Abstract
Genomic selection, enabled by whole genome prediction (WGP) methods, is revolutionizing plant breeding. Existing WGP methods have been shown to deliver accurate predictions in the most common settings, such as prediction of across environment performance for traits with additive gene effects. However, prediction of traits with non-additive gene effects and prediction of genotype by environment interaction (G×E), continues to be challenging. Previous attempts to increase prediction accuracy for these particularly difficult tasks employed prediction methods that are purely statistical in nature. Augmenting the statistical methods with biological knowledge has been largely overlooked thus far. Crop growth models (CGMs) attempt to represent the functional relationships between plant physiology and the environment in the formation of yield and similar output traits of interest. Thus, they can explain the impact of G×E and certain types of non-additive gene effects on the expressed phenotype. Approximate Bayesian computation (ABC), a novel and powerful computational procedure, allows the incorporation of CGMs directly into the estimation of whole genome marker effects in WGP. Here we provide a proof of concept study for this novel approach and demonstrate its use with a simulated data set. We show that this novel approach can be considerably more accurate than the benchmark WGP method GBLUP in predicting performance in environments represented in the estimation set as well as in previously unobserved environments for traits determined by non-additive gene effects. We conclude that this proof of concept demonstrates that using ABC for incorporating biological knowledge in the form of CGMs into WGP is a very promising novel approach to improving prediction accuracy for some of the most challenging scenarios of interest to applied geneticists.

Introduction
Genomic selection (Meuwissen et al. [1]), enabled by whole genome prediction (WGP) methods, is revolutionizing plant breeding (Cooper et al. [2]). Since its inception, attempts to improve prediction accuracy have focused on: developing improved and specialized statistical models (Yang and Tempelman [3], Heslot et al. [4], Kärkkäinen and Sillanpää [5], Technow and Melchinger [6]), increasing the marker density used (Meuwissen and Goddard [7], Erbe et al. [8], Ober et al. [9]), increasing the size and defining optimal designs of estimation sets (Rincent et al. [10], Windhausen et al. [11], Technow et al. [12], Hickey et al. [13]) and better understanding the genetic determinants driving prediction accuracy (Daetwyler et al. [14], Habier et al. [15]).
In-silico based phenotypic prediction, enabled by dynamic crop growth models (CGMs), dates back to the late 60’s (van Ittersum et al. [16]) and it has constantly evolved since then through inclusion of scientific advances made in plant and crop physiology, soil science and micrometeorology (Keating et al. [17]; van Ittersum et al. [16]). CGMs used in plant breeding are structured around concepts of resource capture, utilization efficiency and allocation among plant organs (Cooper et al. [18]; Hammer et al. [19]; Passioura [20]; Yin et al. [21]) and are used to: characterize environments (Chapman et al. [22]; Löffler et al [23]), predict consequences of trait variation on yield within a genotype x environment x management context (Hammer et al. [24]), evaluate breeding strategies (Chapman et al. [25]; Messina et al. [26]; Messina et al. [27]), and assess hybrid performance (Cooper et al. [2]).

Early attempts to extend the use of CGMs to enable genetic prediction have focused on developing genetic models for parameters of main process equations within the CGM (Chenu et al. [28]; Messina et al. [29]; Yin et al. [21]). Linking quantitative trait locus (QTL) models and GCMs for complex traits motivated adapting CGMs to improve the connectivity between physiology and genetics of the adaptive traits (Hammer et al. [30]; Messina et al. [27]; Yin et al. [21]). However, despite a tremendous body of knowledge and experience, CGMs were largely ignored for the purpose of WGP.

There is ample evidence for the importance of epistasis in crops, including for economically important traits such as grain yield in maize (Wolf and Hallauer [31], Eta-Ndu and Openshaw, [32]; Holland [33]). Yield and other complex traits are the product of intricate interactions between component traits on lower hierarchical levels (Cooper et al. [34], Hammer et al. [19], Riedelsheimer et al. [35]). If the relationship between the underlying component traits is non-additive, epistatic effects can occur on the phenotypic level of complex traits even if the gene action is purely additive when characterized at the level of the component traits (Holland [33]). This phenomenon was first described for multiplicative relationships between traits by Richey [36] and later quantified by Melchinger et al. [37]. CGMs, which explicitly model these non-linear relationships among traits, have therefore the potential to open up novel avenues towards accounting for epistatic effects in WGP models by explicit incorporation of biological knowledge.

The target population of environments for plant breeding programs is subject to continuous change, expansion and increases in diversity (Cooper et al. [2]). To select for performance in specific environments, genotype by environment (G×E) interactions have to be predicted. Genomic prediction of G×E interactions is therefore of great interest to scientists and practitioners alike. Previous attempts incorporated G×E interactions in WGP models through environment specific marker effects (Schulz-Streeck et al. [38]) or genetic and environmental covariances (Burgeño et al. [39]). Later Jarquín et al. [40] and Heslot et al. [41] developed WGP models that accounted for G×E interactions by means of environmental covariates.

While these previous attempts are promising, they are purely statistical in nature and do not leverage the substantial biological insights into the functional mechanisms determining performance in specific environments. CGMs are an embodiment of this biological knowledge and might serve as a key component in novel WGP models for predicting G×E interactions. In fact, Heslot et al. [41] recognized this potential for CGMs. However, they employed them only for computing stress covariates from environmental data, which were subsequently used as covariates in purely statistical WGP models.

Given the potential merits of integrating CGMs in WGP, the question arises of how to combine the two in a unified predictive system. The ever increasing computational power of modern computing environments allows for efficient simulation from the most complex of models, such as CGMs (Messina et al. [27]). This computational power is
leveraged by approximate Bayesian computation (ABC) methods, which replace the calculation of a likelihood function with a simulation step, and thereby facilitate analysis when calculation of a likelihood function is impossible or computationally prohibitive. ABC methods were developed in population genetics, where they helped solve otherwise intractable problems (Tavare et al. [42], Pritchard et al. [43], Csilléry et al. [44], Lopes and Beaumont [45]). However, ABC methods are rapidly adopted in other scientific fields, such as ecology (Lawson Handley et al. [46]), systems biology (Liepe et al. [47]) and hydrology (Sadegh and Vrugt [48]). Recently, Marjoram et al. [49] proposed using ABC methods for incorporating the biological knowledge represented in gene regulatory networks into genome-wide association studies, arguing that this might present a solution to the “missing heritability” problem.

Here we make the case that ABC may hold great promise for enabling novel approaches to WGP as well. Thus, the objective of this study is to provide a proof of concept, based on a simulated data set, for using ABC as a mechanism for incorporating the substantial biological knowledge embodied in CGMs into a novel WGP approach.

Materials and Methods

CGM and environmental data

We used the maize CGM developed by Muchow et al. [50], which models maize grain yield development as a function of plant population (plants m$^{-2}$), daily temperature (°C) and solar radiation (MJ m$^{-2}$) as well as several genotype dependent physiological traits. These traits were total leaf number (TLN), area of largest leaf (AM), solar radiation use efficiency (SRE) and thermal units to physiological maturity (MTU). Details on how the values for these traits were generated for the genotypes in the synthetic data set are provided later. However, the values used were within typical ranges reported in the literature. The simulated intervals for TLN, AM, SRE and MTU were [6, 18] (Meghji et al. [51], Muchow et al. [50]), [700, 800] (Muchow et al. [50], Elings [52]), [1.5, 1.7] (Muchow and Davis [53]) and [1050, 1250] (McGarrahan and Dale [54], Muchow [55], Nielsen et al. [56]), respectively, with average values at the midpoints of the intervals.

We chose Champaign/Illinois (40.08° N, 88.24° W) as a representative US corn belt location. Temperature and solar radiation data were obtained for the years 2012 and 2013 (Data provided by the Water and Atmospheric Resources Monitoring Program, a part of the Illinois State Water Survey (ISWS) located in Champaign and Peoria, Illinois, and on the web at www.sws.uiuc.edu/warm). In 2012, we used as sowing date April 1st and a plant population of 5 plants m$^{-2}$. In 2013, the sowing date used was May 1st and the plant population 10 plants m$^{-2}$. The 2012 and 2013 environments therefore differed not only in temperature and solar radiation but also in simulated management practices. The temperature and solar radiation from date of sowing is shown in Fig. 1 and typical growth curves obtained from the CGM for the two environments are shown in Fig. 2.

The CGM can be viewed as a function $F$ of the genotype specific inputs (the physiological traits) and the environment data

\[
F(y_{TLN}, y_{SRE}, y_{AM}, y_{MTU}, \Omega_k)
\]

where $y_{TLN}$, etc. are the values of the physiological traits observed for the $i^{th}$ genotype and the weather and management data of environment $k$ is represented as $\Omega_k$. To simplify notation, we will henceforth use $F(\cdot)_{ik}$ to represent the CGM and its inputs for genotype $i$ in environment $k$. 

Approximate Bayesian Computation (ABC)

ABC replaces likelihood computation with a simulation step (Tavare et al. [42]). An integral component of any ABC algorithm is therefore the simulation model operator $\text{Model}(y^*_{ik} | \theta)$ which generates simulated data $y^*_{ik}$ given parameters $\theta$. In our proof of concept study, the crop growth model $F(\cdot)_{ik}$ represents the deterministic component of $\text{Model}(y^*_{ik} | \theta)$, to which a Gaussian noise variable distributed as $\mathcal{N}(0, \sigma^2_{\varepsilon})$ is added as a stochastic component. If $\text{Model}(y^*_{ik} | \theta)$ is fully deterministic, the distribution sampled with the ABC algorithm will not converge to the true posterior distribution when the tolerance for the distance between the simulated and observed data goes to zero (Sadegh and Vrugt [48]).

The weather and management data $\Omega_k$ was assumed to be known, the physiological traits, however, were unknown and modeled as linear functions of the trait specific marker effects

$$
\begin{align*}
  y_{TLN_i} &= \mu_{TLN} + z_i u_{TLN} \\
  y_{AM_i} &= \mu_{AM} + z_i u_{AM} \\
  y_{SRE_i} &= \mu_{SRE} + z_i u_{SRE} \\
  y_{MTU_i} &= \mu_{MTU} + z_i u_{MTU},
\end{align*}
$$

(2)

where $z_i$ is the genotype vector of the observed biallelic single nucleotide polymorphism (SNP) markers of genotype $i$, $\mu_{TLN}$ etc. denote the intercepts and $u_{TLN}$ etc. the marker effects. For brevity, we will use $\theta$ to denote the joint parameter vector $[\mu_{TLN}, \ldots, \mu_{MTU}, u_{TLN}, \ldots, u_{MTU}]$.

We used independent Normal distribution priors for all components of $\theta$. The prior for $\mu_{TLN}$ was $\mathcal{N}(m_{TLN}, \sigma^2_{\mu_{TLN}})$. To simulate imperfect prior information, we drew the prior mean $m_{TLN}$ from a Uniform distribution over the interval $[0.8 \cdot TLN, 1.2 \cdot TLN]$, where $TLN$ is the observed population mean of TLN. The average difference between $m_{TLN}$ and $TLN$ then is 10% of the latter value. The prior variance $\sigma^2_{\mu_{TLN}}$, which represents the prior uncertainty was equal to 2.25. The prior means of AM, SRE and MTU were obtained accordingly and the prior variances $\sigma^2_{\mu_{AM}}$, $\sigma^2_{\mu_{SRE}}$ and $\sigma^2_{\mu_{MTU}}$ were 150, 0.3 and 225, respectively.

The prior for the marker effects $u_{TLN}$ was $\mathcal{N}(0, \sigma^2_{u_{TLN}})$, which corresponds to the BayesC prior (Habier et al. [57]). In BayesC, the prior variance of marker effects $\sigma^2_{u_{TLN}}$.
which introduces shrinkage, is the same across markers. For simplicity, we set this variance to a constant value and did not attempt to estimate it. Also in this case we simulated imperfect information by drawing the value of $\sigma^2_{u_{TLN}}$ from a uniform distribution over the interval $[0.8 \cdot \text{var}(TLN)/M, 1.2 \cdot \text{var}(TLN)/M]$, where $M$ is the number of markers and var$(TLN)$ the observed population variance of TLN. The prior variances of marker effects of the other traits were obtained accordingly.

The value of $\sigma^2_e$, the variance of the Gaussian noise variable that is part of the model operator $\text{Model}(y_{ik} | \theta)$, was drawn from a uniform distribution over the interval $[0.8 \cdot v_e, 1.2 \cdot v_e]$, where $v_e$ is the residual variance component of the phenotypic grain yield values used to fit the model.

Algorithm 1 in Table 1 shows pseudocode for the ABC rejection sampling algorithm we used. We used the Euclidean distance to measure the distance between the simulated and observed data. The tolerance level $\epsilon$ for the distance between the simulated and observed data was tuned in a preliminary run of the algorithm to result in an acceptance rate of approximately $1 \cdot 10^{-6}$. The number of posterior samples drawn was 100. We will refer to this ABC based prediction method that incorporates the CGM as ABC-CGM. The ABC-CGM algorithm was implemented as a C routine integrated with the R software environment (R Core Team [58]).

**Synthetic data set**

To test the performance of ABC-CGM, we created a biparental population of 1,550 doubled haploid (DH) inbred lines in silico. The genome consisted of a single chromosome of 1.5 Morgan length. The genotypes of the DH lines were generated by simulating meiosis events with the software package hypred (Technow [59]) according to the Haldane mapping function. On the chromosome we equidistantly placed 140 informative SNP markers. A random subset of 40 of these markers were assigned to be QTL with additive effects on either TLN, AM, SRE or MTU. Each physiological trait was controlled by 10 of the 40 QTL, which were later removed from the set of observed markers available for analysis.
Table 1. Pseudo code of ABC rejection sampling algorithm

    increment x
end while
```

Basic ABC rejection sampling algorithm to sample from the approximate posterior distribution of θ.

The additive substitution effects of the QTL were drawn from a Standard Normal distribution. Then raw genetic scores for each physiological trait were computed by summing the QTL effects according to the QTL genotypes of each DH line. These raw scores were subsequently re-scaled linearly to the aforementioned value ranges. Finally, phenotypic grain yield values were created as

$$y ik = F(\cdot)_{ik} + e_{ik},$$

where $e_{ik}$ is a Gaussian noise variable with mean zero and variance $v_e$. The value of $v_e$ was chosen such that the within-environment heritability of $y ik$ was equal to 0.85. We generated 25 synthetic data sets by repeating the whole process.

Estimation, prediction and testing procedure

The models were fitted using $N = 50$ randomly chosen DH lines as an estimation set. The remaining 1500 DH lines were used for testing model performance. Separate models were fitted using the 2012 and the 2013 grain yield data of the estimation set lines. The environment from which data for fitting the model was used will be referred to as estimation environment. Parameter estimates from each estimation environment were subsequently used to predict performance of the lines in the test set in both environments. Predictions for the same environment as the estimation environment will be referred to as observed environment predictions (e.g., predictions for 2012 with models fitted with 2012 data). Predictions for an environment from which no data were used in fitting the model will be referred to as new environment predictions (e.g., predictions for 2013 with models fitted with 2012 data).

As a point estimate for predicted grain yield performance in a specific environment we used the mean of the posterior predictive distribution for the DH line in question. The posterior predictive distribution was obtained by evaluating $F(\cdot)_{ik}$ over the accepted θ samples, using the weather and management data $Ω_k$ pertaining to that environment.

Prediction accuracy was computed as the Pearson correlation between predicted and true performance in the environment for which the prediction was made. The true grain yield performance was obtained by computing $F(\cdot)_{ik}$ with the true values of the physiological traits.

As a performance benchmark we used genomic best linear unbiased prediction...
(GBLUP, Meuwissen et al. [1]). The model is

$$y_{ik} = \beta_0 + z_i u + e_i$$  \hspace{1cm} (4)

where $\beta_0$ is the intercept, $u$ the vector of marker effects and $e_i$ a residual. As before, $z_i$ denotes the marker genotype vector. The GBLUP model was fitted with the R package rrBLUP (Endelman [60]). GBLUP and BayesC are comparable in their shrinkage behavior because both use a constant variance across markers. For GBLUP, predicted values were computed according to eq. (4) as $\beta_0 + z_i u$. Note that because the conventional GBLUP model does not utilize information about the target environment, observed and new environment predictions are identical.

Results and Discussion

Predicting performance in observed environments

The accuracy for observed environment predictions achieved by ABC-CGM was larger than that of the benchmark method GBLUP by 0.15 points, on average (Table 2, Fig. 3). This superiority of ABC-CGM over GBLUP can be explained by the presence of non-additive gene effects which cannot be captured fully by the latter. In the example scenario we studied, the non-additive gene effects on grain yield are a result of non-linear functional relationships between the physiological traits and grain yield, which was particularly pronounced for TLN (Fig. 4). This thus presents a particular case of epistasis, which might be called biological epistasis, that can arise even if the gene effects on the physiological component traits underlying the final trait of interest (grain yield in our case) are purely additive (Holland [33]).

Prediction accuracy for grain yield of DH lines in the test set, averaged over 25 replications. All differences within a row are statistically significant at a significance level of < 0.005.

We accounted for non-linear functional relationships among traits with the CGM. This enabled us to capture biological epistasis through simple linear models relating marker genotypes to the unobserved underlying physiological traits. Previously developed WGP models attempted to capture epistasis by directly fitting non-linear marker effects to the final trait of interest (e.g., Xu [61], Sun et al. [62], Howard et al. [63]). While these models showed some promise, they have not been adopted by practitioners on a larger scale. By combining statistics with biological insights captured by CGMs, ABC-CGM takes a fundamentally different approach and presents a potentially powerful alternative to purely statistical WGP models.

Predicting performance in new environments

New environment prediction accuracy was considerably lower than observed environment prediction accuracy, for both prediction methods (Table 2, Fig. 3). The average prediction accuracy for performance in 2012 when using the 2013 estimation...
Figure 3. Predicted vs. observed grain yield of 1500 DH lines in testing set for prediction methods ABC-CGM (top row) and GBLUP (bottom row). The estimation environment was 2012. Results shown are from a representative example data set. In this example, the accuracy for same environment predictions was 0.82 (ABC-CGM) and 0.72 (GBLUP). For new environment predictions it was 0.64 (ABC-CGM) and 0.47 (GBLUP).

The rank correlation between true performance in 2012 and 2013 was only 0.73 (averaged over 25 simulated data sets), which indicated the presence of considerable G×E interactions, including changes in rank (Fig. 5). That new environment prediction under the presence of G×E interactions is considerably less accurate than observed environment prediction was expected and already observed in other studies (Resende et al. [64], Windhausen et al. [11]). That the reduction in accuracy for ABC-CGM was less severe than for the conventional benchmark method GBLUP is encouraging because it indicates that the former method did succeed in predicting G×E interactions to some degree.

Predicting G×E interactions in new environments in which no yield testing was carried out previously, requires WGP models that link genetic effects (e.g., marker effects) with information that characterizes the environments. Jarquín et al. [40] accomplished this by fitting statistical interactions between markers and environmental covariates. A similar approach was taken by Heslot et al. [41], who in addition used a CGM to extract stress covariates from a large set of environmental variables.

ABC-CGM takes this approach a step further by making the CGM an integral part of the estimation procedure.

However, while novel prediction methods might succeed in narrowing the gap between new and observed environment prediction, the former should always be expected to be less accurate than the latter. Field testing should therefore be carried out in environments of particular importance for a breeding program to achieve the maximum attainable prediction accuracy for these. The same applies for target environments in which G×E interaction effects are expected to be particularly strong.
CGMs can help in identifying such environments, inform experimental design and utilization of managed environments (Messina et al. [27], Messina et al. [29]). However, the range of the target population of environments of modern plant breeding programs is much too large for facilitating yield testing in all of them (Cooper et al. [2]). Predicting performance in completely new environments will therefore always be required and novel methods like ABC-CGM are anticipated to be instrumental for enabling and enhancing success in this particularly daunting task.

Further developments

More sophisticated CGMs For this first proof of concept study, we assumed that the crop growth model used in the estimation process fully represented the systematic component of the data generating process, besides the random noise component. This was clearly a “best case scenario”. However, decades of crop growth modeling research have provided the know-how necessary to approximate real crop development to an almost arbitrary degree of accuracy (Keating et al. [17]), Renton [65], Hammer et al. [30]). Advanced CGMs such as APSIM (Keating et al. [17]), for example, model functional relationships between various crop parameters and external factors such as water and nutrient availability, soil properties as well as weed, insect and pathogen pressure. Thus, the tools are principally available for applying ABC-CGM in much more complex scenarios than the one studied by us.

Stochastic CGMs There are examples of the use of fully deterministic model operators in ABC (Toni et al. [66], Liepe et al. [67]). However, with fully deterministic model operators the sampled distribution would not converge to the true posterior when the tolerance level \( \epsilon \) goes to zero (Sadegh and Vrugt [48]) and instead reduce to a point mass over those parameter values that can reproduce the data. The CGM we used was fully deterministic. We therefore followed the example of Sadegh and Vrugt [48], who constructed a stochastic model operator by adding a random noise variable, with the same probabilistic properties as assumed for the residual component of the phenotype, to the deterministic functional model. A more elegant and possibly superior solution, however, would be to integrate stochastic processes directly into the CGM. While the

Figure 4. Relationship between grain yield in 2012 and total leaf number (TLN). Results shown are from a representative example data set.
vast majority of CGMs are deterministic (Keating et al. [17], van Ittersum et al. [16]), there are examples of stochastic CGMs (Brun et al. [68]). In addition to incorporating inherently stochastic processes of development (Curry et al. [69]), stochastic CGMs could also serve to account for uncertainty in the parameters of the functional equations comprising the model (Wallach et al. [70]).

Advanced ABC algorithms For this proof of concept study we used the basic ABC rejection sampling algorithm (Tavare et al. [42], Pritchard et al. [43]). Considerable methodology related advances have been made, however, over the last decade that have led to algorithms with improved computational efficiency. Of particular interest here are population or sequential Monte Carlo algorithms, which are based on importance sampling (Sisson et al. [71], Toni et al. [66], Peters et al. [72]). These algorithms can dramatically increase acceptance rates without compromising on the tolerance levels. They achieve this by sampling from a sequence of intermediate proposal distributions of increasing similarity to the target distribution. Unfortunately, importance sampling fails when the number of parameters gets large, because then the importance weights tend to concentrate on very few samples, which leads to an extremely low effective sample size (Bengtsson et al. [73]). In the context of sequential Monte Carlo, this is known as particle depletion and was addressed by Peters et al. [72]. We implemented their approach, but were not able to overcome the problem of particle depletion. The number of parameters we estimated was 404 (100 marker effects per physiological trait plus an intercept), which seems well beyond the dimensionality range for importance sampling (Bengtsson et al. [73]).

Another interesting development is MCMC-ABC, which incorporates ABC with the Metropolis-Hastings algorithm (Marjoram et al. [74]). MCMC-ABC should result in high acceptance rates if the sampler moves into parameter regions of high posterior probability. However Metropolis-Hastings sampling too can be inefficient when the parameter space is of high dimension.

The greatest computational advantage of the original ABC rejection algorithm over Monte Carlo based ABC methods is that it generates independent samples and therefore readily lends itself to “embarrassingly” parallel computation (Marjoram et al. [74]). The computation time thus scales linearly to the number of processors available. Using the ABC rejection algorithm therefore allowed us to fully leverage the
high performance computing cluster of DuPont Pioneer. In the era of cloud computing (Buyya et al. [75]), high performance computing environments are readily available to practitioners and scientists in both public and private sectors. Generality, scalability to parallel computations, and ease of implementation make the basic rejection sampler a viable alternative to more sophisticated approaches.

Using prior information We used mildly informative prior distributions, the parameters of which were derived from the population means and variances of the physiological traits. In practice, the required prior information must be obtained from extraneous sources, such as past experiments or from the literature (Brun et al. [68]). Such information is imperfect and only partially matches the true population parameters of the population in question. We determined the prior parameters from the population itself, but perturbed them considerably to simulate erroneous prior information. Specifically, the average relative discrepancy between the prior parameter used and the true population parameter was 10%. When we increased the relative discrepancy to 25%, prediction accuracy dropped, but only slightly (Table S1). Thus, ABC-CGM seems to be relatively insensitive to moderate prior miss specification, as long as the value range supported by the prior distribution is not completely out of scope. If prior information is unavailable, uninformative priors, such as Normal distributions with mean zero and a very large variance, have to be used. This, however, will require a reduced acceptance rate to retain a given tolerance threshold because most of the parameter vectors drawn from the prior in step 1 of the algorithm (1) will be far from the bulk of the posterior. As a consequence, computational efficiency could be reduced considerably.

In contrast to the complex trait of interest, component physiological traits may be realistically modeled based on a relatively simple genetic architecture and for such traits QTL explaining a sizable proportion of genetic variance can be mapped and characterized (Reymond et al. [76], Bogard et al. [77], Yin et al. [78], Welcker et al. [79], Tardieu et al. [80]). In fact, such component trait QTL were already successfully used to parametrize CGMs for studying genotype dependent response to environmental conditions (Chenu et al. [28], Messina et al. [29], Bogard et al. [77], Chenu et al. [81], Yin et al. [78], ). Knowledge about the location of such QTL or of transgenes (Dong et al. [82], Guo et al. [83], Habben et al. [84]), could be incorporated as an additional source of prior information. Then, instead of estimating marker effects for the whole genome, ABC-CGM could focus on the QTL regions, which reduces the dimensionality of the parameter space dramatically. The effects of the QTL estimated in previous experiments could inform prior distributions, too. Prior knowledge about QTL positions and effects should therefore be leveraged for improving prediction accuracy and computational efficiency of ABC-CGM.

Other applications The idea of incorporating biological insights into WGP models is not limited to CGMs. Plant metabolites are chemical compounds produced as intermediate or end products of biochemical pathways. They are seen as potential bridges between genotypes and phenotypes of plants (Keurentjes [85]) and are therefore of particular interest in plant breeding (Fernie and Schauer, [86]). Metabolic networks model the interrelationships between genes, intermediate metabolites and end products through biochemistry pathways (Schuster et al. [87]). Elaborate metabolic network models are available today that allow studying and simulating complex biochemical processes related to important crop properties, such as flowering time, seed growth, nitrogen use efficiency and biomass composition (Dong et al. [82], Pilalis et al. [88], Simons et al. [89], Saha et al. [90]). Liepe et al. [47] demonstrate how ABC can be used for parameter estimation with metabolic and other biochemical networks. Using the
principles outlined here for ABC-CGM, metabolic networks might add valuable biological information for the purpose of WGP, too.

Despite ever increasing sample sizes and marker densities, most of the genetic variance of complex traits remained unaccounted for in genome-wide association studies (Maher [91]). Marjoram et al. [49] argued that signal detection power could be increased by augmenting the purely statistical association models used thus far with biological knowledge. They demonstrate their approach by using ABC for incorporating gene regulatory networks into their analysis. Here we showed that the same principle can be applied to WGP by using ABC for integrating a CGM in the estimation of whole genome marker effects. While this study is only a first step and many open questions remain, we conclude that ABC-CGM presents a promising novel path forward towards a new class of WGP models that leverage previously unused sources of knowledge and information and thereby increase prediction accuracy in settings that have proved challenging thus far for plant breeding.
