Keywords: antibiotic resistance, ribosomal RNA (rRNA), ribosome, RNA methylation, RNA methyltransferase.

ABSTRACT

Methylation of the small ribosome subunit rRNA in the ribosomal decoding center results in exceptionally high-level aminoglycoside resistance. Enzymes that methylate 16S rRNA on N7 of nucleotide G1405 (m⁷G1405) have been identified in both aminoglycoside-producing and clinically drug-resistance pathogenic bacteria. Using a fluorescence polarization 30S binding assay and a new crystal of the methyltransferase RmtC, we report a structure-guided functional study of 30S substrate recognition by the aminoglycoside-resistance 16S rRNA (m⁷G1405) methyltransferases. We find that the 30S binding site for these enzymes directly overlaps that of a second family of aminoglycoside-resistance 16S rRNA (m¹A1408) methyltransferases, suggesting both groups of enzymes may exploit the same conserved rRNA tertiary surface for docking on the 30S. Within RmtC we define an amino-terminal domain surface, comprising basic residues from both the N1 and N2 subdomains, that directly contribute to 30S binding affinity. In contrast, additional residues lining a contiguous adjacent surface on the CTD are found to be critical for 16S rRNA modification but do not directly contribute to binding affinity. Thus, our studies define the critical features of m⁷G1405 methyltransferase-substrate recognition and distinguish at least two distinct, functionally critical contributions of the tested enzyme residues: 30S binding affinity and stabilizing a binding-induced 16S rRNA conformation necessary for G1405 modification. Our study sets the scene for future

high-resolution structural studies of the 30S-methyltransferase complex and potential exploitation of unique aspects of substrate recognition for future therapeutic purposes.

Methylation of 16S rRNA has been identified as a prominent mechanism of self-protection in aminoglycoside-producing bacteria and is emerging as a new threat to the clinical efficacy of aminoglycoside antibiotics (1,2). Both the intrinsic methyltransferases of drug producers and acquired enzymes of human and animal pathogens chemically modify the aminoglycoside binding site in the decoding center of the bacterial 30S subunit to block drug binding and confer exceptionally high-level resistance. Regarding the acquired enzymes specifically, of most concern is that these resistance determinants have been identified on various mobile genetic elements, often in conjunction with other resistance enzymes (2-4). As such, the aminoglycoside-resistance methyltransferases can make the bacteria expressing them pan-resistant to entire subclasses of aminoglycosides (2,5), including even the most recent generation drugs like plazomicin (6,7). More broadly, given the extensive modification of bacterial rRNAs, especially in functionally critical regions like the decoding center, understanding rRNA methyltransferase-ribosome subunit interactions has relevance to both fundamental bacterial physiology as well as mechanisms of antimicrobial resistance.

The aminoglycoside-resistance 16S rRNA methyltransferases are functionally divided into two subfamilies that modify the ribosome at either the N7 position of 16S rRNA nucleotide G1405

(m⁷G1405) or the N1 position of A1408 (m¹A1408). While enzymes from both subfamilies are found in aminoglycoside-producing bacteria, the m⁷G1405 methyltransferases (Fig. 1A) are far more clinically prevalent than their m¹A1408 methyltransferase counterparts (2,8). In contrast, to the single m¹A1408 methyltransferase, NpmA, that was clinically isolated from *E. coli* strain ARS in Japan (9), the m⁷G1405 methyltransferases are globally disseminated and have been found in multiple different human pathogens (2).

Both free and 30S-bound m¹A1408 methyltransferases, including NpmA, have been extensively characterized, revealing the molecular basis of their specific substrate recognition and modification mechanisms (10-15). These enzymes exploit a conserved 16S rRNA tertiary surface adjacent to helix 44 (h44) to dock on the 30S, explaining the requirement for intact 30S as their substrate. Two extended regions that connect the fifth/ sixth and sixth/ seventh β -strands of the methyltransferase core fold (β 5/6 and β 6/7 linkers, respectively) position key residues for recognition and stabilization of A1408 in a flipped conformation for methylation (10,13).

Structures of the m⁷G1405 methyltransferases RmtB (16), which has been identified in multiple Gram-negative pathogens, and Sgm (17), from the producer of sisomicin derivative G52, *Micromonospora zionensis*, have revealed a distinct methyltransferase architecture. Specifically, these enzymes possess a significantly larger N-terminal extension but no extended sequences within the methyltransferase core fold comparable to those in the m¹A1408 methyltransferases. A likely role for the unique N-terminal domain and some functionally critical residues have been identified for 30S interaction by the m⁷G1405 methyltransferases (16,18,19). However, to date, no direct binding analysis to allow dissection of important residues in binding or stabilization of a catalytically competent state of the enzyme-substrate complex has been performed. As such, there is a critical gap in our understanding of m⁷G1405 methyltransferases 30S substrate recognition, despite the potential threat these enzymes pose for clinical aminoglycoside resistance.

Here, we have extended the use of a 30S binding assay previously developed in our lab for studies of NpmA (13) to the m⁷G1405

methyltransferases. From these direct 30S binding measurements and a structure-guided mutagenesis strategy based on a new structure of a m⁷G1405 methyltransferase family member (RmtC), we develop a new model for 30S substrate recognition m⁷G1405 methyltransferases. We identify a molecular surface in the N-terminal domain that is critical for 30S docking, while numerous residues on an adjacent surface of the CTD do not contribute to binding affinity but likely control critical conformational changes necessary for catalysis of rRNA modification.

RESULTS

m⁷G1405 methyltransferases bind 30S with similar affinity and at a site overlapping that of the m¹A1408 methyltransferases—We previously developed a competition fluorescence polarization (FP) assay to measure the binding affinity of wild-type and variant NpmA proteins to define this methyltransferase's mechanism of 30S substrate recognition and m¹A1408 modification (13). We speculated that the close proximity of nucleotides A1408 and G1405 in h44 (Fig. 1B) might also make this assay applicable to direct quantification of m⁷G1405 methyltransferase-30S interactions. In this assay, a fluorescein-labeled, single-Cys variant of NpmA (NpmA-E184C*) is pre-bound to 30S (high FP state) and a range of concentrations of unlabeled competitor protein added to displace the NpmA-E184C* probe (shown schematically in Fig. 1C), allowing determination of the methyltransferase 30S-binding affinity (K_i). We first applied the assay to analysis of 30S-RmtC interaction and observed a RmtC-concentration dependent decrease in FP. The resulting data were fit obtain a K_i of 89.5 nM (Fig. 1C,E). This value is comparable to the 60 nM affinity previously measured for the m¹A1408 methyltransferase NpmA (13). Binding measurements were also performed with RmtA, RmtB, RmtD and RmtD2, which together with RmtC, represent each of the three subclades in the m⁷G1405 methyltransferase phylogenetic tree (Fig. 1A). All binding affinities for these methyltransferases were comparable within a ~2.5-fold range from 48 to 118 nM (Fig. D,E).

These results confirm our established assay using the NpmA-E184C* probe as suitable for direct binding measurements of m⁷G1405

methyltransferases to 30S and thus as a tool to provide a deeper analysis of their substrate recognition mechanism. These data also reveal that the binding site of the m⁷G1405 methyltransferases on the 30S subunit does indeed overlap with that of the m¹A1408 methyltransferases, suggesting they may also exploit the same conserved rRNA tertiary surface for specific substrate recognition. We chose to use RmtC for further structural and functional studies of 30S-m⁷G1405 methyltransferase interaction for several reasons. Most importantly, there has been no such analysis of RmtC to date and this enzyme is both in the same subclade as ArmA and most distant from RmtB (**Fig. 1A**), two commonly observed pathogen-acquired m⁷G1405 methyltransferases. The selection of RmtC thus offers the opportunity to identify conserved features of the 30S recognition mechanism across all m⁷G1405 methyltransferases.

Structure of the RmtC-SAH complex—The X-ray crystal structure of RmtC bound to S-adenosylhomocysteine (SAH), the methylation reaction by-product, was determined and refined at 3.25 Å resolution (**Table 1**). RmtC adopts a fold consistent with those of other m⁷G1405 methyltransferases RmtB and Sgm (16,17), as expected. Specifically, RmtC possesses a large amino-terminal domain (NTD) appended to its carboxy-terminal domain (CTD) methyltransferase fold (**Fig 2A,B**). The NTD is structurally divided into two subdomains, N1 and N2, each comprised of three α-helices. N1 forms a globular three-helical bundle, while the three helices of N2 are extended across the N-terminal half of the CTD (**Fig. 2A**). The CTD adopts a canonical Class I methyltransferase fold with a seven-stranded β-sheet core containing a central topological switch point that forms the SAM binding pocket (**Fig. 2B**).

In the RmtC-SAH complex, the SAH is bound in a pocket lined by numerous conserved residues, with numerous hydrogen binding and hydrophobic interactions. Two highly conserved residues, Arg111 and Asp160, anchor the SAH carboxylate group and ribose hydroxyl groups, respectively (**Fig. 2C**), while Asp188 and Gln212 position the base via hydrogen bonds to the adenine amino group and ring N7. The SAH ribose and adenine moieties are also surrounded by a collection of hydrophobic side chains on each side that define the shape of the binding pocket. Overall,

the interactions made by RmtC with SAH in the SAM binding pocket are consistent with previous structures of RmtB and Sgm bound to cosubstrate (16,17). During the course of this work, a structure of *apo* RmtC (PDB ID: 6CN0) was also deposited by the Center for Structural Genomics of Infectious Diseases. Comparison of the RmtC-SAH complex with this structure reveals the interactions within the SAM binding pocket to be mostly maintained. However, some potential conformational flexibility is apparent in residues Tyr60 and Ser107. These residues line the opening to the SAM binding pocket and may assist in positioning G1405 close to the SAM methyl group for modification (17).

Structural alignment of our RmtC structure with those of RmtB and Sgm confirms these proteins are structurally similar overall (average RMSDs of 2.62 and 3.05 Å, respectively). However, a substantial difference in the orientation of the N1 subdomain relative to the remainder of the protein is apparent in alignments made using only the CTD of each structure (**Fig. 2D**), reducing the average RMSDs to 1.59 and 1.50 Å, respectively. Additionally, at least two residues in all four copies of RmtC in the crystal are disordered in the sequence that links N1 and N2 (between positions 62 and 64). Together, these observations suggest the potential for flexibility in N1 subdomain position relative to the remainder of the protein and the sequence between N1 and N2 may act as a hinge that allows movement of this subdomain (**Fig. 2D**). Given the essential role of the N1 domain in substrate binding (see below), such mobility between the N1 and N2 domains that may be an important aspect of specific 30S substrate recognition.

Identification of potential 16S rRNA-binding residues in RmtC—Previous studies of Sgm, ArmA and RmtB identified the importance of the m⁷G1405 methyltransferase NTD in substrate recognition and have also suggested a specific role in 30S binding for some residues within both protein domains (16-19). The likely importance of conserved positive surface charges in the NTD are further supported by our structure of RmtC in which residues of the N1 and N2 subdomains form an extended, contiguous positively charged surface that could interact with 16S rRNA (**Fig. 3A**). Previous structure-guided mutagenesis of RmtB coupled with tobramycin minimum inhibitory

concentration (MIC) assays identified several residues potentially important for 30S binding (16), including highly conserved residues within a structurally disordered loop (corresponding to RmtC residues 237-246; Loop²³⁷⁻²⁴⁶). In the SAH-bound structure of RmtC, like the previously determined structures of RmtB and Sgm (16,17), there is weak or no density visible for most Loop²³⁷⁻²⁴⁶ residues, including the highly conserved Lys236 and Arg241. The functional importance of these and other conserved residues in the absence of an obvious role in Rmt protein structure or SAM binding is suggestive of an important contribution to 30S substrate recognition. However, to date, no measurements of 30S binding have been made for any m⁷G1405 methyltransferase to directly test the roles of these important residues.

To gain deeper insight into 30S recognition by RmtC and other m⁷G1405 methyltransferases, we therefore selected nine individual residues for site-directed mutagenesis, based on insights from both our RmtC structure and the previous studies of other enzymes (Table 2 and Fig. 3B). Four basic residues in the N1 and N2 domains were substituted with Glu to assess the contribution of the positive surface they collectively form (Fig. 3A). Lys236 in the CTD is conserved in all intrinsic and acquired enzymes, while the remaining residues tested, His54 in the N1 domain and Arg211, Arg241 and Met245, were previously identified in RmtB (16), except. Finally, since Arg241 and Met245 were previously tested only as part of a variant in which the Loop²³⁷⁻²⁴⁶ was replaced by four Ala residues (16), we prepared each individual residue substitution as well as the equivalent loop alteration. All variant RmtC proteins were expressed and could be purified as for wild-type RmtC. To further ensure residue substitutions did not substantially impact protein folding and stability, the unfolding inflection temperature (T_i) was measured for all purified proteins (Table 3). Almost all T_i values for both apparent unfolding transitions were < 2.5 °C different from wild-type RmtC, indicative of retained structural integrity. The only exception was for the RmtC-K20E/R50E double variant which exhibited slightly larger ΔT_i values (4.0 and 4.5 °C). As described in the following sections, each RmtC variant was assessed for 30S binding using the established FP assay and resistance (MIC) against kanamycin and gentamicin in bacteria expressing the enzymes

(Table 3).

Residues in N1 and N2 primarily contribute to RmtC-30S binding affinity—Single substitutions with Glu of each basic residue in either the N1 (K20E and R50E) or N2 (R68E or K72E) domain reduces 30S binding affinity of the protein in FP assays (Fig. 4A,B and Table 3). The extent of the reduction in binding affinities range from ~5-fold for K72E to ~11-13-fold for R50E and R68E, while no binding was measurable for K20E. Consistent with these observations, double substitutions of each pair of residues in N1 or N2 also resulted in affinities below the detectable limit in the assay (Fig. 4A,B and Table 3), revealing the collective contributions of the two N2 residues (Arg68 and Lys72) to binding in addition to the N1 domain (Lys20 and Arg50).

The RmtC proteins with N2 substitutions R68E, K72E or R68E/K72E were next tested for their ability to confer resistance to kanamycin or gentamicin. Intermediate MICs were determined for the single substitutions indicating a partial loss of conferred resistance, while resistance was completely abolished in the double variant (Table 3). The activities of these RmtC variants in bacteria thus correlated well with the measured *in vitro* binding affinities. The effects of substitutions in the N1 domain were also largely consistent in their impact on binding and activity (MIC), though it is noteworthy that the R50E substitution completely restored susceptibility to both antibiotics despite only partially reducing the enzyme's 30S affinity (Table 3). This distinction may reflect a more complex role for Arg50 involving both a contribution to 30S binding affinity and a functionally critical conformational change in enzyme or substrate. For example, Arg50 might promote or stabilize a movement of the N1 subdomain relative to the CTD, as suggested by structural comparisons between RmtC and other enzymes (as noted above).

Finally, among the N1 subdomain variants, substitutions at His54 (to either Ala or Glu) produce the most striking results. For both variants, the enzyme is completely inactive, with MICs for both antibiotics at the same level as in the absence of enzyme, and yet neither substitution impacts 30S binding affinity (Fig. 4C and Table 3). Thus, while clearly critical for RmtC activity, H54 does not directly contribute to 30S binding, but instead must

play a distinct, critical role within the substrate recognition mechanism. This observation, along with the impacts of K20E and R50E, also further points to the primary importance of the N1 subdomain in specific 30S recognition.

Conserved CTD residues surrounding the SAM-binding pocket are functionally critical but do not contribute to 30S binding affinity—The RmtC CTD contains several residues and a structurally disordered loop region (Loop²³⁷⁻²⁴⁶) that are potentially critical for 30S binding. These residues line the protein surface adjacent to His 54 of the N1 domain and surrounding the opening to the SAM-binding pocket (**Table 2** and **Fig. 3B**). Consistent with prior analyses of RmtB (16), replacement of the RmtC loop with four Ala residues (Loop²³⁷⁻²⁴⁶→A₄) ablated the enzyme's ability to confer resistance to kanamycin and gentamicin, with the same result also observed for the single substitution M245A within the loop (**Table 3**). Single substitutions to either Ala to Arg were also made for three basic residues: one within Loop²³⁷⁻²⁴⁶ (Arg241), one immediately preceding the loop (Lys236) and a third more distant in primary sequence but on the adjacent protein surface (Arg211). Each substitution had the same impact on protein activity in all three cases. Substitution with Ala resulted in a partial reduction in resistance conferred by the RmtC variant to kanamycin and/or gentamicin (intermediate MICs), while substitution with Glu fully ablated resistance for all three variant enzymes (**Table 3**).

These results confirm the functional importance of the four tested residues, which line a continuous surface with H54 and the other critical residues of the N1 domain (**Fig. 3B**). The relative effects of Ala and Glu substitutions for each of the three basic residues, R211I, K236 and R241, further suggest direct contact with the negative phosphate backbone of 16S rRNA given the greater defect with the charge reversal. Remarkably, however, none of the substitutions nor the loop swap (Loop²³⁷⁻²⁴⁶→A₄) resulted in a measurable change in 30S binding affinity (**Fig. 5** and **Table 3**). Thus, like the N1 residue His54, these residues do not directly contribute to 30S binding affinity, and instead must play a distinct but critical role in substrate recognition, such as promoting or stabilizing a conformationally altered state of the enzyme and/or substrate necessary for catalysis of

m⁷G1405 modification.

DISCUSSION

The bacterial ribosome is a major target for antibiotics such as aminoglycosides, which typically interfere with the fidelity of mRNA decoding (20,21). Although side effects have limited aminoglycoside use to treatment of serious infections, increasing resistance to other widely used antibiotics has led to a reevaluation of their use in clinical practice (21-23). Additionally, progress in mitochondrial ribosome structural biology (24,25) and semi-synthesis of novel aminoglycosides (26,27) can support future efforts to design new aminoglycosides with fewer side effects. As such, this important class of antimicrobials has the potential to be exceptionally useful in the treatment of serious hospital-based infections, especially those caused by Gram negative pathogens. Unfortunately, however, the clinical emergence over the last decade of aminoglycoside-resistance 16S rRNA (m⁷G1405) methyltransferases (ArmA or Rmt A-H) (2,5) pose a new threat to the efficacy of both current and new aminoglycosides, such as plazomicin (6,7). Detailed studies, such as those described here, of the resistance methyltransferases that incorporate these rRNA modification are thus needed to support development of strategies to counter the effects of these resistance determinants.

Previous studies of m⁷G1405 methyltransferases of pathogenic (RmtB) or aminoglycoside-producer (Sgm) bacterial origin, have begun to reveal some details of 30S substrate recognition by this enzyme family (16-19). However, prior studies have typically relied on enzyme activity (e.g. MIC) measurements to indirectly infer the importance of specific residues in 30S binding. Without direct analysis of specific contributions of key residues to 30S binding affinity or other distinct roles in the process of specific substrate recognition, our understanding of the mechanism of 30S recognition and modification by the m⁷G1405 methyltransferases remained incomplete. We therefore adapted a previously developed FP assay (13) and used it here to more fully define substrate recognition by the m⁷G1405 methyltransferase enzymes.

The applicability of our FP assay using a probe based on the m¹A1408 methyltransferase

30S substrate recognition by RmtC

NpmA to the analysis of m⁷G1405 methyltransferase-30S interaction clearly demonstrates that the 30S binding site of these two groups of enzymes must substantially overlap. Both the m¹A1408 and m⁷G1405 methyltransferases require the intact 30S subunit as their minimal substrate and the molecular basis for this requirement was revealed for the former enzyme subfamily by the structure of the 30S-NpmA complex. NpmA interacts exclusively with 16S rRNA and docks onto a conserved rRNA tertiary surface comprising helices 24, 27 and 45, adjacent to the h44 target site (10). This surface is bound by a group of positively charged residues, Lys66, Lys67, Lys70 and Lys71, that line a single helical region on the β 2/ β 3 linker of the core methyltransferase fold (13). Our results with RmtC suggest that the m⁷G1405 methyltransferases likely exploit the same conserved rRNA tertiary surface for specific substrate recognition and that this is likely accomplished via interactions made by residues of the N1 and N2 domains. Specifically, a group of basic residues, Lys20, Arg50, Arg68 and Lys72, form a single positively charged surface and each contributes directly to 30S binding affinity. Lys20 and Arg50 in the N1 subdomain are highly conserved in all m⁷G1405 methyltransferases further underscoring their importance in 30S binding. In contrast, Arg68 and Lys72 in the first α -helix of the N2 domain are conserved only within the subclade comprising RmtC enzymes. However, in other m⁷G1405 methyltransferases, alternative basic residues positioned on the same surface of the protein may provide equivalent interactions with 16S rRNA, such as Lys76/Lys85 of the second α -helix of the N2 domain RmtB or Arg97/Arg106 of the second and third α -helices of the N2 domain Sgm. Thus, while some specific details may vary among different representatives of the m⁷G1405 methyltransferase subfamily, the extended positive surface created by residues of the N1/N2 domain is likely a critical first step in enzyme-substrate interaction.

Our results also reveal that multiple residues on the adjacent protein surface that surrounds the SAM-binding pocket, including His54 of the N1 subdomain and several others in the CTD, do not contribute to 30S binding affinity despite being critical for RmtC activity. These residues play no obvious direct role in RmtC protein structure and do not interact with SAM; in

fact, despite their functional importance, Lys236, Arg241 and Met245 are in or adjacent to Loop²³⁷⁻²⁴⁶ which is disordered in the free protein. These observations and our findings that alteration of these residues abrogates activity but has no effect on 30S binding affinity suggest that they must play a distinct but essential role in substrate recognition. In NpmA, a single residue, Arg207, exhibits similar properties. Despite making no contribution to 30S binding affinity, Arg207 is nonetheless critical as it directly stabilizes the rRNA backbone of the flipped A1408 nucleotide. Our results suggest similar roles for these conserved residues in RmtC. The three basic residues, Arg211, Lys236, Arg241, likely contact the 16S rRNA backbone to stabilize a binding induced change in its structure. These residues and His54 and Met245 may also directly contact the G1405 nucleotide to position it for catalysis of methyltransfer. Why multiple residues are required in this way is unclear, but it is noteworthy that G1405 is much less directly accessible at the top of h44 than A1408 and may require greater distortion of the native 16S rRNA structure to create a conformation compatible with methylation by the enzyme. The likely need for significant reorganization of 16S rRNA for G1405 methylation was also suggested by previous attempts to dock Sgm on the 30S subunit resulting in no models with the target base within 15 Å of the SAM methyl group (17).

In summary, our model for m⁷G1405 methyltransferase action on the 30S parallels that previously developed for the m¹A1408 methyltransferase NpmA: initial binding to 30S is mediated by multiple residues of the N1 and N2 subdomains (analogous to the NpmA β 2/ β 3 linker), and an extended surface adjacent to this docking point is necessary to promote and/ or stabilize a novel, binding-induced 16S rRNA conformation. In particular, we speculate that one or more of the functionally critical residues on this surface is likely essential for stabilizing G1405 in a flipped conformation for methylation, as commonly observed for other RNA modifying enzymes (10,28-30). A high-resolution structure of a 30S:m⁷G1405 methyltransferase will be necessary to define these specific molecular details. However, our findings suggest that multiple aspects of m⁷G1405 methyltransferase-substrate binding and specific recognition will emerge that may present suitable molecular targets to interfere with the

action of these resistance determinant in pathogenic bacteria.

EXPERIMENTAL PROCEDURES

Sequence analysis—m⁷G1405 methyltransferase sequences were retrieved by BLAST search using RmtB (UniProt ID: Q76G15) as the query sequence. Sequence redundancy was removed using CD-HIT (31) with a cut off of 98% sequence identity and aligned using CLUSTAL omega. A neighbour joining phylogenetic tree was constructed using MEGA 6.0 (32) and the residue propensities were calculated using BioEdit (33).

Protein expression and purification—Constructs for expression of RmtA, RmtB and RmtC from a modified pET44 plasmid (“pET44-HT”) were generated using synthetic *E. coli* codon-optimized genes (GenScript) as described previously (34). Equivalent expression constructs for RmtD and RmtD2 were previously reported (35). Variants of RmtC were prepared using the megaprimer whole-plasmid PCR method (13,36) and confirmed by automated DNA sequencing. Expression of all wild-type methyltransferases and variant RmtC proteins from the modified pET44 vector produced proteins with an N-terminal 6xHis tag and thrombin protease recognition sequence. For all experiments other than structural studies, proteins were used directly as the presence of the N-terminal sequence did not affect methyltransferase activity. For crystallization of RmtC, a construct for expression of tag-free wild-type RmtC (pET44-RmtC) was also generated, essentially as described previously (34).

Recombinant proteins were expressed and purified to near homogeneity using Ni²⁺-affinity and gel filtration chromatographies, as described previously (35). Purified proteins were concentrated to ~1 mg/ml, and flash frozen for storage at -80 °C before use. Tag-free wild-type RmtC was expressed similarly except that terrific broth was used as the bacterial growth medium. Purification was accomplished using heparin-affinity chromatography in 20 mM HEPES buffer pH 7.6, containing 150 mM NaCl, 10% glycerol 6 mM β-mercaptoethanol. After washing with eight column volumes of buffer, the protein was eluted using a 0.15-1 M NaCl gradient in the same buffer. Fractions containing RmtC were pooled, concentrated and the protein further purified by gel

filtration chromatography on a Superdex 75 16/60 gel filtration column preequilibrated with the same buffer but containing no glycerol. Tag-free wild-type RmtC was stored as noted above or used directly for crystallization experiments (see below).

T_i measurements—The thermal stability of wild-type and variant RmtC proteins was assessed using a Tycho NT.6 instrument (NanoTemper) to ensure protein quality between different preparations of proteins and before/after freezing. In this assay, protein unfolding over a 35 to 95 °C temperature ramp is monitored via intrinsic fluorescence at 350 and 330 nm and the “inflection temperature” (T_i) determined for each apparent unfolding transition from the change in the ratio of these fluorescence measurements. All RmtC proteins unfolded in two equivalent apparent transitions; T_i values reported in **Table 3** are the average of two measurements and all replicates were the same within 0.5 °C.

FP assay (K_i determination)—Preparation of 30S ribosomal subunits from *E. coli* (MRE600), generation of the fluorescein-labeled NpmA probe (NpmA-E184C*) and measurement of 30S-Rmt binding were accomplished essentially as previously described (13). Briefly, FP measurements were made using a Biotek Synergy Neo2 instrument with each 100 μl binding reaction containing 30S (50 nM), NpmA-E184C* (50 nM) and Rmt protein (2 nM-10 μM) in 20 mM HEPES buffer, pH 7.0, containing 75 mM KCl, 5 mM Mg(OAc)₂, 2 mM NH₄Cl and 3 mM β-mercaptoethanol. Solutions containing 30S and NpmA-E184C* were mixed first, incubated for 10 minutes at room temperature, aliquoted into the 96 well plate and FP measured to ensure uniform and stable FP signal prior to addition of the competing protein and final FP measurement. Data handling, curve fitting to determine K_i using the one-binding-site competition binding equation and error calculations were performed in GraphPad Prism8. All binding measurements were made in at least three independent experiments for wild-type Rmt enzymes and at least two independent experiments for all RmtC variants, with each comprising technical triplicates or quadruplicates (technical replicates were averaged prior to plotting in GraphPad Prism). Control experiments with the established competitor NpmA (13) or wild-type RmtC were included in all experiments to measure

binding of the different Rmt enzymes and RmtC variants, respectively.

Crystallization, X-ray data collection and structural refinement of the RmtC-SAH complex—Tag-free wild-type RmtC was concentrated to 12 mg/ml in the final purification buffer and mixed with a two-fold molar excess of SAH for 10 minutes at room temperature prior to screening for crystallization conditions on a Crystal Phoenix (Art Robbins Instruments). Initial crystals were obtained at 20 °C using a 1:1 mixture of protein solution and 0.1 M HEPES pH 7.0 buffer containing 2 M ammonium sulfate. An additive screen was used to further optimize crystal size and diffraction with the best diffracting crystal coming from a condition containing 3 mM mellitic acid. X-ray data were collected remotely at the Southeast Regional Collaborative Access Team (SER-CAT) 22-ID beamline at the Advanced Photon Source, Argonne National Laboratory. Data were processed and scaled in Mosflm (37) in space group P61. The structure was determined by molecular replacement in Phenix (38) using a structure of *apo* RmtC (PDB ID: 6CN0) that was deposited into the PDB during the course of this study. The ligand docking and model optimization was accomplished using multiple rounds of refinement and model adjustment in Phenix (38) and Coot (39), respectively. PDB-Redo (40) was also used to

optimize the quality of the final model. Complete X-ray data collection and refinement statistics are provided in **Table 1**.

Kanamycin and gentamicin MIC assays—Fresh lysogeny broth (5 ml) containing 100 µg/ml ampicillin was inoculated (1:100 dilution) with saturated overnight culture of *E. coli* BL21(DE3) harbouring pET-HT plasmid encoding wild-type or variant RmtC. Cells were grown to OD₆₀₀ ~0.1 at 37 °C with vigorous shaking. Cells from 1 ml of this culture were collected by centrifugation, washed twice with phosphate buffered saline solution (0.5 ml) and resuspended in cation-adjusted Mueller-Hinton (CA-MHB) medium to an OD₆₀₀ of 0.1 (5 x 10⁷ cfu/ml). Cells were further diluted 50-fold with CA-MHB and 100 µl used to inoculate (1 x 10⁵ cfu/well) an equal volume of CA-MHB media containing 10 µM IPTG and 4-2048 µg/ml antibiotic that was predisposed on a 96 well plate. For each RmtC protein, four to six individual colonies were tested from at least two independent transformations of bacterial cells with plasmid. Wells with no antibiotic or no cells served as controls in each replicate. Plates were incubated at 37 °C with shaking and OD₆₀₀ measurements taken after 24 hours. The MIC was defined as the lowest concentration of antibiotic that inhibited growth (OD₆₀₀ of <0.05 above background).

Acknowledgements: We thank Dr. Christine M. Dunham for comments on the draft manuscript and members of the Conn and Dunham labs at Emory University for helpful discussions throughout the course of this work.

Conflict of interest: The authors declare that they have no conflicts of interest with the contents of this article.

FOOTNOTES

This work was supported by NIH-NIAID grant R01-AI088025 (to GLC). SER-CAT is supported by its member institutions and equipment grants (S10 RR25528 and S10 RR028976) from the National Institutes of Health. Use of the Advanced Photon Source was supported by the U. S. Department of Energy, Office of Science, Office of Basic Energy Sciences, under Contract No. W-31-109-Eng-38.

Abbreviations used are: AME, aminoglycoside modifying enzyme; CA-MHB, cation-adjusted Mueller-Hinton broth; CTD, carboxy-terminal domain; FP, fluorescence polarization; h44, (16S rRNA) helix 44; MIC, minimum inhibitory concentration; NTD, amino-terminal domain; Rmt, (aminoglycoside) resistance methyltransferase; SAH, S-adenosylhomocysteine; SAM, S-adenosyl-L-methionine; T_i, inflection temperature.

^aValues in parenthesis are 95% CI for the fit K_i . NB indicates “no binding”.

^bValues in parenthesis are the absolute difference in T_i compared to wild-type RmtC.

FIGURE LEGENDS

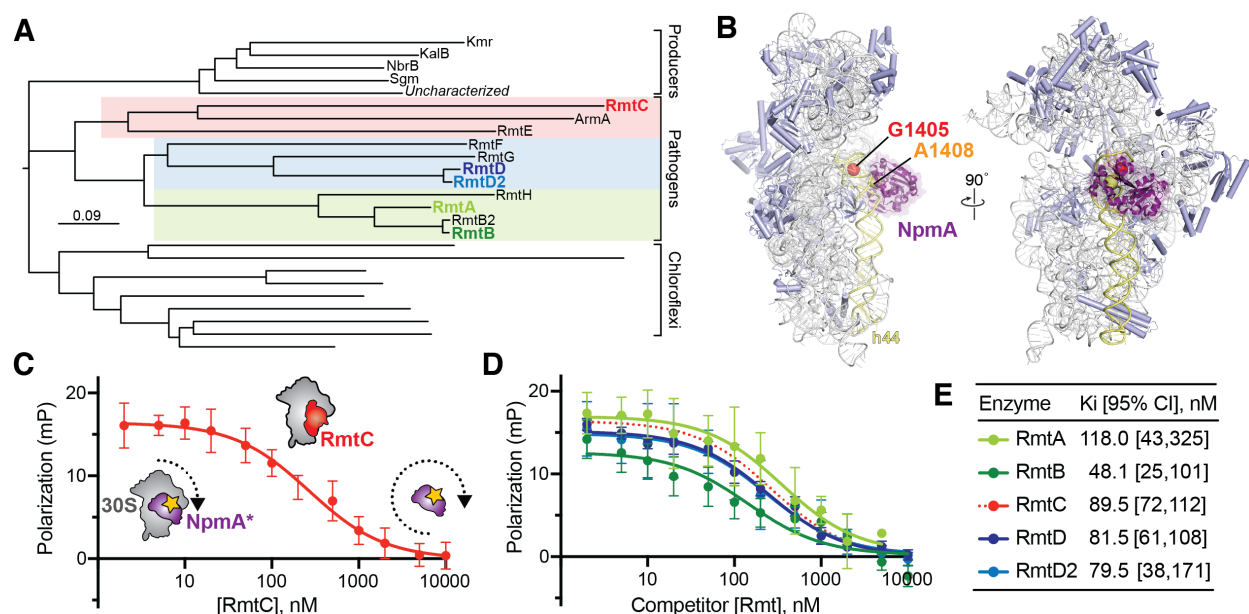

Figure 1. The m⁷G1405 methyltransferase family and binding site on 30S subunit. **A.** Phylogenetic tree of m⁷G1405 methyltransferase enzymes including acquired genes in gammaproteobacterial and Gram-negative pathogenic bacteria, aminoglycoside producing bacteria and uncharacterized homologs belonging to the chloroflexi. Pathogen-associated genes (color-coded regions) are further divided into three subclades represented in this work by RmtA/ RmtB, RmtD/ RmtD2 and RmtC. **B.** Structure of the bacterial 30S subunit bound to NpmA (purple) (PDB ID: 4OX9) showing the proximity of nucleotides G1405 (red) and A1408 (orange) at the top of h44 (yellow) in the ribosome decoding center. **C.** Schematic of the competition FP assay for 30S-methyltransferase binding using the NpmA-E184C* probe (purple) and application to RmtC binding (red). At low competitor concentration (left of plot) high FP signal arises due to NpmA-E184C* interaction with 30S; displacement of the probe by RmtC results in lower FP signal from the free probe (right of plot). **D, E.** Competition FP binding experiments with NpmA-E184C* and five different unlabeled wild-type Rmt enzymes. The RmtC curve in panel D (red dotted line) is the same as in panel C and is shown for comparison. Binding affinities (K_i) and associated 95% confidence interval were obtained from fits to the data shown in panels C and D; Error bars represent SD of the measurements.

30S substrate recognition by RmtC

Figure 2. Structure of the RmtC-SAH complex. **A.** Crystal structure of the RmtC-SAH highlighting (red) the extended N-terminal domain characteristic of the aminoglycoside-resistance 16S rRNA (m^7G1405) methyltransferases. The N-terminal domain is divided into two subdomains, N1 and N2. The locations of the bound SAH (yellow sticks) and a partially disordered loop (Loop²³⁷⁻²⁴⁶) adjacent to the opening to the SAM-binding pocket, are also indicated. **B.** The same view of the RmtC structure as panel A (*right*) but highlighting the seven β -strand core (red) of the C-terminal methyltransferase fold (with N1 and N2 shown as semi-transparent cartoon). **C.** Two orthogonal detailed views of the interactions made with SAH in the SAM-binding pocket. **D.** Alignment of RmtC (red) with the structures of RmtB (PDB ID: 3FRH; orange) and Sgm (PDB ID: 3LCV; blue), shown in two orthogonal views, *top*, reveal potential flexibility in the position of the N1 domain relative to the N2/CTD domains via a hinge region between N1 and N2 (zoomed view).

30S substrate recognition by RmtC

Figure 3. Selection of mutants defining the 30S interaction surface. **A.** The electrostatic surface potential of the RmtC structure reveals the N1 and N2 domains to be rich in positively charged residues (blue). **B.** Locations of positively charged residues in the N1 and N2 domain and other conserved or putative functionally critical residues for 30S interaction. All residues shown as sticks with semi-transparent spheres, as well as R241 located in the partially disordered Loop²³⁷⁻²⁴⁶) were substituted to test their role in 30S recognition (see main text and **Tables 2** and **3** for details).

Figure 4. Functionally critical residues in the NTD contribute primarily to 30S binding affinity. Competition FP binding experiments with unlabeled RmtC proteins with single or double substitutions of basic (Arg/ Lys) residues with Glu in the **A.** N1 subdomain (K20E and R50E) or **B.** N2 subdomain (R68E and K72E). **C.** Competition FP binding experiment with RmtC-H54E. In all panels, the wild-type RmtC fit shown for comparison (dotted black line) is the same as that shown in **Fig 1C,D**. Error bars represent the SEM. Binding affinity (K_i) for each variant protein derived from these data are shown in **Table 3**.

30S substrate recognition by RmtC

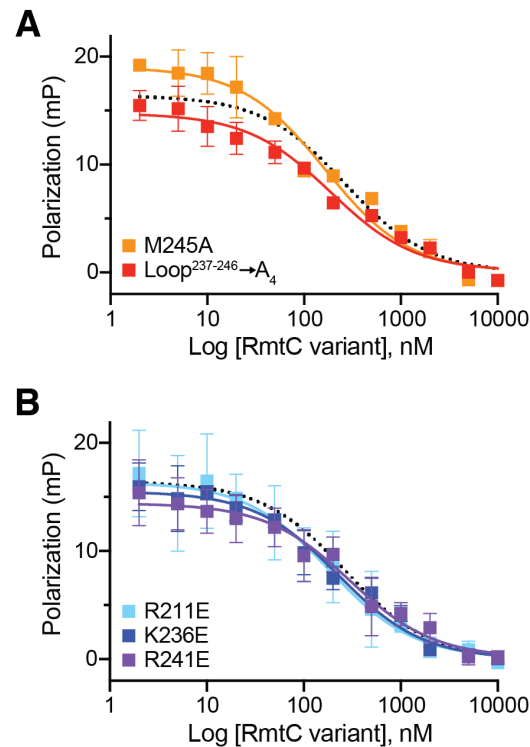

Figure 5. Functionally critical CTD residues do not contribute to 30S binding affinity. Competition FP binding experiments with unlabeled RmtC CTD variant proteins. **A.** Analysis of RmtC with Loop²³⁷⁻²⁴⁶→A₄ (red) or M245A single substitution with the loop. **B.** Analysis of RmtC proteins with single substitutions of basic (Arg/ Lys) residues with Glu within the CTD. In both panels, the wild-type RmtC fit shown for comparison (dotted black line) is the same as that shown in **Fig 1C,D**. Error bars represent the SEM. Binding affinity (K_i) for each variant protein derived from these data are shown in **Table 3**.
