 332 and Supplementary File S1, section 3, for the complete data set). In early embryos, 5 333 monophosphorylated small RNAs exhibit the typical size distribution and sequence 334 biases of piRNA-rich samples: a heterogeneous class of 23 to 30 nt long RNAs. Most of 335 them tend to bear a 5<sup>'</sup> uridine, but 23 to 26 nt long RNAs in the sense orientation to 336 annotated transcripts tend to have an adenosine at position 10 (especially when the 337 matched transcript exhibits a long ORF; see Supplementary File S1, section 4). 338 Vertebrate and *Drosophila* piRNAs display very similar size profiles and sequence 339 biases [79–85]. These 23–30 nt long RNAs may thus constitute the Branchiostoma 340 piRNAs, but surprisingly, they do not appear to bear a 2'-O-methylation on their 3' 341 end (see Discussion). Note that piRNAs appear to be mostly restricted to the germ line 342 and gonadal somatic cells in other model organisms. But they are so abundant in 343 piRNA-expressing cells, and so abundantly maternally deposited in fertilized eggs, that 344 they can still be readily detected in embryonic or adult whole-body small RNA 345 samples [25, 86–90]. It is thus not surprising to observe piRNA candidates in our 346 Branchiostoma whole-body Small RNA-Seq libraries. 347

Fig 4. Size distribution and sequence logos for transcriptome-matching small RNAs in adult males. See Supplementary File S1, section 3, for the other developmental stages. A: Library #1, B: Library #2, C: Library #3, D: Library #4. Numbers of reads are expressed as *parts per million* (ppm) after normalization to the total number of genome-matching reads that do not match abundant non-coding RNAs. For each orientation (sense or antisense-transcriptome-matching reads), a logo analysis was performed on each size class (18 to 30 nt long RNAs).

In summary, transcriptome-matching small RNAs in our *Branchiostoma* libraries 348 contain miRNA and piRNA candidates, but they do not contain any obvious class of 349 presumptive secondary siRNAs that would exhibit a precise size distribution, and 350 possibly a 5' nucleotide bias. If Branchiostoma RdRPs generated secondary siRNAs by 351 polymerizing mature short antisense RNAs (similarly to nematode 22G RNAs according 352 to the prevalent model), then such hypothetical siRNAs should be detected in 353 libraries #3. If Branchiostoma RdRPs generated long antisense RNAs, that would 354 anneal to sense RNAs to produce a Dicer substrate (similarly to fungus and plant 355

319

326

327

328

329

RdRP-derived siRNAs according to the prevalent model), then secondary siRNAs should be detected in libraries #1. As we did not observe candidate siRNA populations in either libraries #1 or 3, our data seem to rule out the existence of secondary siRNAs in *Branchiostoma*, regardless of the mechanistical involvement of RdRPs in their production.

One could imagine that transcriptome-matching siRNAs were missed in our analysis, because of issues with the *Branchiostoma* transcriptome assembly. It is also conceivable that siRNAs exist in *Branchiostoma*, but they do not match its genome or transcriptome (they could match pathogen genomes, for example if they contribute to an anti-viral immunity). We therefore analyzed other potential siRNA types: (i) genome-matching reads that do not match abundant non-coding RNAs (rRNAs, tRNAs, snRNAs, snoRNAs or scaRNAs); (ii) reads that match transcripts exhibiting long ( $\geq 100$  codons, initiating on one of the three 5'-most AUG codons) open reading frames; (iii) reads that do not match the *Branchiostoma* genome, nor its transcriptome (potential siRNAs derived from pathogens). Once again, none of these analyses revealed any siRNA population in *Branchiostoma* (see detailed results in Supplementary File S1, sections 1, 4 and 5). This is in striking contrast to *Cænorhabditis elegans*, where antisense transcriptome-matching siRNAs (mostly 22 nt long, starting with a G) are easily detectable (see Supplementary File S1, section 6, for our analysis of publicly available *C. elegans* data; [22]).

#### Branchiostoma RdRP activity is not clearly detected

Our failure to detect siRNA candidates may simply be due to the fact that they are poorly abundant in the analyzed developmental stages. In order to enrich for small RNA populations derived from RdRP activity, and exclude all the other types of small RNAs, we considered small RNAs mapping on exon-exon junctions in the antisense orientation. The antisense sequence of the splicing donor (GU) and acceptor (AG) sites does not constitute a donor/acceptor pair itself, implying that any RNA antisense to a spliced RNA must have originated from the action of an RdRP on the spliced RNA — it cannot derive from the splicing of an RNA transcribed in the antisense orientation.

We therefore selected all the 18–30 nt RNA reads that map on exon-exon junctions in the annotated transcriptome, and fail to map on the genome. Such reads map almost exclusively in the sense orientation (see Table 1). When focusing on the developmental stage where some transcripts exhibit the highest observed numbers of antisense exon-exon junction reads (15 hpf embryos, for the transcripts of genes BL05604 and BL00515), it appears that these antisense junction reads are highly homogeneous in sequence (sharing the same 5' and 3' ends), they do not map perfectly on the spliced transcript (with 1 mismatch in each), and their total abundance remains very small (less than 10 raw reads per transcript in a given developmental stage) (see Supplementary Fig. S3). RdRP genes themselves appear to be developmentally regulated, with candidate RdRPs harboring intact active sites showing expression peaks at 8 and 18 hpf (see Supplementary Fig. S4).

It is formally possible that the few antisense exon-exon junction reads that we detected derive from an RNA polymerized by an RdRP. But their scarcity, as well as their extreme sequence homogeneity, suggests that they rather come from other sources (*e.g.*, DNA-dependent RNA polymerization, either from a *Branchiostoma* genomic locus or from a non-*Branchiostoma* contaminant) and map fortuitously on the BL05604 or BL00515 spliced transcript sequences. We note that *C. elegans* secondary siRNAs are highly diverse in sequence, and even low-throughput sequencing identifies antisense reads mapping on distinct exon-exon junctions [20]. We thus tend to attribute our observation of rare antisense exon-exon junction small RNAs to rare contaminants or sequencing errors, rather than to genuine RNA-dependent RNA polymerization in

	TT71 1 , • · ·	

Genes were sorted according to the total number of small RNA reads mapping on their exon-exon junctions in our pooled 24 Small RNA-Seq libraries. Numbers of mapped reads were normalized by the total number of genome-matching reads that do not match abundant non-coding RNAs, and expressed as *parts per million* (ppm). Top part: statistics for the whole transcriptome. Bottom part: only the top 10 genes in terms of sense-matching junction reads (left half of the table) or antisense-matching junction reads (right half of the table) are shown.

#### Branchiostoma.

# Candidate *Branchiostoma* pathogens do not appear to be targeted by RNAi

In various other organisms, RNAi participates in the defence against pathogens 410 (reviewed in [91]). Pathogen-specific siRNAs may exist in *Branchiostoma*, and they may 411 have been too poorly abundant to be detected in our analyses of extragenomic, 412 extratranscriptomic reads (see Supplementary File S1, section 5). We thus decided to 413 interrogate specifically the populations of small RNAs mapping on *Branchiostoma* 414 pathogen genomes. Several pathogenic bacteria (Staphylococcus aureus, Vibrio 415 alginolyticus and Vibrio anguillarum; [92,93]) have been described in various 416 Branchiostoma species. We asked whether RNAi could target those pathogens in vivo. 417 Focusing on the small RNA reads that do not map on the *Branchiostoma* genome or 418 transcriptome, we observed large numbers of small RNAs deriving from these three 419 bacterial genomes, indicating that the analyzed *Branchiostoma* specimens were in 420 contact with those pathogens (after excluding reads that map simultaneously on 2 or 3 421 of these bacterial genomes, we detected 1,457,122 S. aureus-specific reads, 113,398 422 V. alginolyticus-specific reads and 103,153 V. anguillarum-specific reads in the pooled 423 24 Small RNA-Seq libraries; for reference: there are 125,550,314 Branchiostoma 424 genome-matching reads in the pooled libraries). Small RNAs mapping on these 425 pathogenic bacterial genomes do not display any obvious size distribution or sequence 426 bias, thus suggesting that they constitute degradation products from longer bacterial 427 RNAs rather than siRNAs (see Supplementary File S1, sections 7–9). 428

Our analyzed Branchiostoma specimens may also have been challenged by429yet-unknown pathogens. Pooling every read that does not map on the Branchiostoma430genome or transcriptome, across all 24 Small RNA-Seq libraries, offers the opportunity431to reconstruct genomic contigs for the most abundant non-Branchiostoma sequences. In432

407

408

> total, we collected 23,557,012 such extragenomic, extratranscriptomic reads. 42,946 433 contigs at least 50 bp long could be assembled from these reads using **velvet** [45]. Of 434 these, 4,804 contigs could be annotated by homology search (see Table 2): 291 appear 435 to match the *Branchiostoma* genome, and the reads supporting these contigs had 436 probably failed to map properly on the genome because of sequencing errors or sequence 437 polymorphism. 438

 Table 2. Annotation of reconstructed genomic contigs assembled from extragenomic, extratranscriptomic

 Small RNA-Seq reads.

Contig origin	Number of contigs	Contig length (bp) (mean $\pm$ st. dev.)
Total	42,946	$60.1 \ (\pm 10.7)$
Prokaryotes	3,552	$65.9 (\pm 18.3)$
Fungi	724	$66.9 (\pm 18.9)$
Viridiplantae	67	$63.3 (\pm 10.3)$
non-Branchiostoma Metazoans	131	$62.8 (\pm 12.3)$
Branchiostoma	291	$64.4 (\pm 13.8)$
Prokaryotic viruses	35	$81.6 (\pm 28.5)$
Eukaryotic viruses	4	$63.8 (\pm 5.91)$
Ambiguous, poorly described and others	38,142	$59.3 (\pm 8.92)$

After assembling extragenomic, extratranscriptomic reads from all 24 libraries, contigs longer than 50 bp were annotated by a **blast** search on the NCBI non-redundant nucleic acid database.

We screened these contigs for potential *Branchiostoma* pathogens, which could be targeted by RNAi. Detected prokaryotic, fungal or non-*Branchiostoma* metazoan sequences may derive from symbiotic or commensal species rather than actual pathogens. Our analyzed adult specimens were collected from the natural environment, where unrelated organisms are expected to contaminate the samples; and our analyzed embryos were produced from gametes collected in non-sterile sea water. Following spawning, these gametes transit through the "atrium" (an open body cavity that putatively hosts various micro-organisms): so *in vitro*-fertilized embryos are also likely to be contaminated with non-pathogenic non-*Branchiostoma* species.

But we also observed several viral contigs, including 4 contigs from eukaryotic viruses. Three of them are matched by low numbers of small RNA reads, but the last one (a contig matching the *Acanthocystis turfacea* Chlorella virus 1 genome) is covered with high read counts in various developmental stages (see Supplementary Fig. S5). That virus is known to infect endosymbiotic algae of the protist *Acanthocystis turfacea*, and some reports suggest that it may also infect mammalian hosts [94], suggesting a broad tropism. Though still disputed [95,96], this observation could suggest that *Branchiostoma* may also be sensitive to that virus. Yet, for this potential pathogen too, detected small RNA reads fail to display any size or sequence bias: they do not appear to be siRNAs (see Supplementary File S1, section 10).

Finally, we considered the possibility that some of the 38,142 un-annotated extragenomic contigs (see Table 2) may originate from unknown pathogens. We selected the 5 contigs displaying the highest read coverage (more than 200 ppm after pooling all 24 Small RNA-Seq libraries): small RNAs mapping on these hypothetical unknown pathogens also do not exhibit particular size or sequence biases, arguing against their involvement in RNAi (see Supplementary File S1, sections 11–15).

Because unambiguous RdRP-derived small RNAs could not be detected with certainty despite our efforts, and because we did not observe any small RNA population with classical siRNA size or sequence bias, we conclude that *Branchiostoma* RdRP genes are not involved in RNAi.

November 28, 2018

## Discussion

In cellular organisms, the only known function for RdRPs is the generation of siRNAs or siRNA precursors. It is thus frequently assumed [32,47] or hypothesized [34] that animal RdRPs participate in RNAi. In particular, it has recently been proposed that arthropod RdRPs are required for RNAi amplification, and arthropod species devoid of RdRPs may rather generate siRNA precursors through bidirectional transcription [47]. While this hypothesis would provide an elegant explanation to the sporadicity of RdRP gene distribution in the phylogenetic tree, the provided evidence remains disputable: it has been proposed that a high ratio of antisense over sense RNA is diagnostic of bidirectional transcription, yet it remains to be explained why RNA-dependent RNA polymerization would produce less steady-state antisense RNA than DNA-dependent polymerization.

Branchiostoma 5' monophosphorylated small RNAs do not appear to bear a 2'-O-methyl on their 3' end: Libraries #2 contain few genome-matching sequences, and their size distribution suggests they are mostly constituted of contaminating RNA fragments rather than miRNAs, piRNAs or siRNAs. In every animal model studied so far, piRNAs were shown to bear a methylated 3' end [25,56–58,85,87,97–99]. The enzyme responsible for piRNA methylation, Hen1 (also known as Pimet in Drosophila, HENN-1 in nematodes), has been identified in Drosophila, mouse, zebrafish and nematodes [55–58,100–102]. In order to determine whether the absence of piRNA methylation in Branchiostoma could be due to an absence of the Hen1 enzyme, we searched for Hen1 orthologs in the predicted Branchiostoma proteome. Our HMMer search identified a candidate, BL03504. Its putative methyl-transferase domain contains every known important amino acid for Hen1 activity according to [103] (see Supplementary Fig. S6), suggesting that it is functional. Further studies will be required to investigate the biological activity of that putative enzyme, and to understand why it does not methylate Branchiostoma piRNAs.

Focusing on small RNA reads mapping on exon-exon junctions in the antisense orientation, we did not observe convincing evidence of RdRP activity in *Branchiostoma*. Even if RdRPs do not participate in RNAi, it could have been anticipated that Small RNA-Seq libraries could capture short degradation products of RdRP-polymerized long RNAs. This observation raises the possibility that the *Branchiostoma* RdRP genes do not express any active RdRP. At least these genes are transcribed: analysis of gene expression in long RNA-Seq data [43] shows a dynamic regulation, especially for the three genes with an intact predicted active site (see Supplementary Fig. S4).

One could hypothesize that these RdRPs do not play any biological function. Yet at least two of them, BL02069 and BL23385, possess a full-length RdRP domain with a preserved catalytic site. The conservation of these two intact genes suggests that they are functionally important. It can therefore be speculated that *Branchiostoma* RdRPs play a biological role, which is unrelated to RNAi. Such a function may involve the generation of double-stranded RNA (formed by the hybridization of template RNA with the RdRP product), but it could also involve single-stranded RdRP products. Future work will be needed to identify the biological functionality of these enzymes. We also note that the fungus *Aspergillus nidulans*, whose genome encodes two RdRPs with a conserved active site, does not require any of those for RNAi [104].

Animal RdRPs thus constitute an evolutionary enigma: not only have they been frequently lost independently in numerous animal lineages, but even in the clades where they have been conserved, their biological function seems to be variable. While RNAi is an ancient gene regulation pathway [1], involving the deeply conserved Argonaute and Dicer protein families, the role of RdRPs in RNAi appears to be accessory. Even though RdRPs are strictly required for RNAi in very diverse extant clades (ranging from nematodes to plants), it would be misleading to assume that RNAi constitutes their

Branchiostoma lanceolatum Hen1 candidate (only the part of the alignment spanning 564 amino acids 661–939 of the Arabidopsis protein is shown). Alignment was performed 565 with **t-coffee** (version 11.00.8cbe486); other alignment programs (Clustal Omega 566 v.1.2.4, t-coffee v.8.93, Kalign v.2.03, MAFFT v.7.215, but not muscle 567 **v.3.8.31**) give the same main result: amino acids and amino acid combinations required 568 for Hen1 catalytic activity [103] are conserved in the Branchiostoma candidate. Amino 569 acids boxed in red were shown to be essential for *Arabodipsis* Hen1 activity; in orange: 570 amino acids whose absence affects Hen1 activity without abolishing it entirely. Amino 571 acid numbering is based on the Arabidopsis sequence. 572

Size distribution and logo analyses of various small RNA classes. File S1. 573 (file 'Supplementary\_Data.pdf') For each of the following classes, small RNA populations 574 were analyzed as in Figure 3B, 3C and 4: reads matching the *B. lanceolatum* genome 575 without matching abundant non-coding RNAs (section 1); reads matching 576 B. lanceolatum pre-miRNA hairpins (section 2); reads matching the B. lanceolatum 577 transcriptome without matching pre-miRNAs or abundant non-coding RNAs (section 3); 578 reads matching *B. lanceolatum* mRNAs with long ORFs (section 4); reads not matching 579 the B. lanceolatum genome or transcriptome (section 5); C. elegans small RNAs cloned 580 with a procedure detecting 5' mono- and polyphosphorylated RNAs [22] (section 6); 581 reads not matching the *B. lanceolatum* genome or transcriptome, and matching the 582 Staphylococcus aureus genome (section 7); reads not matching the B. lanceolatum 583 genome or transcriptome, and matching the *Vibrio alginolyticus* genome (section 8); 584 reads not matching the *B. lanceolatum* genome or transcriptome, and matching the 585 Vibrio anguillarum genome (section 9); reads not matching the B. lanceolatum genome 586 or transcriptome, and matching the Acanthocystis turfacea Chlorella virus 1 (ATCV1) 587 genome (section 10); reads not matching the *B. lanceolatum* genome or transcriptome, 588 and matching non-Branchiostoma contig #18690 (covered with 1,982.33 ppm small 589 RNA reads across all 24 libraries) (section 11); reads not matching the *B. lanceolatum* 590 genome or transcriptome, and matching non-Branchiostoma contig #7601 (covered with 591 1,534.35 ppm small RNA reads across all 24 libraries) (section 12); reads not matching 592 the B. lanceolatum genome or transcriptome, and matching non-Branchiostoma 593 contig #38312 (covered with 236.037 ppm small RNA reads across all 24 libraries) 594 (section 13); reads not matching the *B. lanceolatum* genome or transcriptome, and 595 matching non-Branchiostoma contig #3365 (covered with 223.535 ppm small RNA 596 reads across all 24 libraries) (section 14); reads not matching the *B. lanceolatum* 597 genome or transcriptome, and matching non-Branchiostoma contig #10883 (covered 598 with 205.859 ppm small RNA reads across all 24 libraries) (section 15). 599

 
 Table S1
 Detection of conserved miRNAs. (file 'Supplementary\_Table\_1.pdf')
 600 Branchiostoma lanceolatum orthologs for B. floridae or B. belcheri pre-miRNA hairpins 601 (as described in miRBase v.22) were screened for their predicted secondary structure and 602 the abundance of the small RNAs they generate. Only those hairpins that comply with 603 these rules are shown in this table. First column: name of orthologous pre-miRNA, and 604 genomic coordinates in *B. lanceolatum*. Second column: sequences of the major forms of 605 the 5' arm and 3' arm miRNAs, if expressed at  $\geq 10$  ppm in at least one developmental 606 stage (miRNAs that do not meet that criterion are flagged "low abundance"). Third 607 column: abundance of the 5' arm and 3' arm miRNAs in Libraries #1 along 608 development. Embryonic stages contain mixed sexes; adult stages are shown in blue and 609 pink for males and females, respectively. Trimming (up to 3 nt) and templated 610 extension of miRNA 3' ends were considered when measuring read counts. 611

# Acknowledgments

The authors are grateful to Dr. Darryl Conte for helpful discussions and to Julie 613 Claycomb, Kazufumi Mochizuki and Phillip D. Zamore for critical reading of the 614 manuscript. We thank the *B. lanceolatum* genome consortium for the assembly and 615 annotation of the *B. lanceolatum* genome, Dr. Manuel Irimia for assistance in 616 transcriptomics analyses, and Dr. Ferdinand Marlétaz for sharing unpublished data. 617 This research was supported by an ATIP-Avenir grant from CNRS and Sanofi (to H.S.) 618 and a post-doctoral fellowship from La Ligue contre le cancer (to N.P.). H.E.'s 619 laboratory was supported by the CNRS and the ANR16-CE12-0008-01 and S.B. by the 620 Institut Universitaire de France. We thank the MGX sequencing facility (Biocampus 621 Montpellier, CNRS, INSERM, Univ. Montpellier, Montpellier, France). MGX 622 acknowledges financial support from France Génomique National infrastructure, funded 623 as part of the "Investissement d'avenir" program managed by Agence Nationale pour la 624 Recherche (contract ANR-10-INBS-09). 625
