ABSTRACT:
The flagellum is a large proteinaceous organelle found at the surface of many bacteria, whose primary role is to allow motility through the rotation of a long extracellular filament. It is an essential virulence factor in many pathogenic species, and is also a priming component in the formation of antibiotic-resistant biofilms. The flagellum consists of the export apparatus and stator in the cytosol; the basal body, spanning the bacterial membrane(s) and periplasm; and the hook-filament, that protrudes away from the bacterial surface. Assembly of the bacterial flagellum is initiated by the formation of the basal body MS ring region, constituted of multiple copies of the protein FliF. Here, I report an analysis of the FliF sequence from various bacterial species, demonstrating that its periplasmic region is composed of a domain homologous to that of the type III secretion system proteins PrgK, and of a second globular domain that possesses a similar fold to that of the sporulation complex component SpoIIIAG. I also report a structural model for the FliF oligomer, based on knowledge of the PrgK oligomer. These results further emphasize the similarity between the flagellum, T3SS and sporulation complex, and will facilitate further structural studies.
**INTRODUCTION**

Bacteria interact with their environment using a range of surface appendages, including flagella, pili, fimbriae, and secretion systems. In particular, the flagellum is responsible for motility in many bacteria, but it is also frequently associated with adhesion to surfaces and/or other cells. Flagella are found in many bacterial families, including most gram-positive, proteobacteria and spirochetes. Notably, it is an essential virulence factor in many pathogenic species, such as *Salmonella*, *E. coli*, *Clostridium*, *Pseudomonas*, *Helicobacter*, *Vibrio*, *Burkholderia*, and *Campylobacter*, making the flagellum a potential target for new antibacterial therapeutics.

The bacterial flagellum is constituted of four distinct regions (Figure 1A). On the cytosolic side, the export apparatus and stator are responsible for the assembly and rotation of the system. The membrane-embedded structure that traverses the cytoplasmic membrane and periplasmic space (as well as the outer membrane for gram-negative bacteria) is called the basal body. The hook is a curved filament, ~50 nm in length (for the prototypical *Salmonella typhymurium* flagellum), that protrudes away from the basal body. It is prolonged by the filament, a long structure (up to several μm) responsible for motility and adherence.

Genetic studies have revealed that the inner-membrane protein FliF is the first component of the flagellum to assemble, forming two ring-shaped structures called the MS rings. This in turn recruits elements of the stator and secretion apparatus in the cytosol, leading to a secretion-competent complex, which can export the hook protein to the cytoplasm through its central pore. These observations led to the proposal that FliF is the flagellum assembly platform.

FliF is an ~60 kDa protein, localized to the inner-membrane through the Sec pathway. Sequence analysis has indicated that it possesses two transmembrane helices, flanking a large periplasmic region. At the C-terminus, a cytosolic peptide has been shown to interact with FliG, a component of the flagellum stator. EM reconstructions of purified FliF revealed a homo 26-mer forming the MS ring.
oligomer\textsuperscript{14}, although analyses of intact flagellum particles have identified 24-, 25- and 26-fold symmetry for this region of the basal body\textsuperscript{15}.

A number of components from the cytosolic export apparatus are homologous to that of the type III secretion system (T3SS, Figure 1B), another bacterial complex whose role is to inject so-called “effector” proteins inside the cytosol of target or symbiotic cells\textsuperscript{16}. Indeed, phylogenetic studies have revealed that the flagellum export apparatus is likely the evolutionary ancestor of the T3SS\textsuperscript{17}. In particular, FliF shows significantly sequence homology to an inner-membrane component of the T3SS (24 % sequence homology with the \textit{Salmonella} homologue PrgK, 22 % sequence identity with the EPEC homologue EscJ, for residues 52-217 of FliF)\textsuperscript{11}. Both EscJ and PrgK form a 24-mer ring structure in the inner-membrane, similar to that of FliF, and structural characterization have revealed the molecular details of their architecture and oligomerization\textsuperscript{18,19}. Specifically, the periplasmic region of EscJ and PrgK consists of two globular domains with a canonical “ring building motif” (RBM) fold\textsuperscript{20}, found in several oligomeric proteins. The two RBMs are joined by a rigid linker, which was shown in PrgK to promote oligomerization\textsuperscript{19}.

Recently, two proteins essential for the sporulation process in \textit{Bacillus subtilis}, SpoIIIAH and SpoIIIAG, were shown to be homolgous to PrgK and FliF,\textsuperscript{21,22} This led to the suggestion that these proteins are part of a complex that allow the secretion of proteins and/or nutrients between the mother cell and the endospore (Figure 1C), although such complex has not been observed directly\textsuperscript{23}. Here, I use computational methods to demonstrate that the periplasmic region of FliF includes a PrgK homology domain, as well as a FliF-specific domain, that is similar to that of the sporulation complex component SpoIIIAG. I also report that in the Chlamydiaceae family, the FliF protein differs significantly from other species, as it includes only one RBM of the PrgK homology region, and is fused to a FliG-like domain at the C-terminal cytosolic end. Finally, I combine previously determined EM maps and structural modeling to propose a molecular model for the FliF periplasmic region, revealing that FliF is akin to a fusion of the T3SS basal body inner-membrane components PrgK and PrgH. This unexpected observation has implications in the
understanding of the evolutionary relationship between the flagellum, T3SS and sporulation complex.

**MATERIALS AND METHODS:**

**Sequence mining, analysis and alignment:**

All protein sequences were identified with the National Centre for Biotechnology Information protein database RefSeq\(^{24}\). Multiple sequence alignments were generated with ClustalW\(^ {25}\) using default parameters. Alignment figures were produced with ESPript\(^ {26}\).

Secondary structure elements, signal sequences, transmembrane helices and structural homologues were predicted with the PSIPRED server\(^ {27}\). Protein sequence identity was calculated with the Needleman-Wunsch algorithm on the EBI server\(^ {28}\), using default parameters.

**Modeling and refinement:**

Structure-based alignment and initial models were obtained with Phyre\(^ {29}\), and the models were further refined by performing 1000 cycles of the Relax procedure\(^ {30}\) in Rosetta 3.4\(^ {31}\), using the following flags:

- `database ~rosetta/rosetta_database`
- `in:file:s input.pdb`
- `in:file:fullatom`
- `relax:thorough`
- `nstruct 1000`
- `out:file:silent relax.silent`

The geometry of the obtained models was analyzed with the PSVS suite\(^ {32}\).

**EM map docking and symmetry modeling:**

The flagellum, T3SS, and FlIF EM maps (EMDB ID 1887, 1875 and personal communication from K. Namba), were docked with the MatchMaker tool in
Chimera\textsuperscript{33}. Models of the FliF RBMs were placed in their putative location of the FliF EM map manually using Chimera.

For the EM-guided symmetry modeling of the RBM3, 24-fold, 25-fold and 26-fold symmetry definition files were generated, and used for the rigid-body step of the EM-guided symmetry modeling procedure described previously\textsuperscript{18}. Briefly, the individual domains were manually placed in the corresponding region of the EM map, and 1000 rigid-body decoy models were generated with imposed symmetry and with a restraint for fit into the FliF EM map density, at 22 Å. The obtained models were isolated with the Cluster procedure in Rosetta, and scores calculated with the Score procedure using the lowest-energy model as a template for RMS calculations.

The flags used for the modeling procedure are as follows:

- \texttt{-run:protocol symdock}
- \texttt{-database ~rosetta/rosetta_database}
- \texttt{-in:file:s input.pdb}
- \texttt{-symmetry:symmetry_definition 25.symm}
- \texttt{-symmetry:initialize_rigid_body_dofs}
- \texttt{-edensity:mapfile FliF_map.mrc}
- \texttt{-edensity:mapreso 22.0}
- \texttt{-edensity:grid_spacing 5.0}
- \texttt{-edensity:score_symm_complex true}
- \texttt{-packing:ex1}
- \texttt{-packing:ex2 aro}
- \texttt{-use_input_sc}
- \texttt{-ignore_unrecognized_res}
- \texttt{-out:nstruct 1000}
- \texttt{-out:file:silent phaseI.silent}
- \texttt{-out:file:silent_struct_type binary}
- \texttt{-out:file:fullatom}
- \texttt{-residues:patch_selectors CENTROID_HA}
RESULTS AND DISCUSSION

Characterization of the FliF domain organization

In order to identify conserved features, I gathered FliF sequences from a number of human pathogens, spanning gram-negative, gram-positive and spirochete bacteria. Most of the FliF sequences are similar in length (~ 560 amino acids), but show limited sequence conservation (Table 1). I next used sequence analysis servers to predict secondary structure elements and other structural and functional features. Two transmembrane (TM) helices are predicted, between residues 20-45 and residues 445-470, and a secretion signal peptide targeting it for secretion and inner-membrane localization is predicted at the N-terminus. All FliF sequences show a very similar secondary sequence prediction pattern (Supplementary figure 1), and similarity to PrgK was identified for residues 50-220 in all sequences (hereafter referred to as the PrgK homology domain), but no structural homologues were found for residues 220-440 (FliF-specific domain). Finally, residues 305-360 of the FliF-specific domain are predicted unstructured in all sequences.

I then generated a multiple alignment of all FliF sequences, and mapped the predicted secondary structure and identified domains (Figure 2). This further illustrates the conserved domain organization in all FliF orthologues. The two RBMs of the PrgK homology domain (labeled RBM1 and RBM2) are well conserved, as is the linker L1 between these. It has been shown that in PrgK this linker plays a role in ring assembly, suggesting that this may also the case in FliF. In contrast, the
linker region L2, separating the PrgK homology domain to the FliF-specific domain, is highly variable.

The Chlamydiaceae FliF-FliG fusion protein

While the FliF domain organization described above was found in most FliF sequences, one notable exception was identified, for the Chlamydiaceae family, where the FliF sequence is notably shorter (~330 amino acids). Sequence analysis and multiple sequence alignment from all available Chlamydiaceae homologues (Figure 2A) revealed that the N-terminal signal sequence and the two TM (residues 16-33 and 250-275) are present, but the periplasmic region is significantly shorter. Residues 60-145 were identified as structurally similar to PrgK, but only encompassing RBM2. No structural homologues could be identified for residues 165-235, however the predicted secondary structure matches that of the canonical RBM.

In most orthologues, the C-terminus cytosolic region of FliF (residues 520-560) binds to the protein FliG\textsuperscript{12,13}, a ~37 KDa protein possessing three domains, labeled N, M and C. FliF interacts with domain N, while both M and C bind to the stator (also known as C-ring) component FliM\textsuperscript{35,36}, as illustrated on figure 3B. However, a sequence similarity search revealed that the in the Chlamydia FliF, the cytosolic region is actually homologous to the M region of FliG (Figure 2C), revealing that in this species the protein is in fact a FliF-FliG fusion. Chlamydia is not thought be a flagellated bacterium, and possesses only a few flagellar genes, namely FliF, FliL and FlhA. It does however possess a functional T3SS that is essential for virulence\textsuperscript{37}, and it has been shown that Chlamidia flagellar proteins interact with components of its T3SS\textsuperscript{38}. FliM (and FliN, another C-ring component) is homologous to the Chlamydia T3SS component CdsQ (SpaO in Salmonella)\textsuperscript{39}. It is therefore possible that the FliF-FliG fusion interacts with CdsQ (Figure 2D). This remains to be verified experimentally.

Interestingly, a FliF-FliG fusion is not entirely unprecedented, as two S. typhimurium strains containing such fusions have been reported\textsuperscript{40,41}. In both cases, the fusion does not impair flagellum assembly and rotation, but induces a bias in the rotation
direction. Since it is not yet clear if the *Chlamydia* FliF-FliG fusion protein is part of a proto-flagellum, or contributes to the T3SS, the implications for this observation is not clear.

**Structural modeling of the PrgK homology domain**

Structures of the periplasmic domains of both EscJ\(^{42,43}\) and PrgK\(^{19}\) have been reported. Exploiting this information, a structural model for FliF was generated using the prototypical *Salmonella typhimurium* FliF sequence. Despite the predicted structural homology, the sequence conservation between FliF and PrgK is low (Figure 3A). I therefore employed a secondary structure alignment-based procedure for modeling the PrgK homology domain, which indicated that EscJ is the best modeling template, for the PrgK-homology region spanning residues 50 to 221. However, the relative orientation of the two RBMs in FliF is not known, and may differ from that of PrgK and EscJ. I therefore modeled the two RBMs independently, and refined the obtained models with Rosetta (see Materials and Methods for details). As shown on figure 3B and 3C, both RBMs converged to a local energy minimum within an RMSD of 1 Å to the lowest-energy model in the refinement procedure. The models possess good geometry (table 2), and their overall architecture (Figure 3D and 3E) is expectedly similar to that of EscJ and PrgK.

**The FliF-specific domain is a RBM**

I next sought to generate a structural model for the FliF-specific domain (residues 228-443). As mentioned above, secondary structure prediction indicated that residues 228-309 and residues 356-443 possess defined structure, while residues 310-355 are predicted as intrinsically disordered (Fig 2). I therefore hypothesized that the FliF-specific region consists of two globular domains (D1 and D2) separated by a flexible linker. I attempted to identify structural homologues to these two regions. D1 shows structural homology to EscJ, although only for the first two structural elements (residues 229-268, Supplementary figure 2A). Similarly, D2 shows structural similarity to the sporulation complex protein SpoIIIAH, that also possesses a RBM fold and has been proposed to oligomerize into ring structures \(^{44,45}\)
(Supplementary figure 2B). However, the structural similarity was limited to the last three structural elements (residues 386-436). Based on these observations, I postulated that the FliF-specific domain is a “split” RBM that possesses a large insert in the loop between the second and third strand (Figure 5A). A structural similarity search for the FliF-specific domain with this insert removed (FliF_228-443 Δ274-378) confirmed overall structural similarity to both EscJ and SpoIIIAH (Supplementary figure 2C).

A “split” RBM is not unprecedented, as it is also predicted in the sporulation complex component SpoIIIAG (figure 5B). In both proteins the insert is predicted to possess four β-strands, which may indicate that it forms a small folded domain. Alternatively, it is possible that the insert adopts an extended loop conformation stabilized by β-strands.

In order to build an atomic model for the FliF RBM3, the EscJ-derived model for FliF_230-275 was combined with the SpoIIIAH-derived model for FliF_380-440, and refined with Rosetta. As shown on figure 5C, the RMSD to the lowest energy model is significantly higher than for the RBM1 and RBM2 models (around 3.5 Å for most decoys), which is perhaps expected, as the starting model was a presumably poorer, composite model. Nevertheless there is a clear energy funnel, indicative that the modeling procedure is converging. The obtained FliF RBM3 model, shown on figure 5D, possesses the canonical RBM fold, with an elongated architecture as in the RBM2 of PrgK and in that of SpoIIIAH, with the insert between strands 1 and 2 located on one side of the structure.

Localization of the FliF domains

Previous EM studies have shown that in isolation, FliF forms a doughnut-shaped oligomer with two side rings corresponding to the MS rings seen in the intact basal body15,46. The Flig-binding domain forms the cytoplasmic M ring, but little is known about the organization of the periplasmic domains. However, the organization of the T3SS basal body, and that of PrgK in particular, is well-characterized18,19,47. By comparing the EM reconstructions of the flagellar15 and T3SS47 basal body complexes, localization of the FliF RBMs was inferred. As shown on figure 6A,
density attributed to the two globular domains of PrgK has clear equivalence in the flagellum, suggesting this location corresponds to the PrgK homology domain of FliF. EM map density for the flagellum S-ring corresponds to the T3SS protein PrgH localization, and is also present in purified FliF, confirming that it is not attributed to another flagellar component. The periplasmic region of PrgH is composed of three domains with an RBM fold, including the region corresponding to FliF density, suggesting that in the flagellum, this density can be attributed to the FliF-specific domain, which also possesses an RBM fold.

Based on these observations, I propose that FliF is akin to a PrgK-PrgH fusion (figure 6B), including the two RBMs of PrgK and its C-terminal TM helix, and the N-terminal TM and first RBM from PrgH. This likely explains a major difference between flagellar basal body, where FliF assembles on its own in the inner membrane, and T3SS basal body, where co-expression of PrgK and PrgH is required.

**Modeling of the FliF oligomer**

I next exploited the domain localization proposed above, the structural models of the three FliF RBMs, and the previously determined EM map, to generate a model for the FliF oligomer. To that end, I positioned all three domains so that their termini point towards the correct region of the map, and for RBM1 and RBM2 in an orientation agreeing with the corresponding PrgK oligomers. Figure 7A shows that RBM1 is located near the inner-membrane region, while RBM2 forms the neck of the structure. Finally, the RBM3 is located in the region of density forming the S-ring. The insert in RBM3 points towards the lumen of the ring, and could correspond to the gate density observed in the FliF EM structure.

I next attempted to generate a model for the FliF oligomer. I applied the previously described EM-guided modeling procedure to all three domains individually, using the FliF map as a restraint, and applying 24-, 25- or 26-fold symmetry. In most cases the procedure led to ring models that were too large for the EM map (not shown). This is unsurprising, as it had been reported previously that the procedure requires experimental structures (as opposed to homology models) to converge. The one exception was the modeling of the RBM3, using 25-fold symmetry. This procedure
generated three distinct clusters of models with clear low-energy funnels and good  
fit to EM density (Figure 7B). Close inspection of the clusters reveals that they  
correspond to similar oligomerization modes and use the same interface, but with a  
slightly different angle between the subunits (Figure 7C). I therefore exploited this  
25-mer mode for the RBM3 to generate a complete 25-mer model for FliF. The  
corresponding model, shown in figure 7D and included in the supplementary  
material, matches well with the cryo-EM structure, with only a few loop regions of  
RBM2 and RBM3 located outside of the density. Further refinement of the model,  
including experimentally determined RBM1, RBM2 and RBM3 atomic structures, as  
well as a higher resolution EM map of FliF and of the intact flagellum basal body will  
be required to further refine this model.

CONCLUSION:

In this study I have demonstrated that the periplasmic region of most FliF  
orthologues consists of three globular domains possessing the canonical RBM motif.  
One exception is the Chlamydia FliF parologue, which possesses only two of these,  
and has a FliG domain fusion at its C-terminus. By comparison with the T3SS basal  
body, I also propose the novel concept that FliF is akin to a fusion of PrgK and PrgH.  
Finally I have combined this information to propose a model for the oligomeric  
arrangement of the periplasmic region of FliF. Further experimental validation will  
be required to confirm these results, and to refine the FliF model.  

These results shed new lights on the architecture and evolution of the flagellum MS  
ring. Specifically, the domain organization of FliF highlights similarities with the  
T3SS, but also with the bacterial sporulation complex. The proposed concept that  
FliF corresponds to a fusion of PrgK and PrgH likely explains why FliF can assemble  
spontaneously, while PrgK and PrgH require co-expression. In addition, the  
identification of a Chlamydia FliF-FliG fusion suggests that this may correspond to  
an ancestral complex.
ACKNOWLEDGEMENTS:
I acknowledge Dr Keiichi Namba and Dr Hirofumi Suzuki for providing the FliF EM map. I thank Dr Natalie Zeytuni and Dr Morgan Bye for critical comments on the manuscript. This work was supported by a UBC Centre for Blood Research post-doctoral transition grant.
