16

17 **1 INTRODUCTION**

18 During the perinatal period, the brain matures and is rapidly wired(Semple et al. 2013),
19 rendering it particularly vulnerable to negative life experiences that might lastingly impact
20 brain function and behavior(Levine 2005). This may contribute to the well-established
21 observation that exposure to adverse conditions during childhood is a major risk factor for
22 the later development of psychopathologies(Teicher et al. 2016), including schizophrenia and
23 substance abuse(Agid et al. 1999; Enoch 2011; Dube et al. 2003; Scheller-Gilkey et al. 2002).

24 Prevailing evidence highlights that the dopamine (DA) system may be a prime candidate in
25 mediating the influence of adverse events early in life on vulnerability to
26 psychopathology(Gatzke-Kopp 2011). The DA system develops early during the embryonic
27 period, matures throughout adolescence, and forms stable patterns during young
28 adulthood(Money and Stanwood 2013). This prolonged development provides an extensive
29 window of time in which adverse conditions early in life can tip the balance towards
30 dysfunction(Money and Stanwood 2013). Indeed, alterations in this system have been
31 consistently associated with mental disorders (for a review: (Money and Stanwood 2013)). For
32 example, genetic variations of the DA degradation enzyme COMT are associated with
33 schizophrenia and bipolar disorder as well as an increased risk for psychosis, autism and
34 anxiety(Money and Stanwood 2013). In line, the DA receptor 2 is a major target for
35 antipsychotics.

36 Overall, the associative studies in humans have led to the assumption that childhood
37 adversities result in developmental alterations of the dopaminergic system. To investigate
38 causality, preclinical studies using animal models have adopted behavioral early life stress
39 (ELS) paradigms to mimic negative childhood conditions, aiming to understand the

40 neurobiological substrate by which ELS adds to the development of DA system dysfunction.
41 Although extensive, the existing literature is quite heterogeneous: it uses disparate models
42 and outcome measures, and each study focuses on only a limited number of variables;
43 moreover, preclinical studies are frequently underpowered(Button et al. 2013). The resulting
44 findings are rather incoherent and difficult to interpret. This limitation hinders our
45 understanding of the entire biological system and its development, and delays translational
46 applicability.

47 To overcome these limitations, we performed a meta-analysis, a powerful method still
48 sparsely applied to preclinical research allowing to systematically synthesize the scientific
49 knowledge of a specific topic. Recent advances in the field of statistics such as the 3-level
50 approach (Cheung 2014b; Assink and Wibbelink 2016) along with their implementation in R
51 packages(Viechtbauer 2010; Cheung 2014a) now enable researchers to use more
52 sophisticated and robust methodology when analyzing meta-data. This method allows to
53 include multiple data-points from a single study (nesting), without necessarily knowing their
54 (often unreported) covariance. Ultimately, this substantially increases the flexibility of meta-
55 analysis applications and improves the validity of the conclusions drawn.

56 Here, we aimed to investigate whether preclinical studies support an effect of ELS on
57 dopaminergic signaling. We included diverse types and timings of ELS models(Fig 1), and we
58 operationalized the dopaminergic system by quantifying several biochemical markers in
59 mice and rats(Fig 2), across brain areas(Fig 3), considering possible confounders.

60 We determined whether the quality of the studies affected the estimation of the results. To
61 make our knowledge readily available to others, we organized all information in a freely
62 accessible open-source dataset and created a user-friendly web-app as a tool to guide future

63 (pre)clinical research (e.g. power analysis calculation), thereby avoiding unnecessary
64 replication and limit animal experimentation.

65

66 **2 MATERIALS AND METHODS**

67 The review adhered to SYRCLE (Systematic Review Center for Laboratory animal
68 Experimentation) guidelines for protocol(De Vries et al. 2015), search strategy(Leenaars et al.
69 2012), and risk of bias assessment(Hooijmans et al. 2014).

70 **2.1 THEORETICAL DEFINITIONS AND ASSUMPTIONS**

71 We defined as "*individual comparison*" each test performed within a published study between
72 a control group and an experimental group with a history of ELS. As often occurs in
73 experimental studies(Aarts et al. 2014), multiple outcomes (*individual comparisons*) were
74 collected from the same groups of animals (*nesting*).

75 We defined as "*experiment*" the ensemble of outcome measures from the same animals.
76 According to this definition, each published study can report multiple experiments when
77 conducted on different sets of animals. Similarly, experiments conducted on different sets of
78 animals could potentially be reported in separate publications. For these reasons, we *nested*
79 multiple individual comparisons belonging to the same animals within the same experiments,
80 but considered *experiments* from the same publications as independent from each other.

81 **2.2 SEARCH STRATEGY**

82 A comprehensive literature search was conducted regarding *the effects of early life stress on*
83 *biochemical indicators of dopaminergic signaling* on February 14th 2017. The search string was
84 composed by the factors "dopamine", "early life stress" and "rodents" (Fig 1 and
85 supplementary appendix S1). The search was conducted on the electronic databases PubMed
86 (www.pubmed.com) and Web of Science (www.webofknowledge.com). For a flow chart of the
87 entire methodology, see Fig 4.

88

89 Studies' titles and abstracts were screened, and selected if the inclusion criteria were met
90 (supplementary Table S2-1). In case of doubt, the full text was inspected. Eligible studies were
91 evaluated by two independent reviewers (VB and RAS).

92

93 **2.3 STUDY CHARACTERISTICS**

94 **2.3.1 Selection and data extraction**

95 To limit subjectivity in the data gathering and entry process, data extracted from eligible
96 studies were recorded in a standardized database (doi:10.17632/9x9fc3v26k.1). The following
97 information was included: species, strain, sex, type and timing (relative to age) of the ELS
98 model, outcome, time (relative to age) of outcome, technique used for outcome, brain area
99 investigated, number of animals used, mean, standard deviation (SD) and standard error of
100 the mean (SEM). If only SEM was reported, SD was calculated as $SEM * \sqrt{n}$, where n = amount
101 of animals per group. If number of animals were reported as a range (e.g. 6-8 animals per
102 group), we used the mean of this number (e.g. 7 animals per group). If a single control group
103 was used to compare experimental groups in which ELS was induced with different models
104 (e.g. handling and maternal deprivation), the sample size of the control group was equally
105 divided as control for each experimental group (e.g. $n=10$ in not handled control becomes
106 $n=5$ for control of maternal deprivation and $n=5$ for control of handling)(Vesterinen et al.
107 2014).

108 When the data was not reported numerically in the publication, we contacted two authors
109 per manuscript. If no answer was received within three weeks and after a reminder, the

110 authors were considered not reachable. Only 5 out of 56 contacted authors replied to our
111 request. Given the low response rate, we estimated most of the data presented only in
112 graphs with *Ruler for Windows* (<https://a-ruler-for-windows.en.softonic.com/>). We tested the
113 accuracy of this method by comparing effect sizes calculated from either supplied data or
114 evaluated with the ruler, and verified that they were highly correlated ($R^2 = .74$,
115 supplementary Figure S2-1).

116 Concerning metabolites, some papers reported either concentrations, turnovers or both. In
117 97.5% of cases it was possible to calculate concentrations from turnovers with Pythagoras.
118 Since concentrations and turnovers are related to the same information (though not
119 identical), only concentrations were included in the analysis in order to avoid multi-
120 collinearity. Turnover data-points are available in the MaDEapp (*Meta-Analysis on Dopamine
121 and Early life stress*) for consultation.

122 **2.4 ASSESSMENT OF RISK OF BIAS IN INCLUDED STUDIES**

123 We used the SYRCLE tool to assess the risk of bias (supplementary Table S2-2)(Hooijmans et
124 al. 2014). The criteria are based on the possible presence of selection bias (items 1, 2 and 3),
125 performance bias (items 4 and 5), detection bias (items 7, 8, 9) and attrition bias (item 10).
126 Furthermore, we added the item "*quality of control*" (item 6) to the category performance
127 bias.

128 Since poor reporting of experimental details plays a role in heightening the quantified risk of
129 bias, lack of reporting was scored as *unclear* risk of bias.

130 For quantitative inclusion in the analysis, amount of potential bias was operationalized by
131 summing the risk of bias of each item according to the definition: "yes" = 0, "unclear" = 1,

132 "no" = 2. This produced a continuous variable of integer increment between 0 (no risk bias)
133 and 20 (maximum risk of bias), which was then scaled ($mean = 0$) to interpret the studies as
134 of average risk of bias.

135 **2.5 DATA SYNTHESIS AND STATISTICAL ANALYSIS**

136 **2.5.1 Effect size**

137 We estimated the effect size for each individual comparison with *escalc* (R package *metafor*)
138 as standardized mean difference with *Hedge's G* method, which includes a correction factor
139 for small sample sizes(Vesterinen et al. 2014).

140 **2.5.2 Study of heterogeneity**

141 Heterogeneity was tested with the Cochran Q-test(Moreira et al. 2016) and I^2
142 statistics(Cheung 2014b). Study of the distribution of variance was conducted for models
143 without moderators to determine how much variance could be attributed to differences
144 between effect sizes within experiments (level 2) and to differences between experiments
145 (level 3). Substantial distribution of heterogeneity at these levels further encouraged the use
146 of moderators.

147

148 **2.5.3 Model**

149 We used a 3-level mixed effect model, which accounts for the anticipated heterogeneity of
150 the studies as well as the dependency of effects within experiments. In our experimental
151 design, the 3 levels correspond to variance of effect size between 1) animals, 2) outcomes
152 and 3) experiments.

153 Since pre- and post-natal models act on different times of development that are particularly
154 disparate regarding the array of environmental factors, we considered them as different
155 datasets and consequently analyzed them separately.

156 Effect sizes were considered outliers if their z score was above +3.29 or below -
157 3.29(Tabachnick and Fidell 2013), and removed from the analysis.

158 Since we hypothesized that the effect of ELS on DA signaling may not be evident from an
159 overall estimate, we defined *a priori* possible moderators of this effect. These belonged to
160 two different categories: biological and technical. The biological moderators were: outcome
161 measure used (e.g. DA and metabolites), brain area investigated, sex, species, age as a
162 continuous variable, and whether the outcome was at a RNA level/protein level/functional
163 (referred to as *method of assessment*). Specific regions within the brain areas were
164 investigated only in subgroup analysis due to the limited amount of observations. We
165 considered the type of ELS model and amount of potential bias as technical moderators.
166 These moderators may not underlie a biological difference, but can nevertheless explain
167 heterogeneity across studies. The postnatal ELS model 'handling' has been reported
168 repeatedly to cause effects in the opposite direction to those induced by other ELS
169 models(Levine 2005). We therefore multiplied each calculated effect size for handling by -1
170 (Vesterinen et al. 2014), so that the overall estimate would be in the same direction. We
171 verified that the same conclusions would have been drawn if handling was excluded as a
172 model (supplementary Figure S2-2).

173 To avoid multicollinearity among moderators, we firstly assessed each biological moderator
174 univariately. We set the significance level at $p < .10$ to test whether a moderator significantly
175 reduced the previously quantified heterogeneity. A less restrictive p -value was chosen to

176 assure the inclusion of moderators that have a multivariate but not univariate effect(Hox
177 2010). Only interactions with at least 4 comparisons from 3 different publications from at
178 least two different laboratories were quantitatively assessed. This explains why some of the
179 keywords in our search string were not included in the final analysis (Fig 1).

180

181 **2.5.4 Subgroup analysis**

182 As the 3-level models revealed significant heterogeneity, we conducted subgroup analyses to
183 further investigate its source. In particular, we tested the influence of the technical
184 moderators (type of ELS model and amount of potential bias) as well as of the brain regions
185 within the brain areas previously described (Fig 3), in subsets of the dataset with sufficient
186 observations. For information on the type of ELS model used, please see supplementary
187 appendix S2-1.

188

189 **2.5.5 Sensitivity analysis and publication bias**

190 According to the standards of meta-analyses, we should investigate the robustness of our
191 effect sizes by performing analysis only on those studies that were blinded and randomized.
192 Unfortunately, the amount of blinded and randomized studies was insufficient to proceed
193 with this approach. As an alternative, we performed the analysis by including the amount of
194 potential bias as a moderator. The results of this sensitivity analysis should be interpreted as
195 the effects of ELS on biochemical markers of the dopaminergic system on studies of average
196 risk of bias.

197 To detect publication bias, funnel plots' asymmetry for each outcome variable was
198 qualitatively evaluated. To the best of our knowledge, there are no available methods to
199 quantify missing data (due for example to publication bias) in a multi-level setting(Assink and
200 Wibbelink 2016). Nonetheless, we evaluated publication bias with Egger's regression(Egger et
201 al. 1997). However, these results should be interpreted with caution as they are not based on
202 a 3-level model. Lastly, we excluded those studies responsible for funnel plot asymmetry and
203 conducted sensitivity analysis on the remaining dataset in the attempt to evaluate the
204 influence of publication bias in the meta-analysis.

205 Data are presented as *Hedge's G* and 95% C.I. Data analysis was conducted with the computer
206 program R (version 3.2.3)(Team 2015), with the aid of the following R packages: 1)
207 *metafor*(Viechtbauer 2010) for conducting the analysis, 2) *ggplot2*(Wickham 2009) for
208 graphics, and 3) *shiny*(Chang et al. 2017) to create the MaDEapp.

209 **3 RESULTS**

210 **3.1 STUDY SELECTION AND CHARACTERISTICS**

211 **3.1.1 Study selection and data extraction**

212 The process of study selection is illustrated in the flow chart (Fig 4). The search string
213 identified a total of 979 unique research papers. Statistical measurements (e.g. mean, SD and
214 N) for quantitative analysis were extracted from 90 peer-reviewed publications (that met our
215 pre-specified inclusion criteria as described in the methods section. Three
216 publications(Arborelius and Eklund 2007; Kippin et al. 2008; Kosten, Zhang, and Kehoe 2005)
217 were excluded from the analysis as it was not possible to extract nor infer any statistical
218 measurement. Similarly, information was lacking from 23 comparisons of three other
219 publications (Kikusui, Faccidomo, and Miczek 2005; Ognibene et al. 2008; Kirsten et al. 2012).

220 The included studies dated between 1996 and 2016, used ~2600 animals yielding a total of
221 1009 comparisons from 152 experiments. The publications were analyzed in two separate
222 datasets, respectively using prenatal (41 publications) and postnatal (49 publications) ELS
223 models. For a summary of experimental characteristics across studies see supplementary
224 Table S3-1.

225 Four observations of the prenatal dataset (striatal Th (Baier et al. 2014), striatal DA(Basta-Kaim
226 et al. 2011), striatal HVA(Z. D. Ling et al. 2004), striatal DR2(Son et al. 2007)) and 6
227 observations of the postnatal dataset (striatal DR1(Y. Zhang et al. 2013), striatal DR2(Y. Zhang
228 et al. 2015), DAT in the VTA area(Tien et al. 2013), striatal DOPAC(Ognibene et al. 2008),
229 cortical DA(Matthews et al. 2001) and limbic HVA(Kubesova et al. 2015)) were excluded from
230 the analysis as outliers.

231 **3.1.2 List of included publications**

232 The publications included in the analysis were:(Adrover et al. 2007; Alonso, Navarro, and
233 Rodriguez 1994; Baharnoori, Bhardwaj, and Srivastava 2013; Baier et al. 2014; Bakos et al.
234 2004; Basta-Kaim et al. 2011; Berger et al. 2002; Bingham et al. 2013; Bitanihirwe et al. 2010;
235 Brenhouse, Lukkes, and Andersen 2013; Cabib, Puglisi-Allegra, and D'Amato 1993; Cai et al.
236 2013; Camp, Robinson, and Becker 1984; Carboni et al. 2010; Chocyk et al. 2011; Kwok Ho
237 Christopher Choy, De Visser, and Van Den Buuse 2009; K. H C Choy and van den Buuse 2008;
238 Cory-Slechta et al. 2009; Cory-slechta et al. 2013; Dallé, Daniels, and Mabandla 2016; Delattre
239 et al. 2016; L. W. Fan et al. 2011; L.-W. Fan et al. 2011; Gerardin et al. 2005; Gondré-Lewis et al.
240 2015; Gracia-Rubio et al. 2016; Granholm et al. 2011; Hall et al. 1999; Emily Hensleigh and
241 Pritchard 2015; E. Hensleigh and Pritchard 2014; Hermel et al. 2001; Hill et al. 2014; J. W.
242 Jahng et al. 2010; Jeong Won Jahng et al. 2012; Katunar et al. 2010; Kawakami et al. 2013;
243 Kikusui, Faccidomo, and Miczek 2005; Kirsten et al. 2012; Kubesova et al. 2015; Lazzaretti et
244 al. 2015; Lejeune et al. 2013; Li et al. 2014; Z. D. Ling et al. 2004; Z. Ling et al. 2004; Z. Ling et
245 al. 2009; Liu et al. 2016; Lovic et al. 2013; Luchicchi et al. 2016; Madruga et al. 2006; Matthews
246 et al. 2001; Meyer, Nyffeler, Schwendener, et al. 2008; Meyer, Nyffeler, Yee, et al. 2008; Novak
247 et al. 2013; Ognibene et al. 2008; Orelan et al. 2011; Ozawa et al. 2006; Pallarés et al. 2013;

249 Nylander 2003; Rentesi et al. 2013; Reynaert et al. 2016; Reznikov and Nosenko 1995;
250 Romano-López et al. 2015; Eva Romero et al. 2007; E Romero et al. 2010; Rossi-George et al.
251 2011; Rots et al. 1996; Sasagawa et al. 2017; Silvagni et al. 2008; Silveira et al. 2010; Son et al.
252 2007; Tien et al. 2013; Vazquez et al. 2007; Vuillermot et al. 2012; Wang et al. 2009; Weston,
253 Sobolewski, et al. 2014; Weston, Weston, et al. 2014; Winter et al. 2009; Womersley et al.
254 2011; Zager, Mennequier, and Palermo-Neto 2012; Zavitsanou et al. 2013; Y. Zhang et al. 2015;

255 X. Y. Zhang, Kehoe, and Kosten 2006; Y. Zhang et al. 2013; X. Zhu et al. 2010; X. Zhu et al.

256 2011; Y. Zhu, Carvey, and Ling 2007; Zuckerman et al. 2003)

257

258 **3.2 META-ANALYSIS: PRENATAL ELS**

259 **3.2.1 Heterogeneity**

260 Substantial heterogeneity was recorded in the prenatal dataset ($Q(378) = 954.969, p < .001$),
261 indicating that our search string identified a diverse range of experiments. In particular, 34.7%
262 of variance could be attributed to within-sampling variance, 18.7% to within-experiment
263 variance and 46.6% to between-experiment variance. These results suggested the use of
264 moderators.

265 **3.2.2 Moderators**

266 Potential moderators (supplementary Table S3-2) - such as brain area, sex, and species - were
267 selected prior the beginning of the study based on hypotheses of the ELS literature.

268 As identified with univariate analysis of potential moderators (supplementary Table S3-3),
269 outcome measure ($F(7,371) = 3.956, p < .001$) and brain area investigated ($F(4,374) = 6.144,$
270 $p < .001$) were significant moderators in the prenatal dataset, explaining 4.3% and 6% of
271 variance respectively. There was no detectable moderating effect of sex, species, age used,
272 and method of assessment (RNA, protein or functional level).

273 **3.2.3 Model**

274 The moderators that were univariately identified were included in the 3-level model to
275 investigate the effects of ELS on markers of dopaminergic signaling. We hypothesized that
276 the effects were dependent on the outcome analyzed and that they differed across brain
277 areas.

278 Of the 20 interactions between outcome measure and brain area with enough data-points,
279 only 2 reached statistical significance (Fig 5). For a summary of all interactions, see

280 supplementary Table S3-4. In particular, in the striatal zone, Th was decreased (*Hedge's G(se)*
281 = $-1.164(.295)$, $p < .001$, supplementary Fig S3-1) while DOPAC was increased (*Hedge's G(se)* =
282 $.323(.136)$, $p = .018$, Fig 6A) following prenatal ELS.

283 Fig6B shows a cumulative forest plot of striatal DOPAC to exemplify that the chronological
284 combining of the experiments shows consistency since 2010, and that subsequent
285 experiments have not contributed to the direction nor the size of the effect. The cumulative
286 forest plot does not correct for the multi-level structure of the model.

287 The interaction between outcome measure and brain area explained 22.2% of variance in the
288 prenatal dataset. We identified 17 interactions with enough comparisons to further address
289 heterogeneity ($Q(346) = 742.97$, $p < .001$).

290

291 **3.2.4 Subgroup analysis**

292 Subgroup analysis was used to further investigate the unexplained heterogeneity deriving
293 from the 3-level model. The type of ELS model and sub-brain areas were univariately
294 evaluated as potential moderators for each interaction between outcome measure and brain
295 area.

296 In the prenatal dataset, 15 interactions had enough observations to be considered for further
297 subgroup analysis. Of these, 5 had a significant test of ELS model as moderator
298 (supplementary Table S3-5), namely DOPAC and D1R in the striatal area, DA in the cortical
299 area, and Th in the VTA area.

300 Subgroup analysis revealed that injection of LPS or PolyI:C has consistently different effects
301 than maternal restraint. In particular, LPS and PolyI:C significantly increased DOPAC in the

302 striatum (*LPS: Hedge's G(se) = .941(.229), p < .001; PolyI:C: Hedge's G(se) = .608 (.238), p = .016*),
303 while restraint did not (*Hedge's G(se) = .012(.207), p = .956*, Fig 6A). Conversely, restraint
304 decreased Th in the VTA area (*Hedge's G(se) = -.85(.348), p = .03*) whilst LPS injection did not
305 (*LPS: Hedge's G(se) = .026(.188), p = .889*, supplementary Fig S3-2). Concerning cortical DA,
306 the effects of PolyI:C and restraint had opposite directions but did not reach statistical
307 significance, whilst the LPS model could not be quantitatively evaluated. Concerning D1R, no
308 significant effects of the subgroup analyses were recorded.

309 Sub-brain area was a significant moderator only for DA in the striatal area (including nucleus
310 accumbens, dorsal and central striatum and nucleus caudatus; supplementary Fig S3-3). In
311 particular, DA was increased in the nucleus accumbens after ELS (*Hedge's G(se) = .392 (.159)*,
312 *p = .01*) but it was unaffected in other parts of the striatum (*Hedge's G(se) = -.122 (.146), p =*
313 *.40*). For a summary of all subgroup analyses, see supplementary Table S3-6.

314

315 **3.3 META-ANALYSIS: POSTNATAL ELS**

316 **3.3.1 Heterogeneity**

317 Our search identified a diverse range of experiments in the postnatal dataset, as shown by
318 the substantial heterogeneity recorded ($Q(381) = 1061.278, p < .001$). In particular, 33.1% to
319 within-sampling, 46.9% to within-experiment, and 20.1% to between-experiment variance.

320 **3.3.2 Moderators**

321 Univariate analysis of potential moderators (supplementary Table S3-7, *p*-value significance
322 set at $< .10$) identified outcome measure ($F(8, 373) = 9.139, p < .001$) and brain area
323 investigated ($F(4,377) = 2.035, p = .089$) as significant moderators, explaining 10.3% and 0.8%
324 of variance respectively. Other moderators, such as species and sex of the animal, had no
325 detectable moderating effect.

326 **3.3.3 Model**

327 The moderators that were univariately identified were included in the 3-level model to
328 investigate the effects of ELS on markers of dopaminergic signaling. We hypothesized that
329 the effects were dependent on the outcome analyzed and that they differed across brain
330 areas.

331 Of the 17 interactions with sufficient comparisons, 3 reached statistical significance (Fig 7,
332 supplementary Table S3-8). In particular, in the striatal zone, DOPAC (*Hedge's G*(*se*) =
333 $.541(.207), p = .009$, Fig 8), HVA (*Hedge's G*(*se*) = $.555(.22), p = .012$, supplementary Fig S3-4)
334 and DA (*Hedge's G*(*se*) = $.307(.147), p = .038$, supplementary Fig S3-5) were increased.

335 The interaction between outcome measure and brain area explained 15.3% of variance in the
336 postnatal dataset. We identified 16 interactions with enough comparisons to further address
337 heterogeneity ($Q(345) = 898.4, p < .001$).

338

339 **3.3.4 Subgroup analysis**

340 The moderator effects of the ELS model used and sub-brain areas were evaluated with a
341 subgroup analysis.

342 In the postnatal dataset, 16 interactions had sufficient observations to be further analyzed. Of
343 these, 7 revealed a significant impact of the ELS model used (supplementary Table S3-9):
344 HVA, DOPAC and DA in the cortical area, HVA and DOPAC in the striatal area, DOPAC in the
345 limbic area, and DA in the VTA area.

346 Subgroup analysis showed that the effects of ELS model as moderator in striatal DOPAC (Fig
347 8) and HVA (supplementary Fig S3-4) were mainly due to handling. In particular, handling
348 decreased HVA (*Hedge's G*(*se*) = $-.778(.295)$, $p = .03$) as well as DOPAC (*Hedge's G*(*se*) = $-.77(.301)$, $p = .029$) in the striatum, whilst separation of the mother from the pups had no
349 effect (HVA: *Hedge's G*(*se*) = $.08(.227)$, $p = .735$; DOPAC: *Hedge's G*(*se*) = $-.205(.239)$, $p = .411$).

351 Sub-brain area was not a potential moderator in any of the interactions evaluated.

352 For a summary of all subgroup analyses, see supplementary Table S3-10.

353 **3.4 SENSITIVITY ANALYSIS**

354 Sensitivity analysis was conducted to test the robustness of our findings. We examined
355 whether the quality of the studies included had an impact on the interpretation of our results.

356 **3.4.1 Quality of the studies: SYRCLE bias report**

357 No publication reported information on all SYRCLE potential bias items. Overall, of the 90
358 publications, 37 (41%) reported randomization sequence of the animals in the experiments, 3
359 (3.3%) random housing allocation, 59 (65%) random group allocation, 49 (54.4%) random
360 selection of the animals (Fig 9). In 11 (12%) publications the caretaker were reported blinded
361 to the experimental condition, in 20 (22.2%) the experimenters blinded. Handling of
362 incomplete data was reported in 42 publications (46.7%). 11 studies (12.2%) did not report
363 sufficient information to evaluate the quality of the control group. Only 11 studies yielding a
364 total of 117 comparisons reported being blinded and randomized.

365

366 **3.4.2 Sensitivity analysis for potential bias**

367 Since the amount of publications was insufficient to evaluate the robustness of our effects in
368 a blinded and randomized dataset, we operationalized the amount of potential bias and
369 performed the analysis again by including this factor as a moderator. Therefore, the results of
370 this sensitivity analysis were interpreted as the effects of ELS on markers of DA signaling on
371 studies of average bias.

372 The amount of potential bias was a significant moderator in the prenatal dataset ($F(1, 377) =$
373 $3.536, p = 0.061$); yet, this did not affect the qualitative interpretation of the meta-analysis.

374 In the postnatal dataset, the test of moderators for amount of potential bias was not
375 significant ($F(1, 380) = 0.500, p = 0.480$). The interpretation of the results did not change, with
376 the exception of DA in the striatal area, of which the effect size was decreased and the effect
377 at a trend level ($Hedge's G(se) = -.289(.15), p = .057$).

378

379 **3.4.3 Publication bias**

380 Due to the lack of methods to quantitatively evaluate publication bias in a multi-level setting,
381 we qualitatively estimated the risk for publication bias with funnel plots (Fig 10). Publication
382 bias was more pronounced in the prenatal than the postnatal dataset. The same conclusion
383 was reached when performing Egger's regression (no multi-level regression models): there
384 was evidence for publication bias in the prenatal ($z = -5.014, p < .001$) but not in the
385 postnatal ($z = -0.612, p = 0.54$) datasets. The presence of publication bias in the prenatal
386 dataset may indicate an overestimation of the reported effect sizes.

387 Furthermore, we conducted an analysis of influential cases by removing studies with large
388 standard error as well as residual values. Since the results did not change qualitatively,
389 publication bias was considered low-to-moderate.

390 **3.5 MADEAPP**

391 Finally, we created a MaDEapp (<https://vbonapersona.shinyapps.io/MaDEapp/>), a web-
392 based app with a user-friendly interface in which each researcher can perform his/her own
393 meta-analysis on the topic of ELS and biochemical indicators of the dopaminergic signaling.
394 The app offers the possibility to choose across a wide variety of options, such as outcome
395 measures, brain areas, sex of the animals, type and timing of the ELS model. Based on the
396 characteristics indicated, the app reports forest, funnel and cumulative plots. The forest plot
397 includes a 3-level effect estimate (Hedge's G and CI), which can be used for future power
398 calculation.

399 For example, a researcher is interested in the effects of postnatal ELS on DR1 in the striatal
400 area. In MaDEapp, the researcher selects the “postnatal” dataset, with “DR1” as outcome
401 measure in the “striatal area” (Fig. 11). The resulting forest plot reports the estimated *Hedge’s*
402 $G (CI) = -.5 [-.91, -.1]$. The estimated effect size is smaller than 0. From this exploration, the
403 researcher hypothesizes that postnatal ELS decreases DR1 expression in the striatal area. The
404 effect size -.5 may be an overestimation of the real size of the effect due to potential
405 (publication) bias. The researcher would then use an effect size of -.45 for power calculation
406 for his/her future experiments.

407

408 **4 DISCUSSION**

409 Schizophrenia and addiction are examples of psychiatric disorders reported to be linked to
410 DA dysfunction. Childhood trauma is a well-documented risk factor (Teicher et al. 2016;
411 Gatzke-Kopp 2011; Money and Stanwood 2013; Grace 2016). This clinical observation led to
412 the hypothesis that the dopaminergic system mediates the risk of ELS. Although this link has
413 been causally investigated in more than 90 rodent publications over 20 years, no consensus
414 has yet been reached on the extent, directionality and specificity of this effect. Therefore, we
415 performed a meta-analysis to question: Do rodent studies support long-lasting effects of ELS
416 on biochemical indicators of the dopaminergic system? Overall, our results indicate that only
417 a limited number of comparisons were significant suggesting that the effects of ELS on the
418 dopaminergic system may not be apparent on a biochemical level.

419 **4.1 METHODOLOGICAL CONSIDERATIONS**

420 Dopaminergic signaling involves multiple interdependent elements (e.g. precursors,
421 metabolites, receptors), which altogether contribute to the system as a whole. Data on these
422 elements are sometimes gathered from the same animals, and are therefore dependent on
423 each other (Aarts et al. 2014). In a meta-analysis setting, dependency implies overlap of
424 information, which ultimately leads to an erroneous interpretation of the results (Rosenthal
425 1991; Van den Noortgate et al. 2013). To deal with this obstacle, several strategies have been
426 adopted: from selecting only one effect size per study to ignoring the problem
427 altogether (Cheung 2014b). Although sophisticated methods such as multivariate and
428 multilevel analysis exist, these have the strong limitation that the needed covariance between
429 the dependent effects is rarely reported in publications (Hox 2010). The 3-level approach that
430 we used overcomes both limitations: it corrects for dependency of observations, without the

431 use of covariances(Assink and Wibbelink 2016). To the best of our knowledge, this approach
432 has never been used before in rodent literature. Although this powerful and practical method
433 was initially created for human studies(Cheung 2014b), its applicability in preclinical research
434 is warranted due to the multiple-outcome nature of such studies. The method is already
435 available in the R packages *metafor* and *metaSEM*.

436 Together with the application of a 3-level mixed effect meta-analysis to preclinical literature,
437 we here promote the use of tools to facilitate data exploration and advocate open science.
438 We created MaDEapp, a freely available user-friendly app that allows to run a tailor-made
439 meta-analysis on ELS and the dopaminergic system, depending on the specific question one
440 has. Each individual can select a set of characteristics (e.g. prenatal/postnatal models, sex,
441 age). The app returns a forest plot in which the total univariate 3-level estimate is presented,
442 as well as a funnel plot to evaluate publication bias. This can be used to generate hypotheses,
443 evaluate estimated sample sizes for power analysis, and explore which outcomes/brain areas
444 have received most attention and which did not. We believe this app is a useful tool to guide
445 future research on the topic.

446 MaDEapp and the analysis here presented are complementary. Meta-analysis is a statistical
447 test, and it is limited by the frequency (*power*) and quality (*potential bias*) of the published
448 data. In our analysis there was no significant effect of postnatal ELS on DR1 in the striatum (p
449 = .053); however, when we analyzed the same outcome univariately with MaDEapp, the
450 confidence interval of the estimate did not include 0 and could be interpreted as “significant”.
451 This discrepancy may be due to a lack of power to confirm the effect in our analysis or due to
452 an increased bias not corrected for in the more specific model used by the app. Therefore,
453 non-significant results should be interpreted as lack of confirmation of an effect, not as

454 evidence of no effect, since the meta-analysis could be underpowered to detect a specific
455 marker in a specific brain area. Alongside, the use of the app should be intended as
456 exploratory only and not as confirmatory.

457

458 **4.2 QUALITY OF THE STUDIES**

459 Meta-analysis as a methodology is not simply the collection of statistical methods used to
460 achieve integration of available evidence. Its power lies in the application of systematic
461 scientific strategies to the literature review(Cornell and Mulrow 1999). In addition to
462 summarizing effects' estimates, it allows to evaluate the extent to which conclusions are at
463 risk of bias.

464 In our analysis, surprisingly few studies (12%) reported being randomized as well as blinded.
465 On the other hand, random allocation to group (41%) as well as blinded assessor (22.2%) was
466 comparable(Antonic et al. 2013) or better(Egan, Sena, and Vesterinen 2011) than previous
467 publications in neuroscience. Although it is likely that investigators did take measures to
468 reduce bias, lack of their reporting induced an unclear risk(Kilkenny et al. 2013; Landis et al.
469 2012) and hindered estimation of the value of the publications(Kilkenny et al. 2013). The
470 importance of quality of reporting has been an emerging issue in preclinical
471 research(Kilkenny et al. 2013; Landis et al. 2012). Despite the increased awareness, the quality
472 of reporting of the publications included in this meta-analysis has not improved since 2005
473 (supplementary Fig S4-1). Such evidence should encourage preclinical researchers as well as
474 reviewers to adhere to reporting guidelines such as ARRIVE(Kilkenny et al. 2013).

475 Although imprecise reporting does not necessarily imply poor study quality, underpowered
476 experiments seriously hamper research interpretation(Button et al. 2013). From the reported
477 amount of animals included per experiment, we back-calculated the power at the beginning
478 of the study, assuming at least one true positive effect per publication. We performed this
479 analysis considering small (*Hedge's G* = .5), medium (*Hedge's G* = .8) or large (*Hedge's G* = 1)
480 effect sizes (supplementary Fig S4-2). When considering a large effect size, 391 comparisons
481 (38.7%) had power below chance level, and only 63 (6.2%) had power >.8, a cut-off
482 value(Cohen 1992) generally aimed at in preclinical research. Although 43 papers (47%) had
483 at least one comparison with power >.5, only 5 papers (5.5%) had at least one comparison
484 with power >.8. This means that the vast majority of the experiments was not sufficiently
485 powered to reliably detect an effect – an (already dramatic) best-case scenario given that the
486 percentages were calculated assuming that the studies compared only two groups (t-tests) as
487 well as a large and truly existing effect. Future preclinical studies should be grounded in
488 power calculations based on realistically estimated effects. Although for each single study the
489 amount of animals will be larger, overall higher power will lead to more reliable, reproducible
490 and therefore higher quality research.

491 **4.3 ELS CAUSES LIMITED ALTERATIONS ON BIOCHEMICAL MARKERS OF THE DA** 492 **SYSTEM**

493 In our analysis, we evaluated the dopaminergic system by including numerous biochemical
494 markers across brain areas as well as potential moderators. These gave rise to a myriad of
495 viable comparisons. Despite the extent, only a handful of significant effects were identified,
496 thereby suggesting that biochemical indicators of the DA system well adapt to ELS
497 interventions. Clearly, we cannot exclude the possibility that other indicators of the DA

498 system (e.g. electrophysiological parameters or behavioral tests that critically depend on DA
499 function) would have yielded clearer results. This awaits future investigation.

500 Prenatal and postnatal ELS were treated separately because the prenatal environment differs
501 substantially from that postnatally. Nonetheless, both datasets shared consistent findings.
502 Specifically, the striatal area was the most vulnerable: following prenatal ELS, Th was
503 decreased and DOPAC increased; while postnatal ELS caused an increased in DOPAC as well
504 as HVA. These changes were stable and reliable: the analysis used is adequately conservative
505 and robust, and the effects survived sensitivity analysis and publication bias corrections. The
506 stability of the effects is also qualitatively substantiated by the cumulative plots, which
507 operationalize how subsequent experiments update our knowledge of the previously
508 estimated effect size. Our results display that these were durable over time, and that
509 replication after the initial 3-5 studies might not be very informative on these variables
510 (except as a positive control in a study investigating another variable), as additional
511 experiments did not alter the estimated effect. All in all, the sparse effects here reported are
512 reliable and of medium size, suggesting that the system is damaged, which may in turn
513 contribute to the vulnerability of ELS-dependent disorders.

514 The results can be interpreted as either hyper- or hypo-activation. For instance, the increase
515 in metabolites can indicate an increase in the available amount of the substrate DA
516 (hyperactivation) as well as an increased conversion rate causing less DA (hypoactivation).
517 Similarly, the decrease in Th (precursor conversion enzyme) is not necessarily indicative of a
518 decrease in DA function. Although our analysis suggests that postnatal ELS increases DA
519 levels in the striatum, the effect is small in size and less robust than the other effects
520 mentioned above. The mismatch between DA precursor and metabolism may suggest

521 changes in the intermediate stage of DA conversion. For example, the DA converting enzyme
522 COMT has been repeatedly shown to interact with ELS for the later development of
523 psychiatric disorders(Lovallo et al. 2017; Klaus et al. 2017; Sheikh et al. 2017). On the other
524 hand, L-DOPA – product of Th and precursor of DA – has been suggested to act as a novel
525 transmitter itself or may have neurotropic functions, and thereby be transiently involved in
526 perinatal developmental processes(Braun et al. 1999). Since the interaction between ELS and
527 L-DOPA has not been further investigated, the link remains circumstantial.

528 We defined *a priori* several factors established in preclinical literature to be potential
529 moderators of ELS effects. To our surprise, species, sex and method of assessment were not
530 significant moderators. Although males, mice and protein as method of assessment were the
531 most described conditions, plenty of observations were present for all groups. Nonetheless,
532 the lack of evidence for a moderator effect should not be interpreted as evidence for
533 absence: mice/rats should be chosen according to standard practice, both sexes should
534 always be considered(Bale and Epperson 2015), and there is substantial evidence that a
535 decrease in RNA level does not automatically result in a decrease in protein and therefore in
536 function, as e.g. shown in a systems approach(Williams et al. 2016).

537 Lastly, the unexplained variance may not only indicate methodological differences, but also
538 underlie additional biological moderators, such as sub-brain areas or differences across
539 hemispheres (lateralization).

540 **4.4 TRANSLATIONAL POTENTIAL?**

541 The translational applicability of preclinical studies depends on the understanding of
542 psychopathological clinical and intermediate phenotypes. For example, ELS is a main risk
543 factor for schizophrenia as well as substance abuse disorder. However, these diseases have

544 opposite intermediate phenotypes: while schizophrenia is supposed to be characterized by
545 hyperreactivity of the DA system although presumably to its afferent control(Grace 2016),
546 substance abuse may be linked to DA hypo(re)activation(Wise and Koob 2014). To what
547 extent do ELS studies in rodents accurately model these two conditions?

548 Three factors currently limit answering this question. Firstly, ELS in humans is a complex
549 concept, generally involving low socio-economic status, physical and/or psychological abuse,
550 poor living conditions and high caloric food (Teicher et al. 2016). Conversely, animal models
551 are extremely controlled and standardized pre- and postnatally. Although this facilitates the
552 definition of "traumatic early life" as well as the deriving caused effects, one can question its
553 ecological validity. Secondly, the dual hypo- / hyper- interpretation of the ELS-induced
554 phenotype in rodents prevents a whole-system level comparison, and restricts it to a micro
555 level, focusing on a particular compound in a particular brain area. Thirdly, the DA-dependent
556 changes in schizophrenia and addiction are most likely far more complex than the ones
557 observed following ELS in rodents. For example, our analysis failed to confirm any effect of
558 ELS on DA receptors. This was surprising, as changes in the availability of DA receptors is a
559 consistent characteristic across different types of addictions(Nutt et al. 2015) as well as in
560 schizophrenia(Sanyal and Van Tol 1997). Although the discrepancy could partly be due to a
561 power problem of the meta-analysis, these limitations challenge the reliability of ELS models
562 for translational purposes, at least with regard to these specific aspects of the
563 abovementioned human disorders. It cannot be excluded that more relevant models may
564 become apparent in light of different ELS theories(Daskalakis et al. 2013).

565 Lastly, although our study supports that ELS causes some changes in the DA system, these
566 associations remain at a correlational level in humans and should be interpreted as such.

567

568 **4.5 LIMITATIONS OF THE STUDY**

569 Despite our efforts to be as comprehensive as possible in the description of the effects of ELS
570 on the DA system, we encountered several important limitations. Firstly, we investigated the
571 DA system by evaluating the effects of ELS on biochemical markers. Although this provides a
572 thorough conceptualization of the system, it does not supply a comprehensive functional
573 evaluation. For example, the approach here reported is unable to operationalize DA
574 innervations, projections and tone. ELS has been reported to alter DR3-signalling and
575 neuronal activity in the lateral septum(Shin et al. 2018). Chronic stress in adulthood has been
576 reported to change DA neurons' activity in a stressor-dependent manner(Valenti, Gill, and
577 Grace 2012). These reports suggest that spontaneous activity, bursting and timing of
578 dopaminergic firing may be susceptible to ELS action, yet they are not apparent from
579 assessment of ligands, receptors and metabolites. Despite the high relevance of such
580 measurements, these were excluded from the analysis as the publications on the topic are
581 scarce and their integration not straightforward in a meta-analytic setting.

582 Secondly, the classification of "timing" of ELS to either prenatal or postnatal may be too
583 reductionist, since neuronal circuits are shaped by experiences during critical periods of
584 development of variable length (from days to years depending on the species) (Hensch
585 2005). The interested researcher can further explore this avenue by combining our dataset
586 with RNA expression of Th or DA receptors found in the Allen Developing Mouse Brain
587 Atlas(Thompson et al. 2014). Unfortunately, the literature so far published is insufficient to
588 investigate how stress during specific postnatal days in which a certain RNA *X* is highly
589 expressed uniquely alters its functioning later in life.

590 Thirdly, due to insufficient data-points per outcome per brain area in several cases, a
591 meaningful quantitative estimation was not possible for all combinations of outcome*area.
592 All currently available measurements are reported as supplementary material and can be
593 further investigated via MaDEapp.

594 Fourthly, we included data only from published studies. Especially in the prenatal dataset,
595 there is evidence of low-to-medium publication bias as qualitatively estimated with a funnel
596 plot and sensitivity analysis, which may result in an overestimation of the effect sizes. Despite
597 the robustness of our methodology, this limitation should be considered in future power
598 calculations.

599 Lastly, we limited our analysis to baseline (i.e. unchallenged) conditions. Future studies should
600 focus on conditions where the DA system is challenged, as ELS manipulations can interact
601 with later life challenges to result in a pathological phenotype(Daskalakis et al. 2013).

602

603 To conclude, ELS induces a few yet robust effects on biochemical indicators of the DA system,
604 with – based on the currently available studies – the striatum being the brain area most
605 affected. Although the changes observed can be interpreted as both hypo- and hyper-
606 activation of the DA system, the effects were consistent across prenatal and postnatal ELS
607 models, sex, species and method of assessment.

608 **5 ACKNOWLEDGMENTS**

609 This work was supported by the Consortium on Individual Development (CID), which is
610 funded through the Gravitation program of the Dutch Ministry of Education, Culture, and
611 Science and Netherlands Organization for Scientific Research (NWO grant number
612 024.001.003). R.A.S. was supported Netherlands Organization for Scientific Research (NWO
613 Veni grant 863.13.02).

614 We thank Prof. Joop Hox for his input on multilevel methods, and Erik-Jan van Kesteren for
615 his programming expertise. We also gratefully acknowledge the in depth discussions and
616 feedback on the methods by Prof. Herbert Hoijtink and Dr Remmelt Schür.

1165 **7 FIGURE CAPTIONS**

1166 Fig 1. **Search string and inclusion criteria.** Graphical representation of the three main components of
1167 the search string. Items highlighted in bold were ultimately included in the analysis; other items were
1168 not included in the final analysis as explained in the methods' section.

1169

1170 Fig 2. **Graphical representation of signaling pathway.** Dopamine is synthesized by the enzyme
1171 tyrosine hydroxylase (Th). When released in the synaptic cleft, DA can 1) bind post-synaptic receptors
1172 (DR1-DR5), 2) bind auto-receptors, 3) bind dopamine transporters (DAT), 4) be converted to the
1173 metabolites DOPAC, 3MT and HVA by the action of the enzymes MAO and COMT(Meiser, Weindl, and
1174 Hiller 2013). Items in large (purple) font were included in the meta-analysis.

1175

1176 Fig 3. **Graphical representation DA system projections.** DA neurons are mainly situated in the
1177 midbrain, and can be subdivided with respect to their projection site(Grace 2016). In particular, DA
1178 neurons define separate populations of neurons that project to specific brain regions(Swanson, n.d.;
1179 Menegas et al. 2015). The major DA pathways are 1) mesocortical pathway, which defines projections
1180 from the VTA to the prefrontal cortex (PFC); 2) mesolimbic, from VTA to limbic system; 3) and
1181 nigrostriatal pathway, from substantia nigra (SN) to dorsal striatum, caudate nucleus and putamen.
1182 Other projections connect VTA to the hypothalamus, hippocampus and amygdala. Besides hosting
1183 dopaminergic neurons, these brain areas are involved in the feedback response to stress(Keller-Wood
1184 2015).

1185

1186 Fig 4. **Flow-chart of study selection and analysis.**

1187

1188 Fig 5. **Summary of effects: prenatal dataset.** Boxplot representing the summary of effect estimates
1189 for every combination between outcome variable (biochemical markers) and brain area. White bars =
1190 enough comparisons for meaningful quantification (rule of thumb: at least 4 comparisons from 3
1191 papers), black bars = number of comparisons insufficient for analysis.

1192

1193

1194 Fig 6. **Striatal DOPAC in the prenatal dataset.** (A) Forest plot. Results of univariate and 3-level meta-
1195 analysis are reported (bottom diamonds), as well as subgroup analysis on the ELS model used. (B)
1196 Cumulative forest plot. This plot displays the accumulation of evidence over time as the individual
1197 comparisons are added in chronological order. M = males, F = females, Method = method of
1198 assessment, hip = hippocampus, N = amount of animals, SEM = standard error of the mean, CI =
1199 confidence interval. Following the name of the study, _n represents the number of the experiment, .n =
1200 represents which comparison within that experiment.

1201

1202 Fig 7. **Summary of effects: postnatal dataset.** Boxplot representing the summary of effect estimates
1203 for every combination between outcome variable (biochemical markers) and brain area. White bars =
1204 enough comparisons for meaningful quantification (rule of thumb: at least 4 comparisons from 3
1205 papers), black bars = number of comparisons insufficient for analysis.

1206

1207 Fig 8. **Striatal DOPAC in the postnatal dataset.** Forest plot. Results of univariate as well as 3-level
1208 meta-analysis are reported (bottom diamonds), as well as subgroup analysis on the ELS model used. *
1209 = effect sizes of handling were multiplied by -1 to maintain consistency directionality of the other
1210 models. A decrease in the graph identifies an increase in DOPAC in ELS animals. M = males, F =
1211 females, Method = method of assessment, hip = hippocampus, N = amount of animals, SEM =
1212 standard error of the mean, CI = confidence interval, MD = mother separated from the pups, LPS =
1213 injection of LPS. Following the name of the study, _n represents the number of the experiment, .n
1214 represents which comparison within that experiment.

1215

1216 Fig 9. **Risk of bias assessment.** Each bar represents a different risk of bias item. Yes = measurements
1217 have been taken to avoid bias; no = no measurements were taken to avoid bias; unclear = not enough
1218 information provided in the paper to determine the risk of bias.

1219

1220 Fig 10. **Funnel plots.** Publication bias was evaluated by qualitatively assessing symmetry in funnel plot
1221 in the (A) prenatal and (B) postnatal datasets.

1222

1223 Fig 11. **MaDEapp.** Screen shot for visualization of MaDEapp, a web-based tool to perform *ad hoc*
1224 meta-analysis of the topic of ELS and biochemical indicators of the DA system. The app can be found
1225 at ****website****.

ELS models

Prenatal

Injection LPS

Injection Poly I:C

Maternal immune activation

Restraint

Chronic unpredictable stress

Other injections (e.g. glucocorticoids)

Postnatal

Removal dam from litter (MD/MS)

Removal pup from litter (isolation)

Handling

Injection LPS (in pups)

Licking and grooming

Limited nesting and bedding

Communal housing

Other injections

Outcome measures

DA

DA precursors (tyrosine, **Th**, L-DOPA)

DA metabolites (**DOPAC**, **HVA**, **3-MT**)

DA turnovers (DOPAC/DA, HVA/DA, 3-MT/DA)

DA receptors (**DR1**, **DR2**, **DR3**, DR4, DR5)

DA transporter (**DAT**)
