Abstract

Cell shapes and connectivities evolve over time as colony shapes change or embryos develop. Shapes of intercellular interfaces are closely coupled with the forces resulting from actomyosin interactions, membrane tension, or cell-cell adhesion. While it is possible to computationally infer cell-cell forces from a mechanical model of collective cell behavior, doing so for temporally evolving forces in a manner that is robust to digitization difficulties is challenging. Here, we introduce a method for Dynamic Local Intercellular Tension Estimation (DLITE) that infers such temporal force evolutions with less sensitivity to digitization ambiguities or errors. This method builds upon prior work on single time points (CellFIT). We validate our method using synthetic geometries. DLITE's inferred cell colony tension evolutions correlate better with ground truth for these synthetic geometries than tension values inferred from methods that consider each time point in isolation. We introduce cell connectivity errors, angle estimate errors, connection mislocalization, and connection topological changes to synthetic data and show that DLITE has reduced sensitivity to these conditions. Finally, we apply DLITE to time series of human induced pluripotent stem (hIPS) cell colonies with endogenously expressed GFP-tagged ZO-1. We find major topological changes in cell connectivity, e.g. mitosis, can result in an increase in tension. This supports a correlation between the dynamics of cell-cell forces and colony rearrangement.

26

Significance statement

27   Cell-cell tensions play an important role in the dynamics of tissue morphogenesis. Mathematical modeling tools have helped understand the role of cell-substrate and cell-cell adhesion in tissue organization. In particular, recent modeling studies have shown that an inferential approach without a constitutive equation can estimate distribution of tensions in a single image of a cell monolayer (CellFIT). Here, we include the dynamics of monolayer morphogenesis in the estimation of cell-cell tensions. Such a formulation, termed DLITE, performs better across time in both synthetic geometries and time series of hIPS cell colonies with endogenously expressed GFP-tagged-ZO-1. We also show that DLITE is robust to digitization ambiguities during segmentation. Such a method can shed some light on physical mechanisms that drive morphogenesis.

Introduction

Cell shape, forces, and function are closely related [1, 2, 3, 4]. Cell shape affects the organization and transmission of cytoskeletal forces and the structures that create them [5, 6, 7]. Cell membrane tension partially governs processes from intracellular endocytic bud morphology during trafficking [8] to tissue level remodeling events such as wound healing [9], development [10], expansion [11], migration [12, 13] and cancer invasion [14]. Mechanical rearrangement occurs as cells transmit these forces across the membrane [15] and cell-cell adhesion complexes such as adherens and tight junctions [16, 17]. These apical cortical complexes [18] depend on the activity of the actomyosin cytoskeleton [19, 20]. The mechanotransduction of intercellular forces can alter and regulate biochemical signalling pathways [21, 22] with force and deformation at a particular time point partially regulating future force and deformation.

Force-mediated collective behaviours are crucial for the dynamics of tissue reshaping. This is commonly evidenced by apoptosis in cell cultures or by the intercalation and extrusion of cells during development [23, 24]. We can examine the role of tension in tissue remodeling using direct force measurement techniques such as atomic force microscopy (AFM) or micro-pipette aspiration [25, 26, 27]. These direct measurement techniques offer precise force characterization in cells and tissues but perturb the actomyosin network [28, 29]. As a result, these methods can alter the force responses of the system at subsequent time points. Alternative optical measurement techniques that use Förster Resonance Energy Transfer (FRET) tension probes or traction force microscopy (TFM) can assay force [30, 31, 32] without the mechanical disruption associated with direct measurements [33]. These optical approaches can be applied across extended periods but, like the prior physical techniques, they can be difficult to implement in a high-throughput context. Each of these measurement techniques has its distinct set of advantages, depending on the biological problems being studied. Complementary to these approaches, force inference from the geometry of the cell boundary can allow for the estimation of normalized tensions solely from images of labeled confluent cells without further condition requirements.

Intercellular forces can be inferred at cell-cell interfaces using a mechanical model predicated on the assumption that forces are balanced where multiple cell-cell interfaces meet [34, 35, 36]. These mechanical models cover a range of complexities, assumptions, and use cases [37]. Here we deal with the subset devoted to the representation of tensions in a two-dimensional plane of curved edges

3

58 digitized from the apical interfaces of a confluent cell colony (Fig. 1A,B). We build upon prior rep-

59 resentations of this system, notably that used in the Cellular Force Inference Toolkit (CellFIT) [34],

60 and develop an alternate problem formulation that treats tension estimation as a temporally evolv-

61 ing problem, borrowing information from prior time points to increase model prediction stability and

62 boost resistance to ambiguities or errors that arise during the digitization process (Fig. 1C). This pro-

63 vides a non-disruptive means to infer intercellular forces in time-lapse imaging of cell colonies. We

64 term this technique Dynamic Local Intercellular Tension Estimation, or DLITE. Here, we validate

65 DLITE against a range of synthetic data, for which known tension ground truths are available, and

66 use it to predict tensions in time series of human induced pluripotent stem (hIPS) cell lines with the

67 endogenously GFP-labeled tight junction protein ZO-1.

Methods

68

Assumptions

69

70 We employed a curvilinear description of a tissue by defining a colony as a directed planar graph

71 comprising cells (c), edges (e) and nodes (n) (Fig. 1B, for more details see SOM and [38, 34]). Forces

72 exerted by the actomyosin cortex result in tangential stresses in the form of tension (t) along an edge.

73 Cells resist deformation by means of a normal stress exerted as pressure (p) inside every cell. Along

74 each edge, we assumed that the interfacial tensions are constant and that the intracellular pressures

75 are uniform within a cell. At the length scale of the whole cell, we ignored membrane bending and

76 assumed that edge tensions and cell pressures exclusively govern cell shape. We treated viscous forces

77 as negligible and therefore assumed that the colony shape is quasi-static, i.e. at each time point the

78 colony is in mechanical equilibrium.

Governing equations and system specification

79

80 A general force balance at every node in a colony can be written as

$$n_{\text{residual}} = \underbrace{\left| \sum_{i=1}^{e_n} t_i v_i \right|}_{\text{(Tension balance per node)}} , \tag{1}$$

81 where n is a node, t, and v represent the tension/tangential stress and local tangent unit vector of an

4

82 edge connected to node n respectively, e_n is the number of edges connected to node n and n_{residual} is

83 the magnitude of the resultant tension vector coming into a node (ideally 0). This notation is shown

84 in Fig. 1B. This equation applies when employing a curvilinear description of tissue and applies to a

85 node that is both connected to at least three edges and is in mechanical equilibrium [34]. The pressure

86 difference between adjacent cells can be estimated using Laplace's law as

$$e_{\text{residual}} = \underbrace{p_i - p_j - \frac{t}{r}}_{\text{(Pressure balance per edge)}} , \tag{2}$$

87 where e is an edge, p_i and p_j are the pressure of adjacent cells i and j respectively and e_{residual} is

88 the residual error from the pressure balance. Here, t and r represent the tension and radius of the

89 interfacial edge e. The system of equations for tension and pressure are generally overdetermined;

90 there is no unique solution to this system [34]. Therefore, we can only infer the relative distribution

91 of tensions from the shape of the edges and not the absolute values.

92   To compute the dynamics of cell-cell forces, we reformulated the tension balance (Eq. 1) as a local

93 optimization problem defined as

$$\underset{t}{\text{minimize}} \quad f(t) = \sum_{j=1}^{N} \left(n_{\text{j,residual}} + \underbrace{\frac{n_{\text{j,residual}}}{\sum_{i=1}^{e_{n_j}} | t_i v_i |}}_{\text{Regularizer}} \right), \tag{3}$$

94 where n_j and e_{n_j} represent the jth node and the number of edges connected to node n_j, and N is the

95 total number of nodes in the colony. Here, $n_{j,\text{residual}}$ is the tension residual at a given node (Eq. 1)

96 and the regularizer is the magnitude of the tension residual divided by the sum of the magnitude of the

97 tension vectors acting on that node. Since tension cannot be negative, we set a lower tension bound

98 of zero. In Eq. 3, the regularized term ensures that the system of equations does not converge to the

99 globally trivial solution (tension = 0 along all edges) [39]. Pressure in each cell was computed using

$$\underset{p}{\text{minimize}} \quad g(p) = \sum_{j=1}^{E} e_{j,\text{residual}}^2, \tag{4}$$

100 where E is the total number of edges in the colony and e$_j$ is the residual error from the pressure balance

101 at the jth edge. Tension and pressure solutions were normalized to an average of 1 and 0 respectively,

102 similar to prior work [34, 36, 35]. In contrast to previous methods, DLITE uses the values of tension

103 at each edge and pressure in each cell from the previous time point as an initial guess for the current

5

104 timepoint. This mode of time-stepping in the optimization procedure enables us to use information

105 from previous time points to predict the values of tension and pressure at the current time point and

106 forms the basis of DLITE's improved performance across time-series.

Tracking nodes and edges

108 An essential distinguishing characteristic of DLITE is the ability to provide an initial guess for each

109 edge tension and each cell pressure, allowing us to incorporate a time history of cell-cell forces.

110 However, this requires node, edge, and cell tracking over time. To implement tracking we first as-

111 sign labels to nodes, edges, and cells at the initial time point. Then, nodes are tracked by assigning the

112 same label to the closest node at the next time point. Edges are tracked by comparing edge angles con-

113 nected to nodes with the same label and cells are tracked by matching cell centroid locations across

114 time. Our model optimization pipeline was implemented using Scipy's unconstrained optimization

115 algorithm 'Limited-memory Broyden–Fletcher–Goldfarb–Shanno (L-BFGS)' [40]. The global opti-

116 mization technique 'Basinhopping' was used to seek a global minimum solution at the first time point

117 [41].

Geometries for model validation

119 Validation of DLITE requires the generation of dynamic 2D geometries with curvilinear edges whose

120 cortical tensions are known. Many standard mathematical models describe the modification of cell-

121 shape via applied forces that are either explicitly or implicitly specified. Such models include cellular

122 Potts models [42, 43], Vertex models [44, 45] and cell-level finite element models [46, 47, 48]. Im-

123 plicit models define an energy function relating the variation of tension and other properties in a 2D

124 monolayer to cell shape. The gradient of this energy function leads to the movement of each vertex.

125 Here, we employ an implicit model using the energy minimzation framework Surface Evolver [49],

126 which is designed to model soap films. The energy function (W) was defined as

$$W = \underbrace{\sum_{j=1}^{E} t_j L_j}_{\text{Tension energy}} + \underbrace{\sum_{k=1}^{C} p_k A_k}_{\text{Pressure energy}} , \tag{5}$$

127 where t_j, L_j are the tension and length of the jth edge and p_k, A_k are the pressure and area of the kth

128 cell respectively. E and C are the total number of edges and cells in the colony (see SOM for details).

6

129 Here, the tension energy represents a net energy contribution due to adhesion forces that stabilize
130 a cell-cell interface and actomyosin cortical tensions that shorten cell-cell contacts. Pressure was
131 enforced as a Lagrange multiplier for an area constraint. Cell boundaries were free to move along the
132 surface. Such a model outputs a minimum energy configuration through gradient descent, providing
133 ground truth tensions to which we compare inference model outputs. While the model utilized here
134 describes a monolayer as a 2D surface embedded in 3D space, it is possible to extend this work to 3D,
135 covering the complex 3D structure present in many systems [36].

Sources of error due to digitization

137 Transforming single or multi-channel z-stacks of cell colonies into a connected network suitable for
138 tension inference requires: *(i.)* Image pre-processing to produce a binary or otherwise simplified rep-
139 resentation, *(ii.)* Skeletonization, creating a network of 0-width lines connecting nodes at junction
140 points and *(iii.)* Post-processing of the skeletonized representation. Inherent ambiguities in this pro-
141 cess introduce several challenges to successful tension inference. Some of these challenges, such as
142 incorrectly detecting an edge, occur in single frames (Fig. 1C, Time t-1) while others, such as edge
143 tracking across biological network reorganization, are only present in time series data (Fig. 1C, Time
144 t). These challenges tend to occur more frequently as digitization is increasingly automated, creating
145 a trade-off between data reliability and throughput.

Results

147 DLITE is built to use the tension at a specific cell-cell junction at a given time point as an initial guess
148 to calculate tensions at the next time point. This logical progression then allows us to infer forces over
149 time and test the strength of the inference method by correlation to ground truth values for synthetic
150 geometries. We demonstrate robustness and sensitivity of DLITE by validating it against ground-truth
151 tensions for multiple synthetic geometries, multiple tension perturbations within a colony, connectiv-
152 ity ambiguities at single or multiple time points, curve-fit errors, node location errors, and topological
153 changes like the shrinkage of cell-cell contacts. At each point, we compare predictions to those pro-
154 duced by the state of the art CellFIT technique. We then apply DLITE to movies of skeletonizations
155 of endogenously tagged tight junction ZO-1 (*zonulae occludentes*-1) in an hIPS cell line and demon-
156 strate improved tension stability in the inference of cell-cell forces during colony dynamics.

Validation of DLITE as a dynamic tension-inference tool

We validated DLITE in three steps. First, we compared edge tension and cell pressure solutions obtained using our implementation of the CellFIT algorithm and DLITE to ground truth values in synthetic geometries made available via the current version of CellFIT called ZAZU (Fig. S1). We re-implemented the CellFIT algorithm in Python because the source code of ZAZU is not publicly available. Both our re-implementation of CellFIT (Fig. S1B) and DLITE (Fig. S1C) perform identically with respect to the ground truth for single frames (Fig. S1A), with an average error of ~ 0.02 (Fig. S1D).

Second, to generate a time-series of synthetic geometries, we simulated colonies that deformed smoothly across time using Surface Evolver [49]. Initial geometries were created from random Voronoi tessellations followed by Lloyd relaxation [50]. In order to generate a time-series, we performed multiple Evolver simulations where the tension of a few randomly selected edges were either increased or decreased between time points (Fig. 2A). Average edge tension at each time point was normalized to 1. We then stripped all tension and pressure information from the resulting shapes and used these shapes as input to our method. Using DLITE and CellFIT separately, we inferred colony forces and compared the two approaches (Fig. 2B, D). Initially, both methods performed identically, but began to show divergence after 3 frames. Importantly, we observed that the values of tension predicted using our method remain closer together over time and are better correlated (r = 0.94 (DLITE) vs r = 0.75 (CellFIT)) to the ground truth (Fig. 2 B, D). Further, we observed that the variation in tension defined by the change in edge tension over time denoted as Δtension, using DLITE also correlates better to the ground truth change in edge tension (Fig. 2C). The improved performance of DLITE at later time points (Fig. S2B) results from DLITE use of information from prior time points to improve tension predictions in the presence of large curve-fit residuals (Fig. S2A), thereby reducing sensitivity to curve-fitting errors. In the absence of an informed prior, i.e. when we use random initial guesses sampled from a random Gaussian distribution at every time point, we observed poor performance of DLITE, with correlations ranging from 0.75 to 0.89.

Third, to ensure robustness of the performance of DLITE, we tested multiple tension perturbations via different combinations of increasing and decreasing edge tension in the same geometry (Fig. S4) and similar perturbations in other randomly generated geometries (Fig. S5). In all cases, we observed equivalent or better correlation of both the tension and change in edge tension with the ground truth

8

187 using DLITE as compared to CellFIT.

DLITE is robust to digitization ambiguities

189 The input to a force-inference model is a map of colony shape as a series of curved edges and the nodes

190 where edges join (Fig. 1B). Segmentation transforms image data into information about the isolated

191 geometric structures [51, 52]. Subsequently, skeletonization methods extract lines that characterize

192 the topology and connectivity of the tension bearing network in the colony. Ambiguities or errors in

193 this mapping present challenges to force inference techniques that rely on precise colony connectivity

194 and edge tracing [34, 35, 36]. Some of these conditions are shown in Fig. 1C. New methods have

195 improved the quality and repeatability of predicted network topology and connectivity; both deep

196 learning models and traditional computer vision techniques have made significant advances in 2D/ 3D

197 biological segmentations [53, 54, 55, 56]. Despite these advances, current skeletonization methods

198 continue to require semi-manual post-processing because of the ambiguities present in the structures

199 during imaging and errors resulting from the image capturing modalities. This semi-manual cleanup

200 becomes increasingly impractical for larger colonies and time series. As a result, we require force-

201 inference techniques robust to errors in mapping. As we demonstrate below, our inference method

202 has increased robustness to multiple edge/node mapping errors. Therefore, our method decreases

203 the number of manual corrections required, and increases the tractability for inferring forces. Here

204 we evaluate the effects of edge/node mapping errors on force-inference in a single image and in a

205 time-series.

206 We first analyzed, at a single time point, the effect of a missing intersection between two edges, a

207 commonly occurring connectivity error. As before, we generated a synthetic colony image to initialize

208 the system with known edge tensions. Fig. 3A shows a random Voronoi tessellation generated using

209 Surface Evolver where 50 edges (out of 330 total) have larger values of tension than others. The ground

210 truth tensions were the inputs given to Surface Evolver (Fig. 3A). A single edge was deliberately traced

211 incorrectly to introduce a connectivity error (Fig. 3A, *inset*). This error resulted in the loss of a triple

212 junction and loss of cellular integrity. Since the node of interest is now connected to two edges instead

213 of three, we can no longer conduct a tension balance at that location. Such an ill-posed problem

214 results in a singular tension matrix G_γ (Eq. 6), implying that CellFIT is unable to infer a correct

215 tension distribution (Fig. 3A&B). However, the use of a regularizer in DLITE (Eq. 3) reduces the

9

216 effect of local tension errors on the global data set. As a result, we find that at a given time point,

217 DLITE is able to provide a good estimate of the tension of the neighboring edges, even in the presence

218 of connectivity errors (Fig. 3C, see also Figs. S6, S7).

219 A commonly occurring digitization challenge results from poor estimation of edge curvature due

220 to incorrect values of between-edge angles at a particular node. Errors in curve-fitting can lead to poor

221 tension residuals (Eq. 1) or large condition numbers of tension matrices (Eq. 6), which is defined as

222 the ratio of the largest to smallest singular values in the SVD (Singular Value Decomposition) of the

223 given tension matrix. Subsequently, this leads to poor inference of tension (Fig. 2). This is especially

224 problematic when cell-cell junctions are distinctly non-circular, as they commonly are. To simulate

225 this, we generated a time-series of synthetic geometries using Surface Evolver such that later time

226 points are distinctly non-circular (Fig. S3A). The large curve-fit residuals at later time points (Fig.

227 S3B) lead to ill-conditioned tension matrices and errors in tension inference (Fig. S3C). However,

228 DLITE uses tension information from prior time points to retain the distribution of tensions and is not

229 poorly scaled by these curve-fit errors (Fig. S3C).

230 Another major digitization challenge for force-inference models is the accurate determination of

231 node locations. Localization errors in node coordinates also have the downstream impact of changing

232 connected edge curvatures (Fig. 5B). We simulated this type of error by adding levels of Gaussian

233 noise to nodes in a synthetic colony (Fig. 5A, red nodes). Noise levels 1 (Fig. 5C, F), 2 (Fig. 5D, G)

234 and 3 (Fig. 5E, H) refer to the Gaussian noise terms with a mean of 0 and standard deviations of 0.1,

235 0.5, and 1 respectively. Red node coordinates are (480.95, 525.7), (487.76, 536.94), (498.63, 522.1),

236 (524.25, 503.43), (535.62, 515.97), arranged from left to right. In all cases, we observed equivalent

237 (Noise level 1) or improved performance (Noise levels 2, 3) when using DLITE compared to CellFIT.

238 Thus, DLITE offers improved quality of tension inference in the presence of ambiguities in node

239 location.

240 Finally, we considered a class of mapping challenges that are unique to time-series data – identifi-

241 cation of edges from one frame to the next. Misidentification of edges frequently occurs when an edge

242 is lost for a single frame, severing the edge's connection to its prior label. Fig. 3D shows a time-series

243 with a missing edge (edge label 33) and two missing cells at time point 8. The missing edge leads

244 to the loss of a triple junction, and consequently a singular tension matrix (Fig. 3E, CellFIT). For

245 tracking purposes, missing an edge also means that the edge that was being tracked up to that point

246 no longer exists, and therefore a new edge label is assigned. Since edges with new labels do not have

10

247 an initial tension guess from an identical label at prior time points, these edges are given an initial

248 guess for the value of tension equal to the average initial guess of all edges connected to that edge.

249 By using such a scheme, DLITE can predict tension and Δtension (change in edge tension of an edge

250 label between adjacent time points) that correlates well with the ground truth (Fig. 3E, F). Thus, in

251 both images and movies of colonies, we find that use of information from the neighbouring region

252 allows DLITE to handle digitization ambiguities and errors better and robustly predict the distribution

253 of cell-cell forces.

DLITE is robust to topological changes

255 Network topology or the structure of edges and vertices often display changes in time-series data. In

256 Fig. 3D, for example, there are two topological changes at time points 6 and 8 (edge labels 8 and 25

257 respectively) that result in differences between CellFIT and DLITE (Fig. 3E, F), with DLITE showing

258 better correlation to the ground truth. Handling of a time-ordered network requires the tracking of

259 nodes, edges, and cells over time. This can be done in 2 ways – if, for example, a single edge ceases

260 to exist at a certain time point, we can choose to either keep that edge label and assume that it has

261 temporarily left the field of view or assign new edge labels ensuring that the lost edge label ceases

262 to exist [57]. Here, we choose the second option in order to condition the network based only on the

263 immediately prior time point. Thus, an edge label that could not be tracked after a time point no longer

264 exists and is assigned a new label. These rules were applied to nodes and cells as well.

265   If the observed topologies of a cellular network are constantly changing, how then does it affect

266 inferred cell-cell forces? To study the effect of topological changes, we take advantage of the fact

267 that decreasing the tension of two edges in a triple junction results in a decrease of the length of the

268 third connected edge in Surface Evolver. Fig. 4A shows an example time series where edge label 15

269 disappears at time point 18. This single topological change leads to an ill-conditioned tension matrix

270 (Eq. 6, Fig. 4B, C). However, DLITE retains the correct distribution of tensions at time point 18 (see

271 also Fig. 3E, edge label 25 at time point 8 and Fig. S8A) using the initial guess from prior time points.

272 While this specific network structure led to an ill-conditioned tension matrix after a single edge loss,

273 this is not always the case. If the tension matrix is well-conditioned after the topological change (Fig.

274 3E, edge label 8 at time point 6 and Fig. S8B), then CellFIT retains a good solution quality. However,

275 Δtension is less smooth, and both the tension and Δtension still correlate better to the ground truth

11

276 while using DLITE (Fig. 3E,F and Fig. S8B). Thus, force inference in dynamic network topologies

277 benefits from incorporating a temporal history of cell-cell forces.

Application to ZO-1 tight junctions

279 Finally, we applied DLITE to experimental images of colonies of hIPS cells. ZO-1 in hIPS cells was

280 tagged at its endogenous locus with mEGFP and visualized using a spinning confocal disk microscope

281 (see SOM for more details). We chose this system because tight junctions (or *zonulae occludentes*)

282 are known to form a selective barrier, regulating paracellular diffusion through the spaces between

283 cells. Injury of tight junctions can impair barrier function, leading to complications in lungs [58, 59],

284 kidneys [60], eyes [61] or the small intestine [62]. The actin cytoskeleton plays an important role in

285 the regulation of this barrier function [63], and is connected to the rest of the tight junction complex

286 through ZO-1 proteins [64, 65]. Recent studies suggest that actin polymerization and transient Rho

287 activation ('Rho flares') act to quickly restore barrier function upon localized ZO-1 loss at cell-cell

288 contacts [66]. Mechanical cues from the polymerization and branching of the actin network can lead

289 to reshaping of tight junctions, resulting in varying barrier phenotypes.

290 Using a skeletonization of segmented GFP images, we predicted the evolution of intercellular

291 forces in three different ZO-1 time series using both DLITE and CellFIT (Fig. 6A, B and C). Since no

292 ground truth is available in this case, we determined the quality of predicted tensions using condition

293 numbers (κ) of the tension matrix (Eq. 6) and tension residuals. We note that the relative distribution of

294 tensions range from 0 to 3, such that the average tension is normalized to 1. The time interval between

295 adjacent time points was 3 minutes. The example frames shown in Fig. 6A, B, C are organized as raw

296 GFP (upper), CellFIT predicted tensions (middle) and DLITE predicted tensions (lower). In every

297 frame, we observed at least one kind of digitization error, leading to poor tension matrix condition

298 numbers or tension residuals. Single frame errors such as curvature errors (Fig. 6A - Time 0, $\kappa = 69$

299 and Fig. 6B - Time 0, $\kappa = 23$), connectivity errors (Fig. 6A - Time 10, $\kappa = 136$ and Fig. 6C - Time 6,

300 $\kappa = 10^{18}$), node location errors (Fig. 6B - Time 5, $\kappa = 10^{16}$ and Fig. 6C - Time 0, $\kappa = 10^{16}$) and time-

301 series specific errors such as new edges (Fig. 6A - Time 5, $\kappa = 32.5$), missing edges (Fig. 6C - Time

302 3, $\kappa = 31$) and topological changes (Fig. 6B - Time 25, $\kappa = 46$) result in loss of tension stability and

303 errors (Fig. 6A, CellFIT). Despite these digitization errors, DLITE shows increased tension stability

304 (Fig. 6A, DLITE), demonstrating its utility. Heatmaps of dynamic edge tension and change in edge

12

305 tension (Δtension) for the time-series in Fig. 6 are also shown in Fig. S9. The improved performance

306 of DLITE is predicated on reduced tension residuals at every time point (Fig. S10). Importantly, the

307 reduction in tension residuals is accompanied by a reduced dynamic change in edge tension (Δtension,

308 Fig. S9), indicating a smoothness across time.

309 Interestingly, we observed an increase in tension adjacent to a dividing cell immediately after a

310 mitotic event (Fig. 7A, red box) in a time-series of ZO-1 GFP with a single mitotic event at time

311 point 14. This increase in tension post-mitosis was observed using both methods (Fig. 7C, edge labels

312 3, 10 and 11), but only after the removal of digitization errors during a semi-manual skeletonization

313 process. This step was important to ensure non-poorly scaled CellFIT solutions, such as the ones at

314 time points 2 and 13. As before, both the tension residuals (Fig. 7B) and the dynamic change in

315 tension (Δtension, Fig. 7D, E) were reduced when using DLITE. The reduction in Δtension was

316 determined to be sensitive to the time interval. The standard deviation of Δtension across time was

317 significantly reduced at a time lag of 1 frame (3 minutes), but showed no difference between methods

318 for a time lag of 5 frames (15 minutes).

Discussion

320 In this study, we have presented a new method, DLITE, which is based on a local optimization of

321 tension residuals to compute dynamic cell-cell forces. We validated the predictive power of DLITE

322 using synthetic geometries generated by Surface Evolver [49] and showed that DLITE performs better

323 than the prior state-of-the-art method CellFIT [34] when applied to time-series data. Importantly, this

324 method incorporates a framework to track nodes, edges, and cells across time.

325 We demonstrated that DLITE is robust to digitization challenges common in time series data such

326 as poor estimates of edge angle, errors in node location, connectivity errors and topological changes

327 that occur as cells move and encounter different neighbors. Finally, we applied DLITE to estimate

328 edge tensions in multiple time-series of ZO-1 tight junctions and showed improved stability in tension

329 predictions and an increase in tension post mitosis. We indicated that DLITE displays a reduced

330 Δtension compared to CellFIT, indicating greater temporal smoothness. We observed this reduction

331 in three other scenes of the ZO-1 tight junction.

332 The need for dynamic force-inference tools to understand cell shape and colony rearrangement is

333 driven by their applicability to morphogenic processes from wound healing to germ-band extension to

13

334 colony reorganization [1, 2, 3, 4]. These processes rely on transient mechanical forces that are ideally

335 detected by the extended non-perturbing observations for which DLITE is designed. Computing the

336 dynamics of cell-cell forces via this computational framework complements experimental advances

337 and enable data-driven estimation of intercellular forces, particularly as biological data sets grow in

338 size.

339 While useful, DLITE makes assumptions about the system that create limitations. Specifically,

340 DLITE assumes 1) edges are circular arcs, 2) that tension is correlated from timepoint-to-timepoint,

341 and 3) that sufficient computational resources are available. 1) The tensions calculated using DLITE

342 depend on fitting circular arcs to every edge. This approximation breaks down if the edge is not under

343 sufficient tension or the cytoskeleton is strongly perturbing it inhomogeneously across the interface.

344 Under these conditions the inferred tensions will not approach the ground truth. 2) Using local opti-

345 mization seeded with tensions from the prior time point assumes that the tensions are correlated across

346 these time points. This is evidently true as the inter-frame interval approaches zero and evidently false

347 as the same interval approaches infinity. DLITE's informed prior decreases in usefulness as we in-

348 crease this interval or the timescale of our system's force variance decreases. 3) Finally, as the amount

349 of biological data increases, implementation of DLITe must be optimized for computation speed in

350 large colonies.

351 DLITE offers comparable tension inference to existing methods when applied to single time

352 points, increased performance when applied across time points, increased stability in the face of seg-

353 mentation challenges, and increased stability when applied to limited experimental data sets. Future

354 use of DLITE will look at dynamic changes in cell-cell forces in larger data sets of ZO-1 tight junc-

355 tions, allowing the visualization of cell-cell forces during large scale colony reorganization.

Competing Interests

357 The authors declare that they have no competing financial interests.

Figure 1: 3D cell view of tight junction location, how this is represented in the model, and the challenges in doing so. (A) 3D view of tight junctions in human induced pluripotent stem (hIPS) cells from the Allen Cell Explorer (Green - Tight junctions, Purple - Membrane, Blue - Nucleus). We infer cell-shape and edge shape from tight junctions as they localize to the tension bearing apical surface of epithelial-like tissues. (B) Schematic of cell-interface representation used in DLITE and CellFIT force-inference techniques [34]. A colony is represented as a set of nodes (n), edges (e) and cells (c). Edges are directional. Tension balance occurs at each node (red arrows at n_5 and n_6). Pressure difference ($\Delta p_{d,b}$) across a junction is estimated using Laplace's law (red arrows at $e_{5,6}$). (C) Ambiguities in image segmentation introduce challenges to successful tension inference. Time t - 1 shows single time point challenges like spurious edge/node detection, irregular edge curvature, node location errors and incomplete segmentation. Time t shows time lapse challenges like biological network reorganization and topological changes.
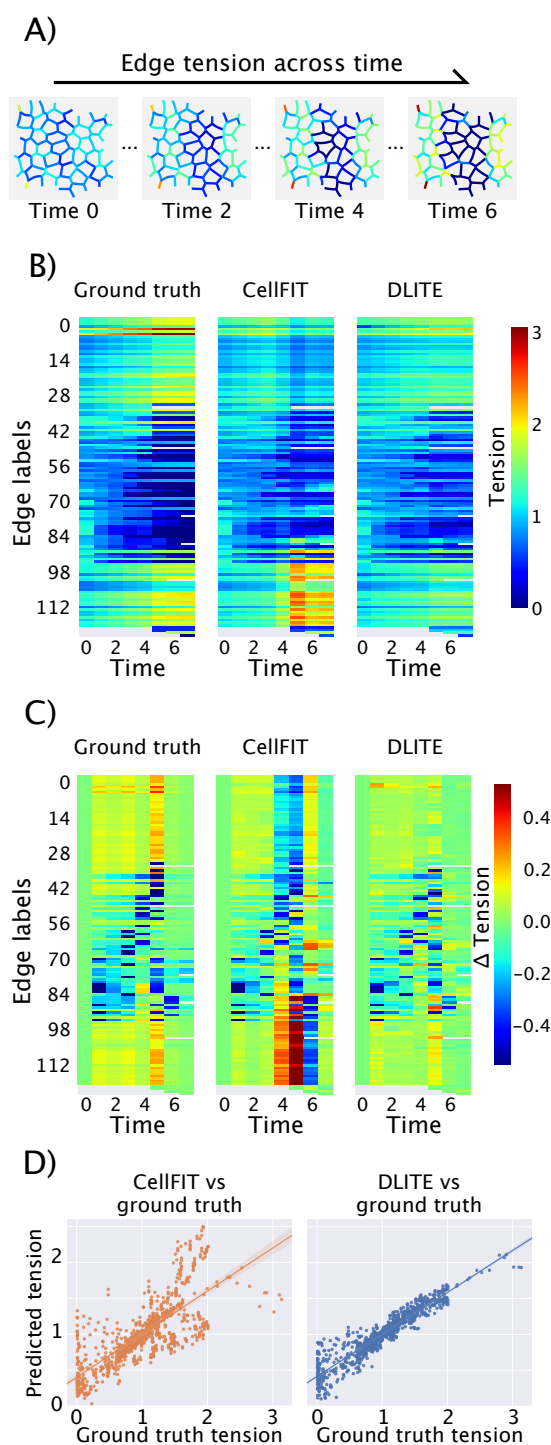

16

Figure 2: Comparison of DLITE and CellFIT force-inference techniques for digitized time series. Synthetic colonies were generated from random Voronoi tessellations and morphed to minimum energy configurations (Eq. 5) using Surface Evolver [49]. A random set of edges within the colony were perturbed by decreasing or increasing their tensions, resulting in a new colony structure; repeating this process produced a time-series of colony rearrangement. (A) Time-series of a synthetic colony showing the decrease in tension of 70 edges in the middle of the colony and the increase in tension of 40 edges along the boundary. (B) Heatmap of dynamic edge tensions for ground truth, CellFIT, and DLITE. (C) Heatmap of dynamic change (derivative of tension) in edge tensions for ground truth, CellFIT, and DLITE. (D) A comparison of inferred vs ground truth tensions for CellFIT (r = 0.75) and DLITE (r = 0.94). Here, r is the Pearson's correlation coefficient.

Dynamic tension estimation

Figure 3: Reduced sensitivity to connectivity errors in DLITE. (A) Ground truth tensions for a synthetic geometry containing 330 edges generated used Surface Evolver with a single edge connectivity error (circled in red). (B) Edge tensions computed using CellFIT for the geometry in (A). (C) Edge tensions computed using DLITE for the geometry in (A). (D) Time-series of a synthetic geometry containing 37 edges generated using Surface Evolver with a single edge connectivity error at time 8 (circled in red). This edge is found again in time step 10 (representing a transient encoding error) but treated as a new edge. (E) Heatmap of dynamic edge tensions for ground truth, CellFIT (r = 0.14) and DLITE (r = 0.87) for the time-series in (D). (F) Heatmap of dynamic change (derivative of tension) in edge tensions for ground truth, CellFIT, and DLITE for the time-series in (D).
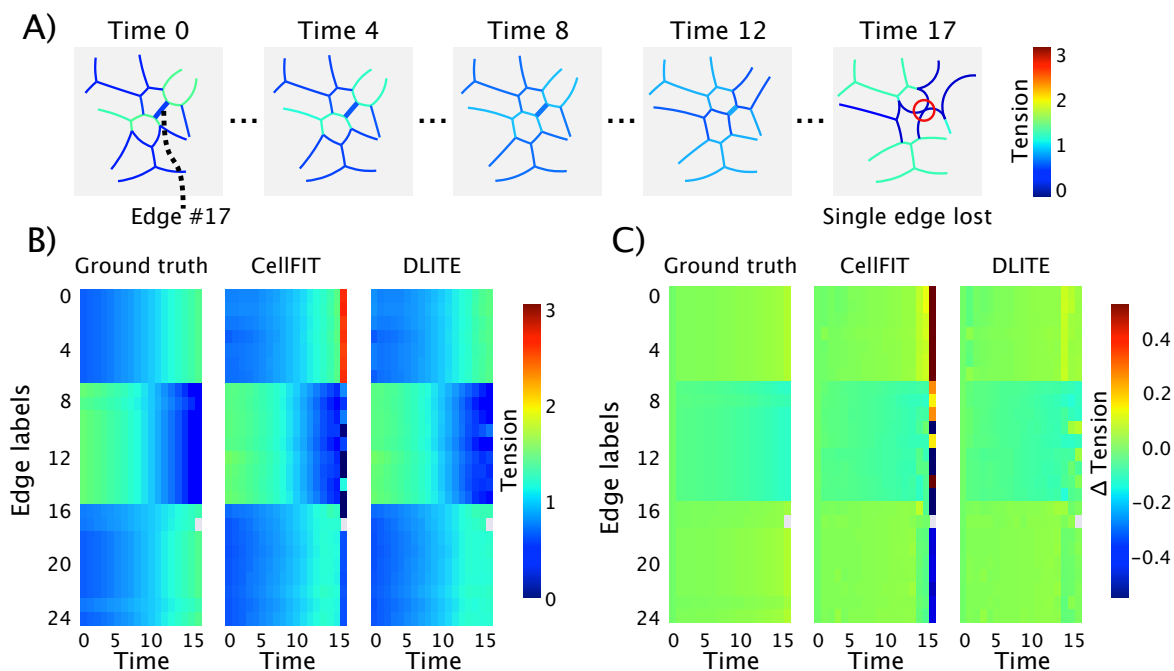

18

Figure 4: Reduced sensitivity to topological changes in DLITE. (A) Time-series of a synthetic geometry containing 24 edges generated using Surface Evolver where edge label 17 disappears at time 17 (circled in red). (B) Heatmap of dynamic edge tensions for ground truth, CellFIT (r = 0.75), and DLITE (r = 0.98). DLITE shows reduced disruption to tension prediction on topological change and more closely matches the ground truth tension. (C) Heatmap of dynamic change (derivative of tension) in edge tensions for ground truth, CellFIT and DLITE.
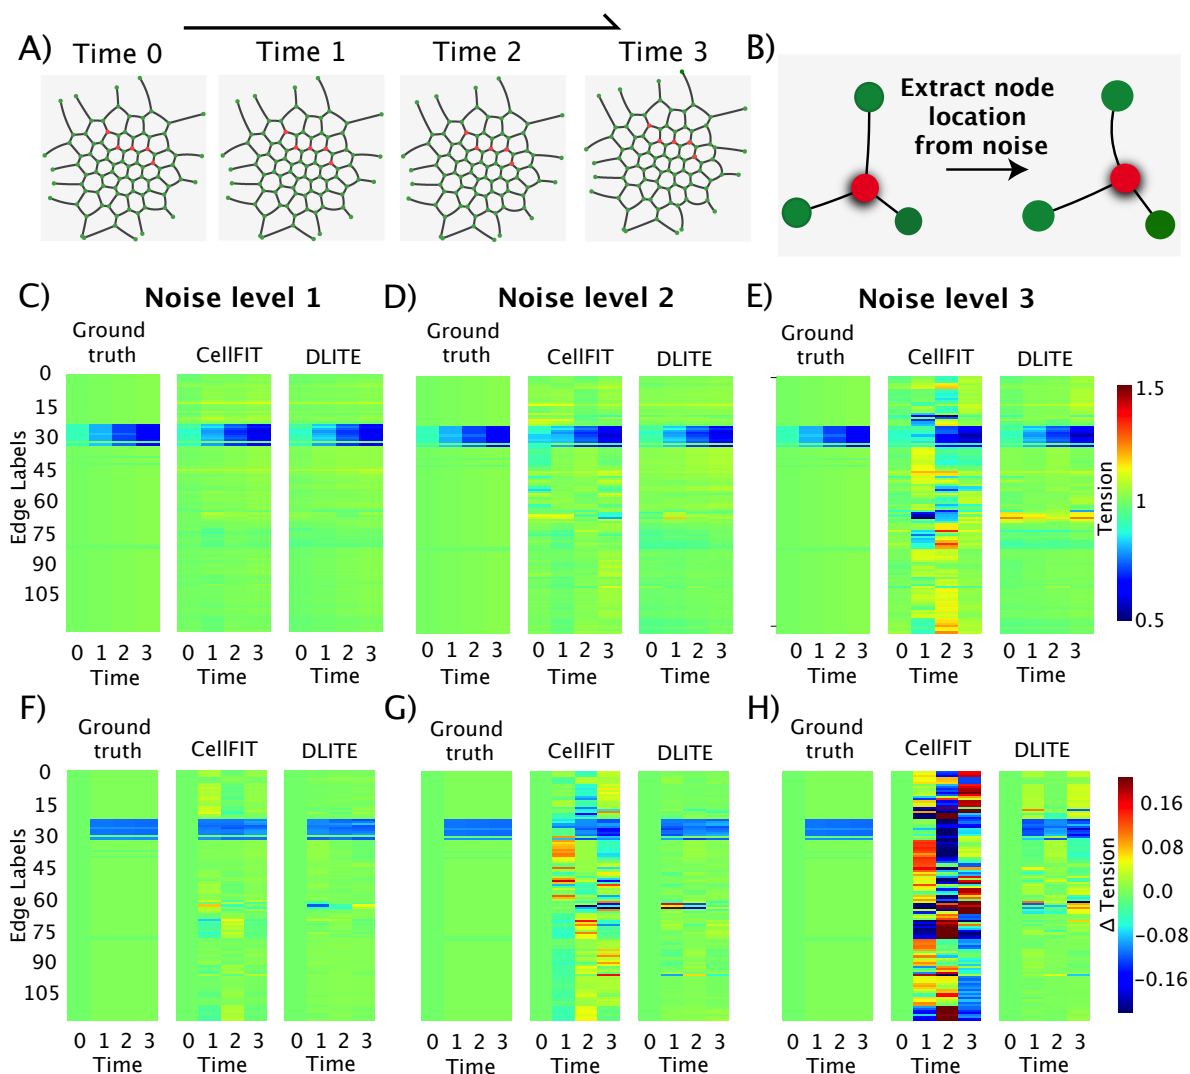

Dynamic tension estimation

Figure 5: Reduced sensitivity to node location errors in DLITE. Noise levels 1, 2 and 3 correspond to random Gaussian noise added to red node locations, all with a mean 0 and standard deviation 0.1, 0.5 and 1 respectively. (A) Time-series of synthetic colony generated using Surface Evolver. The five nodes subject to perturbation with noise are shown in red. (B) Change in shape of a single triple junction around the red node in the presence of noise. (C, D, E) Heatmap of dynamic edge tensions for ground truth, CellFIT and DLITE at Noise levels 1, 2 and 3 respectively. (F, G, H) Heatmap of dynamic change (derivative of tension) in edge tensions for ground truth, CellFIT and DLITE at Noise levels 1, 2 and 3 respectively.
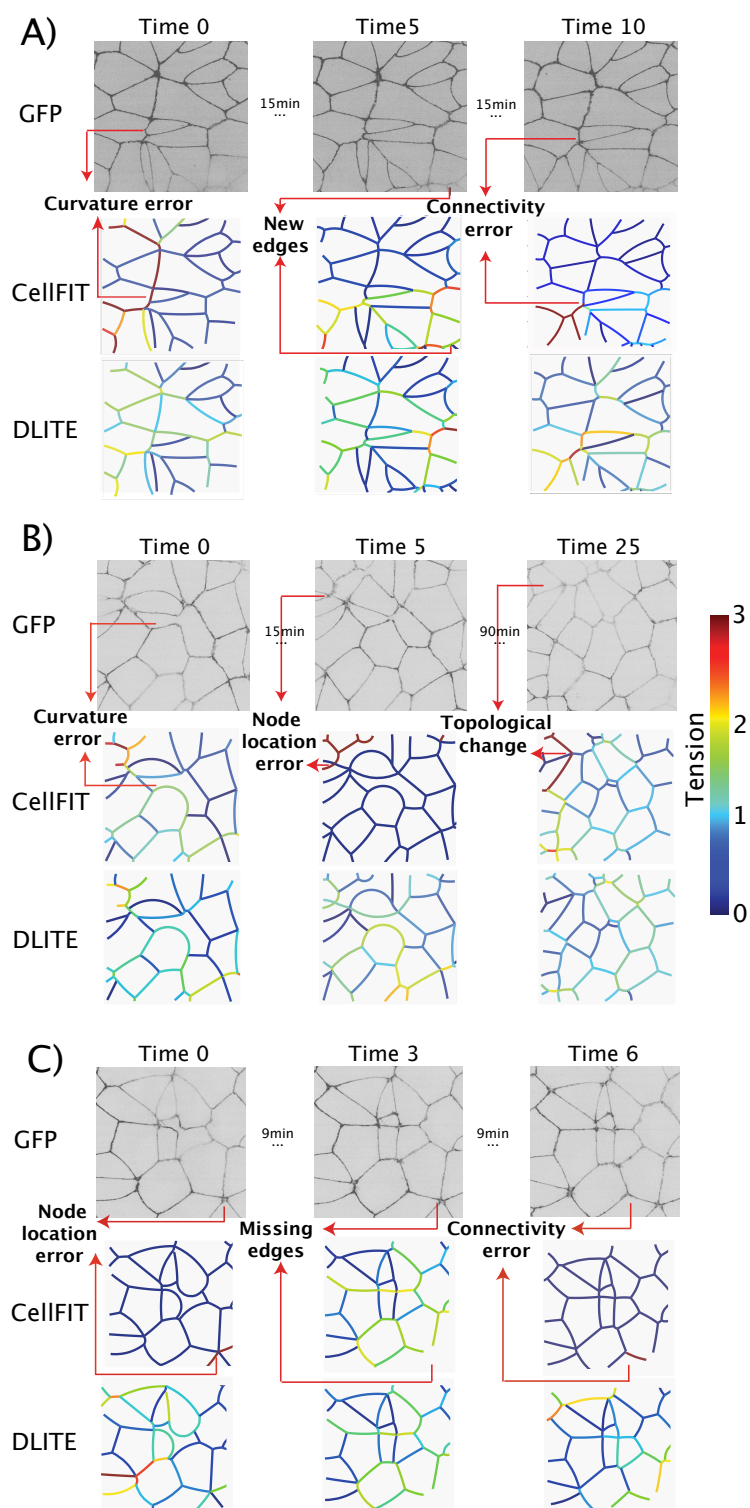

Dynamic tension estimation

Figure 6: DLITE shows increased tension stability during tension inference in mutliple time-series of ZO-1 labeled hIPS cells. Example frames from three time series are shown in A, B and C and arranged as ZO-1 GFP (upper) and colony edge tensions predicted by CellFIT (middle) and DLITE (lower). Here we use κ to denote the condition number of the tension matrix G_γ (Eq. 6). (A) DLITE shows increased stability to curvature errors (Time 0, $\kappa = 69$), new edges (Time 5, $\kappa = 32.5$), connectivity errors (Time 10, $\kappa = 136$). (B) DLITE shows increased stability to curvature errors (Time 0, $\kappa = 23$), node location errors (Time 5, $\kappa = 10^{16}$) and topological changes (Time 25, $\kappa = 46$). (C) DLITE shows increased stability to node location errors (Time 0, $\kappa = 10^{16}$), missing edges (Time 3, $\kappa = 31$) and connectivity errors (Time 6, $\kappa = 10^{18}$).)

21

Dynamic tension estimation

Figure 7: Dynamic cell-cell forces from a time-series of ZO-1 tight junction locations in hIPS cells. DLITE shows reduced fluctuation in tension change, showing more temporally correlated tension predictions. (A) Time-series of ZO-1 GFP images (upper) and dynamics of colony edge tension predicted by DLITE (lower). The following time points are shown: 0, 5, 10, 15, 20 and 25. Time 15 shows an increase in tension along a ridge in the middle of the colony following a mitotic event and the forming of a new edge (circled in red). The time interval between adjacent time points was 3 minutes. (B) Tension residuals at every time point showing an estimate of central tendency and corresponding confidence interval. (C) Heatmap of dynamic edge tensions predicted by CellFIT and DLITE. (D) Heatmap of dynamic change (derivative of tension) in edge tensions predicted by CellFIT and DLITE. (E) Distribution of Δtension (derivative of tension) at every time point for CellFIT and DLITE.

Supplementary Online Material

Data structures

We implemented our code using the standard scientific Python stack. An object/class groups similar constructs together. Here, we defined 4 main objects - nodes, edges, cells and colonies. Nodes are objects with a unique location (x, y) and node label. Edges are objects that are connected to two unique nodes with a defined edge curvature, direction and edge label. Cells are objects with a unique cell label that contain a particular list of nodes and edges, where a combination of the contained edges forms a cycle. Colonies are objects comprising a list of cells and stray edges (edges that are not part of any cell). Each class has several other defined properties that were useful for time-series tracking and cell-cell force inference.

Curve-fitting

We fit a circular arc to a given list of (x, y) edge co-ordinates using a least squares fitting routine from the Python module Scipy [40].

Cell finding algorithm

Given a list of nodes and edges, we loop through every edge to find the two (or fewer) cells of which each edge might be a part. We start from an initial edge and find the closest edge that forms the smallest (or largest) angle with the current edge. We repeated this process by setting the new edge as current edge, until the second node of the current edge is identical to the first node of the initial edge , thus indicating a complete cycle. We validated this algorithm in planar graphs generated using the NetworkX module [67]. In pseudocode, this can be formulated as shown in Algorithm 1.

Surface Evolver simulations

Synthetic geometries were generated using the Surface Evolver [49], which provides a precise way to make model geometries using soap film physics. An initial surface was first defined in a datafile comprising a list of vertices, edges, facets and bodies, along with any volume or area constraints.

23

Algorithm 1 Cell finding algorithm

1: **procedure**
2:     **for** *edge* in *edges* **do**
3:         *Conn edges* ← Network connectivity of *edge*
4:         *next edge* ← max, min angle of *Conn edges*
5:         **if** *cell found* **then return** False
6:         **while** cell not found **do**
7:             *Current edge* ← *Next edge*
8:             *Conn edges* ← Network connectivity of *Current edge*
9:             *next edge* ← max, min angle of *Conn edges*
10:             **if** *cell found* **then return** Cell

Since we defined a 2D string model with a space dimension of 2, we enforced area constraints on the facets instead of volume constraints on the bodies. To generate the datafile, we made random Voronoi tessellations. This was followed by Lloyd relaxation to make a more uniform tessellation. Edges were then assigned random tensions. All cells were assigned the same fixed area in a single simulation (typically 5000). Evolver then uses gradient descent to morph the surface to a minimum energy (W) configuration. This energy (W) was defined as Eq. 5 with the pressure energy enforced as an area constraint. Multiple mesh refinement steps (adjustments of every vertex in the system) were used to ensure a minimum of 10 mesh points along every edge (for better curve-fitting). The evolved geometries were screened for edges that form cell-cell interfaces (as opposed to edges along the boundary that do not form an interface). These edges, along with their corresponding nodes and cells, were stored using our data structures.

In order to generate a time-series, we took a given geometry and perturbed the tension of random edges. Surface Evolver was used to solve for the minima. This was the next frame t + 1. We repeated this tension perturbation procedure uniformly, such that the geometry was smoothly changing its curvature along every edge in correlation with a changing tension (Eq. 5). By stitching together multiple Evolver geometries that progressively showed increasing or decreasing curvature/tension of certain edges, we were able to generate movies of colony rearrangement that was smooth across time, for whom the ground truth tensions were the input to Surface Evolver.

CellFIT solution

CellFIT [34] evaluates the tension balance as a matrix system defined as

$$G_\gamma \gamma = 0, \tag{6}$$

where γ is a list of surface tension magnitudes and G_γ is a matrix of edge tension coefficients (sin's and cos's). Since the system of equations is over-determined, this is formulated as a constrained least squares (Karush Kuhn Tucker or KKT) matrix, which can be written as

$$\begin{bmatrix} G_\gamma^T G_\gamma & C_1^T \\ C_1 & 0 \end{bmatrix} \begin{bmatrix} \gamma_1 \\ \vdots \\ \gamma_N \\ \lambda_1 \end{bmatrix} = \begin{bmatrix} 0 \\ \vdots \\ 0 \\ N \end{bmatrix}, \tag{7}$$

where $C_1 = [1, \ldots, 1]$, λ_1 is a Lagrange multiplier, and N is the number of edge tensions. This normalizes the average edge tension to 1. Similarly, the pressure balance is evaluated as a matrix system

$$G_p p = q, \tag{8}$$

where p is a matrix of cell pressures and q is a matrix of edge tensions divided by edge curvatures (t/r), as per Laplace's law. This is also formulated as a constrained least squares matrix as

$$\begin{bmatrix} G_p^T G_p & C_2^T \\ C_2 & 0 \end{bmatrix} \begin{bmatrix} p_1 \\ \vdots \\ p_M \\ \lambda_2 \end{bmatrix} = \begin{bmatrix} q_1 \\ \vdots \\ q_M \\ 0 \end{bmatrix}, \tag{9}$$

where $C_2 = [1, \ldots, 1]$, λ_2 is a Lagrange multiplier and M is the number of cell pressures. This normalizes the average edge pressure to 0.

Force-inference algorithm

In pseudocode, the force-inference algorithm can be formulated as shown in Algorithm 2.

25

Dynamic tension estimation

Algorithm 2 Dynamic cell-cell force inference algorithm

1: **procedure**

2:     **for** $frame$ in $movie$ **do**

3:         *edges, nodes* ← trace of *image*

4:         *cells* ← *edges, nodes*

5:         *colony* ← *cells*

6:         **if** *labels* is *empty* **then return** *new labels* ← *nodes, edges, cells*

424 Cell plating for imaging

425 Human induced pluripotent stem cells (hiPSCs) were plated on glass-bottom multiwell plates (1.5H
426 glass; Cellvis) coated with phenol red–free GFR Matrigel (Corning) diluted 1:30 in phenol red–free
427 DMEM/F12 (Life Technologies). Cells were seeded at a density of 2.5×10^3 in 96-well plates and
428 (12.5–18) imaged 3–4 days later. A detailed protocol can be found at the Allen Cell Explorer (Allen
429 Institute for Cell Science, 2017).

430 Live-cell imaging

431 Cells were imaged on a Zeiss spinning-disk microscope with a Zeiss $100\times/1.25$ W C-Apochromat
432 Korr UV Vis IR objective, a CSU-X1 Yokogawa spinning-disk head, and Hamamatsu Orca Flash 4.0
433 camera. Microscopes were outfitted with a humidified environmental chamber to maintain cells at
434 37°C with 5 % CO_2 during imaging. Time-lapse movies were acquired every 3 minutes for 1.5 hours.
