## 1 **Abstract**

2 Two recent studies have re-analyzed published data and found that when datasets are  
3 analyzed independently there was limited support for the widely accepted hypothesis that  
4 changes in the microbiome are associated with obesity. This hypothesis was reconsidered  
5 by increasing the number of datasets and pooling the results across the individual datasets.  
6 The Preferred Reporting Items for Systematic Reviews and Meta-Analyses (PRISMA)  
7 guidelines were applied to identify 10 studies for an updated and more synthetic analysis.  
8 Alpha diversity metrics and the relative risk of obesity based on those metrics were used to  
9 identify a limited number of significant associations with obesity; however, when the results  
10 of the studies were pooled using a random effects model significant associations were  
11 observed between Shannon diversity, number of observed OTUs, and Shannon evenness  
12 and obesity status. They were not observed for the ratio of *Bacteroidetes* and *Firmicutes*  
13 or their individual relative abundances. Although these tests yielded small P-values, the  
14 difference between the Shannon diversity index of non-obese and obese individuals was  
15 2.07%. A power analysis demonstrated that only one of the studies had sufficient power to  
16 detect a 5% difference in diversity. When Random Forest machine learning models were  
17 trained on one dataset and then tested using the other 9 datasets, the median accuracy  
18 varied between 33.01 and 64.77% (median=56.67%). Although there was support for a  
19 relationship between the microbial communities found in human feces and obesity status,  
20 this association is relatively weak and its detection is confounded by large interpersonal  
21 variation and insufficient sample sizes.

## 22 **Importance**

23 As interest in the human microbiome grows there is an increasing number of studies that  
24 can be used to test numerous hypotheses across human populations. The hypothesis

25 that variation in the gut microbiota can explain or be used to predict obesity status has  
26 received considerable attention and is frequently mentioned as an example for the role of  
27 the microbiome in human health. Here we assess this hypothesis using ten independent  
28 studies and find that although there is an association, it is smaller than can be detected  
29 by most microbiome studies. Furthermore, we directly tested the ability to predict obesity  
30 status based on the composition of an individual's microbiome and find that the median  
31 classification accuracy is between 33.01 and 64.77%. This type of analysis can be used to  
32 design future studies and expanded to explore other hypotheses.

## 33 Introduction

34 Obesity is a growing health concern with approximately 20% of the youth (aged 2-19) in  
35 the United States classified as either overweight or obese (1). This number increases  
36 to approximately 35% in adults (aged 20 or older) and these statistics have seen little  
37 change since 2003 (1). Traditionally, the body mass index (BMI) has been used to classify  
38 individuals as non-obese or obese (2). Recently, there has been increased interest in  
39 the role of the microbiome in modulating obesity (3, 4). If the microbiome does affect  
40 obesity status, then manipulating the microbiome could have a significant role in the future  
41 treatment of obesity and in helping to stem the current epidemic.

42 There have been several studies that report observing a link between the composition  
43 of microbiome and obesity in animal models and in humans. The first such study used  
44 genetically obese mice and observed the ratio of the relative abundances of *Bacteroidetes*  
45 to *Firmicutes* (B:F) was lower in obese mice than lean mice (5). Translation of this result  
46 to humans by the same researchers did not observe this effect, but did find that obese  
47 individuals had a lower diversity than lean individuals (6). They also showed that the  
48 relative abundance of *Bacteroidetes* and *Firmicutes* increased and decreased, respectively,  
49 as obese individuals lost weight while on a fat or carbohydrate restricted diet (7). Two  
50 re-analysis studies interrogated previously published microbiome and obesity data and  
51 concluded that the previously reported differences in community diversity and B:F among  
52 non-obese and obese individuals could not be generalized (8, 9). Regardless of the results  
53 using human populations, mechanistic studies using animal models that were manipulated  
54 with antibiotics or colonization with varied communities were manipulated with antibiotics or  
55 underwent colonization with varied communities appears to support the association since  
56 these manipulation yielded variation in animal weight (10–13). The purported association  
57 between the differences in the microbiome and obesity have been widely repeated with  
58 little attention given to the lack of a clear signal in human cohort studies.

59 The recent publication of additional studies that collected BMI data for each subject as  
60 well as other studies that were not included in the earlier re-analysis studies offered the  
61 opportunity to revisit the question relating the structure of the human microbiome to obesity.  
62 One critique of the prior re-analysis studies is that the authors did not aggregate the  
63 results across studies to increase the effective sample size. It is possible that there were  
64 small associations within each study that were not statistically significant because the  
65 individual studies lacked sufficient power. Alternatively, diversity metrics may mask the  
66 appropriate signal and it is necessary to measure the association at the level of microbial  
67 populations. Walters et al. (8) demonstrated that Random Forest machine learning models  
68 were capable of predicting obesity status within a single cohort, but did not attempt to test  
69 the models on other cohorts. The purpose of this study was to perform a meta-analysis of  
70 the association between differences in the microbiome and obesity status by analyzing  
71 and applying a more systematic and synthetic approach than was used previously.

## 72 **Results**

73 ***Literature Review and Study Inclusion.*** We followed the Preferred Reporting Items  
74 for Systematic Reviews and Meta-Analyses (PRISMA) guidelines to identify studies to  
75 include in our meta-analysis (14). A detailed description of our selection process and  
76 the exact search terms are provided in the Supplemental Text and in Figure 1. Briefly,  
77 we searched PubMed for original research studies that involved studying obesity and the  
78 human microbiome. The initial search yielded 187 studies. We identified ten additional  
79 studies that were not designed to explicitly test for an association between the microbiome  
80 and obesity. We then manually curated the 196 studies to select those studies that  
81 included BMI and sequence data. This yielded 10 eligible studies. An additional study was  
82 removed from our analysis because no individuals in the study had a BMI over 30. Among  
83 the final 10 studies, 3 were from identified from our PubMed search (10, 15, 16), 5 were

84 originally identified from the 10 studies that did not explicitly investigate obesity but included  
85 BMI data (17–21), and two datasets were used (22, 23) because these publications did  
86 not specifically look for any metabolic or obesity conditions but had control populations  
87 and enabled us to help mitigate against publication biases associated with the bacterial  
88 microbiome and obesity. The ten studies are summarized in Table 1.

89 **Alpha diversity analysis.** We calculated the Shannon diversity index, observed richness,  
90 and Shannon evenness, the relative abundance of *Bacteroidetes* and *Firmicutes*, and  
91 the ratio of their relative abundance (B:F) for each sample. Once we transformed each  
92 of the six alpha diversity metrics to make them normally distributed, we used a t-test  
93 to identify significant associations between the alpha diversity metric and whether an  
94 individual was obese for each of the ten studies. The B:F and the relative abundance  
95 of *Firmicutes* were not significantly associated with obesity in any study. We identified  
96 seven P-values that were less than 0.05: three studies indicated obese individuals had  
97 a lower richness, two studies indicated a significantly lower diversity, one study indicated  
98 a significantly lower evenness, and one study indicated a significantly higher relative  
99 abundance of *Bacteroidetes* (Figures 2 and S1). These results largely match those of the  
100 Walters and Finucane re-analysis studies. Interestingly, although only two of the ten studies  
101 observed the previously reported association between lower diversity and obesity, the  
102 other studies appeared to have the same trend, albeit the differences were not statistically  
103 significant. We used a random effects linear model to combine the studies using the  
104 study as the random effect and found statistical support for decreased richness, evenness,  
105 and diversity among obese individuals (all  $P < 0.011$ ). Although there was a significant  
106 relationship between these metrics and obesity status, the effect size was quite small.  
107 The obese individuals averaged 7.47% lower richness, 0.88% lower evenness, and 2.07%  
108 lower diversity. There were no significant associations when we pooled the phylum-level  
109 metrics across studies. These results indicate that obese individuals do have a statistically  
110 significant lower diversity than non-obese individuals; however, it is questionable whether

111 the difference is biologically significant.

112 **Relative risk.** Building upon the alpha diversity analysis we calculated the relative risk  
113 of being obese based on an individual's alpha diversity metrics relative to the median  
114 metric for that study. The results using relative risk largely matched those of using the  
115 untransformed alpha diversity data. Across the ten studies and six metrics, the only  
116 significant relative risk values were the richness, evenness, and diversity values from the  
117 Goodrich study (Figures 3 and S2). Again, although the relative risk values were not  
118 significant for other studies, the values tended to be above one. When we pooled the  
119 data using a random effects model, the relative risk associated with having a richness,  
120 evenness, or diversity below the median for the population was significantly associated  
121 with obesity (all  $P < 0.0044$ ). The relative risks associated with alpha diversity were small.  
122 The relative risk of having a low richness was 1.30 (1.13-1.49), low evenness was 1.20  
123 (1.06-1.37), and low diversity was 1.27 (1.09-1.48). There were no significant difference  
124 in the phylum-level metrics. Again, the relative risk results indicate that individuals with a  
125 lower richness, evenness, or diversity are at statistically significant increased risk of being  
126 obese, it is questionable whether that risk is biologically or clinically relevant.

127 **Beta diversity analysis.** Following the approach used by the Walters and Finucane  
128 re-analysis studies, for each dataset we calculated a Bray-Curtis distance matrix to  
129 measure the difference in the membership and structure of the individuals from each  
130 study. We then used AMOVA to test for significant differences between the structure  
131 of non-obese and obese individuals (Table 1). The Escobar, Goodrich, and Turnbaugh  
132 datasets indicated a significant difference in community structure (all  $P < 0.05$ ). Because  
133 it was not possible to ascertain the directionality of the difference in community structure  
134 nor perform a pooled analysis using studies that had non-overlapping 16S rRNA gene  
135 sequence regions it is unclear whether these differences reflect a broader, but perhaps  
136 small, shift in community structure between non-obese and obese individuals.

137 ***Development of a microbiome-based classifier of obesity.*** The Walters re-analysis  
138 study suggested that it was possible to classify individuals as being non-obese or obese  
139 based on the composition of their microbiota. We repeated this analysis with additional  
140 datasets using OTU and genus-level phylotype data. For each study we developed a  
141 Random Forest machine learning model to classify individuals. Using ten-fold cross  
142 validation, the observed AUC values varied between 0.52 and 0.69 indicating a relatively  
143 poor ability to classify individuals (Figure 4A). So that we could test models on other  
144 datasets, we trained models using genus-level phylotype data for each dataset. The  
145 cross-validated AUC values for the models applied to the training datasets varied between  
146 0.51 and 0.65, again indicating a relatively poor ability to classify individuals from the  
147 original dataset (Figure 4B). For each model we identified the probability where the sum  
148 of the sensitivity and specificity was the highest. We then used this probability to define  
149 a threshold for calculating the accuracy of the models when applied to the other nine  
150 datasets (Figure 5). Although there was considerable variation in accuracy values for each  
151 model, the median accuracy for each model varied between 0.33 (Turnbaugh) and 0.65  
152 (HMP) (median=0.57). When we considered the number of samples, balance of non-obese  
153 and obese individuals, and region within the 16S rRNA gene it was not possible to identify  
154 factors that predictably affected model performance. The ability to predict obesity status  
155 using the relative abundance of OTUs and genera in the communities is only marginally  
156 better than random. These results suggest that given the large diversity of microbiome  
157 compositions it is difficult to identify a taxonomic signal that can be associated with obesity.

158 ***Power and Sample Size Estimate Simulations.*** The inability to detect a difference  
159 between non-obese and obese individuals could be due to the lack of a true effect or  
160 because the study had insufficient statistical power to detect a difference because of  
161 insufficient sampling, large interpersonal variation, and unbalanced sampling of non-obese  
162 and obese individuals. To assess this, we calculated the power to detect differences of  
163 1, 5, 10, and 15% in each of the alpha diversity metrics using the sample sizes used in

164 each of the studies (Figures 6, S3-S8). Although there is no biological rationale for these  
165 effect sizes, they represent a range that is plausible. Only the Goodrich study had power  
166 greater than 0.80 to detect a 5% difference in Shannon diversity and six of the studies had  
167 enough power to detect a 10% difference (Figure 6). None of the studies had sufficient  
168 power to detect a 15% difference between B:F values (Figure S5). In fact, the maximum  
169 power among any of the studies to detect a 15% difference in B:F values was 0.25. Among  
170 the tests for relative risk, none of the studies had sufficient power to detect a Cohen's  
171 d of 0.10 and only two studies had sufficient power to detect a Cohen's d of 0.15. We  
172 next estimated how many individuals would need to have been sampled to have sufficient  
173 power to detect the four effect sizes assuming the observed interpersonal variation from  
174 each study and balanced sampling between the two groups. To detect a 1, 5, 10, or  
175 15% difference in Shannon index, the median required sampling effort per group was  
176 approximately 3,400, 140, 35, or 16 individuals, respectively. To detect a 1, 5, 10, and 15%  
177 difference in B:F values, the median required sampling effort per group was approximately  
178 160,000, 6,300, 1,600, or 700 individuals, respectively. To detect a 1, 5, 10, and 15%  
179 difference in relative risk values using Shannon diversity, the median required sampling  
180 effort per group was approximately 39,000, 1,500, 380, or 170 individuals, respectively.  
181 These estimates indicate that most microbiome studies are underpowered to detect modest  
182 effect sizes using either metric. In the case of obesity, the studies were underpowered to  
183 detect the 0.90 to 6% difference in diversity that was observed across the studies.

## 184 **Discussion**

185 Our meta-analysis helps to provide clarity to the ongoing debate of whether or not there  
186 are specific microbiome-based markers that can be associated with obesity. We performed  
187 an extensive literature review of the existing studies on the microbiome and obesity and  
188 performed a meta-analysis on the studies that remained based on our inclusion and

189 exclusion criteria. By statistically pooling the data from ten studies, we observed significant,  
190 but small, relationships between richness, evenness, and diversity and obesity status as  
191 well as the relative risk of being obese based on these metrics. We also generated Random  
192 Forest machine learning models trained on each dataset and tested on the remaining  
193 datasets. This analysis demonstrated that the ability to reliably classify individuals as being  
194 obese based on the composition of their microbiome was limited. Finally, we assessed the  
195 ability of each study to detect defined differences in alpha diversity and observed that most  
196 studies were underpowered to detect modest effect sizes. Considering these datasets  
197 are among the largest published, it appears that most human microbiome studies are  
198 underpowered to detect differences in alpha diversity.

199 Alpha diversity metrics are attractive because they distill a complex dataset to a single  
200 value. For example, diversity is a measure of the entropy in a community and integrates  
201 richness and evenness information. Two communities with little taxonomic similarity can  
202 have the same diversity. Among ecologists the relevance of these metrics is questioned  
203 because it is difficult to ascribe a mechanistic interpretation to their relationship with  
204 stability or disease. Regardless, the concept of a biologically significant effect size needs  
205 to be developed among microbiome researchers. Alternative metrics could include the  
206 ability to detect a defined difference in the relative abundance of an OTU representing a  
207 defined relative abundance. What makes for a biologically significant difference or relative  
208 abundance is an important point that has yet to be discussed in the microbiome field. The  
209 use of operationally defined effect sizes should be adequate until it is possible to decide  
210 upon an accepted practice.

211 By selecting a range of possible effect sizes, we were able to demonstrate that most  
212 studies are underpowered to detect modest differences in alpha diversity metrics and  
213 phylum-level relative abundances. Several factors interact to limit the power of microbiome  
214 studies. There is wide interpersonal variation in the diversity and structure of the human

215 microbiome. In addition, the common experimental designs limit their power. As we  
216 observed, most of the studies included in our analysis were unbalanced for the variable  
217 that we were interested in. This was also true of those studies that originally sought to  
218 identify associations with obesity. Even with a balanced design, we showed that it was  
219 necessary to obtain approximately 140 and 6,300 samples per group to detect a 5%  
220 difference in Shannon diversity or B:F, respectively. It was interesting that these sample  
221 sizes agreed across studies regardless of their sequencing method, region within the 16S  
222 rRNA gene, or subject population (Figure 6). This suggests that regardless of the treatment  
223 or category, these sample sizes represent a good starting point for subject recruitment  
224 when using stool samples. Unfortunately, few studies have been published with this level  
225 of subject recruitment. This is troubling since the positive predictive rate of a significant  
226 finding in an underpowered study is small leading to results that cannot be reproduced  
227 (24). Future microbiome studies should articulate the basis for their experimental design.

228 Two previous reviews (8, 9) have stated that there was not a consistent association between  
229 alpha diversity and obesity; however, neither of these studies made an attempt to pool  
230 the existing data together to try and harness the additional power that this would give and  
231 they did not assess whether the studies were sufficiently powered to detect a difference.  
232 Additionally, our analysis used 16S rRNA gene sequence data from ten studies whereas  
233 the Finucane study used 16S rRNA gene sequence data from three studies (7, 10, 21)  
234 and a metagenomic study (25) and the Walters study used 16S rRNA gene sequence  
235 data from five studies (10, 15, 20, 21, 26); two studies were included in both analyses (10,  
236 21). Our analysis included four of these studies (10, 15, 20, 21) and excluded three of  
237 the studies because they were too small (7), only utilized metagenomic data (25), or used  
238 short single read Illumina HiSeq data that has a high error rate making it untractable for  
239 *de novo* OTU clustering (26). The additional seven datasets were published after the two  
240 reviews were performed and include datasets with more samples than were found in the  
241 original studies. Our collection of ten studies allowed us to largely use the same sequence

242 analysis pipeline for all datasets and relied heavily on the availability of public data and  
243 access to metadata that included variables beyond the needs of the original study. To  
244 execute this analysis, we created an automated data analysis pipeline, which can be easily  
245 updated to add additional studies as they become available. Similarly, it would be possible  
246 to adapt this pipeline to other body sites and treatment or variables (e.g. subject's sex or  
247 age).

248 Similar to our study, the Walters et al (8) generated Random Forest machine learning  
249 models to differentiate between non-obese and obese individuals. They obtained similar  
250 AUC values to our analysis; however, they did not attempt to test these models on the  
251 other studies in their analysis. When we performed the inter-dataset cross validation the  
252 median accuracy across datasets was only 56.67% indicating that the models did a poor  
253 job when applied to other datasets. This could be due to differences in subject populations  
254 and methods. Considering the median AUC for models trained and tested on the same  
255 data with ten-fold cross validation only varied between 0.51 and 0.65 and there was not  
256 a strong signal in the alpha diversity data, we suspect that there is insufficient signal to  
257 reliably classify individuals.

258 Although we failed to find an effect this does not necessarily mean that there is no role  
259 for the microbiome in obesity. There is strong evidence in murine models of obesity that  
260 the microbiome and level of adiposity can be manipulated via genetic manipulation of the  
261 animal and manipulation of the community through antibiotics or colonizing germ free mice  
262 with diverse fecal material from human donors (5, 10–13). These studies appear to conflict  
263 with the observations using human subjects. Recalling the large interpersonal variation in  
264 the structure of the microbiome, it is possible that each individual has their own signatures  
265 of obesity. Alternatively, it could be that the involvement of the microbiome in obesity is at  
266 the level of a common set of metabolites that can be produced from different structures of  
267 the microbiome.

## 268 **Methods**

269 **Sequence Analysis Pipeline.** All sequence data were publicly available and were  
270 downloaded from the NCBI Sequence Read Archive, the European Nucleotide Archive,  
271 or the investigators' personal website ([https://gordonlab.wustl.edu/TurnbaughSE/\\_10/\\_09/](https://gordonlab.wustl.edu/TurnbaughSE/_10/_09/STM/_2009.html)  
272 [STM/\\_2009.html](https://gordonlab.wustl.edu/TurnbaughSE/_10/_09/STM/_2009.html)). In total seven studies used 454 (6, 15, 16, 18, 20–22) and three studies  
273 used Illumina sequencing (17, 19, 23). All of these studies used amplification-based  
274 16S rRNA gene sequencing. Among the studies that sequenced the 16S rRNA gene,  
275 the researchers targeted the V1-V2 (20), V1-V3 (15, 16, 18), V3-V5 (21, 22), V4 [(19);  
276 (23); ], and V3-4 (17) regions. For those studies where multiple regions were sequenced,  
277 we selected the region that corresponded to the largest number of subjects (6, 21). We  
278 processed the 16S rRNA gene sequence data using a standardized mothur pipeline. Briefly,  
279 our pipelines attempted to follow previously recommended approaches for 454 and Illumina  
280 sequencing data (27, 28). All sequences were screened for chimeras using UCHIME and  
281 assigned to operational taxonomic units (OTUs) using the average neighbor algorithm  
282 using a 3% distance threshold (29, 30). All sequence processing was performed using  
283 mothur (v.1.37.0) (31).

284 **Data Analysis.** We split the overall meta-analysis into three general strategies using R  
285 (3.3.0). First, we followed the approach employed by Finucane et al (9) and Walters et al  
286 (8) where each study was re-analyzed separately to identify associations between BMI  
287 and the relative abundance of *Bacteroidetes* and Firmicutes, the ratio of *Bacteroidetes*  
288 and *Firmicutes* relative abundances (B:F), Shannon diversity, observed richness, and  
289 Shannon evenness. After each variable was transformed to fit a normal distribution a  
290 two-tailed t-test was performed for comparison of non-obese and obese individuals (i.e. BMI  
291 > 35.0). We performed a pooled analysis on these measured variables using linear random  
292 effect models to correct for study effect to assess differences on the combined dataset  
293 between non-obese and obese groups using the lme4 (v.1.1-12) R package. Next, we

294 compared the community structure from non-obese and obese individuals using analysis  
295 of molecular variance (AMOVA) with Bray-Curtis distance matrices (32). This analysis was  
296 performed using the vegan (v.2.3-5) R package. For both analyses, the datasets were  
297 rarefied (N=1000) so that each study within a study had the same number of sequences.  
298 Second, for each study we partitioned the subjects into a low or high group depending  
299 on whether their alpha diversity metrics were below or above the median value for the  
300 study. The relative risk (RR) was then calculated as the ratio of the number of obese  
301 individuals in the low group to the number of obese individuals in the high group. We then  
302 performed a Fisher exact-test to investigate whether the RR was significantly different from  
303 1.0 within each study and across all of the studies using the epiR (0.9-77) and metafor  
304 (1.9-8) packages. Third, we used the AUCRF (1.1) R package to generate Random Forest  
305 models. For each study we developed models using either OTUs or genus-level phylotypes.  
306 The quality of each model was assessed by measuring the area under the curve (AUC) of  
307 the Receiver Operating Characteristic (ROC) using ten-fold cross validation. Because the  
308 genus-level phylotype models were developed using a common reference, it was possible  
309 to use one study's model (i.e. the training set) to classify the samples from the other studies  
310 (i.e. the testing sets). The optimum threshold for the training set was set as the probability  
311 threshold that had the highest combined sensitivity and specificity. This threshold was  
312 then used to calculate the accuracy of the model applied to the test studies. To generate  
313 ROC curves and calculate the accuracy of the models we used the pROC (1.8) R package.  
314 Finally, we performed power and sample number simulations for different effect sizes for  
315 each study using the pwr (1.1-3) R package and base R functions. We also calculated the  
316 actual sample size needed based on the effect size of each individual study.

317 ***Reproducible methods.*** A detailed and reproducible description of how the data were  
318 processed and analyzed can be found at [https://github.com/SchlossLab/Sze\\_Obesity\\_](https://github.com/SchlossLab/Sze_Obesity_mBio_2016/)  
319 [mBio\\_2016/](https://github.com/SchlossLab/Sze_Obesity_mBio_2016/).

## 320 **Acknowledgements**

321 The authors would like to thank Nielson Baxter and Shawn Whitefield for their suggestions  
322 on the development of the manuscript. We are grateful to the authors of the studies used  
323 in our meta-analysis who have made their data publicly available or available to us directly.  
324 Without their forethought studies such as this would not be possible. This work was  
325 supported in part by funding from the National Institutes of Health to PDS (U01AI2425501  
326 and P30DK034933).
