

RH: DIFFUSION MODELS FOR QUANTITATIVE TRAIT EVOLUTION

Beyond Brownian motion and the Ornstein-Uhlenbeck process: Stochastic diffusion models for the evolution of quantitative characters.

E-mail: s.blomberg1@uq.edu.au

1 *Abstract.*—Gaussian processes such as Brownian motion and the Ornstein-Uhlenbeck process have been popu-
2 lar models for the evolution of quantitative traits and are widely used in phylogenetic comparative methods.
3 However, they have drawbacks which limit their utility. Here we describe new, non-Gaussian stochastic differ-
4 ential equation (diffusion) models of quantitative trait evolution. We present general methods for deriving new
5 diffusion models, and discuss possible schemes for fitting non-Gaussian evolutionary models to trait data. The
6 theory of stochastic processes provides a mathematical framework for understanding the properties of current,
7 new and future phylogenetic comparative methods. Attention to the mathematical details of models of trait
8 evolution and diversification may help avoid some pitfalls when using stochastic processes to model macroevo-
9 lution.

11 Traits, Comparative Methods)

12

13 “Brownian motion is a poor model, and so is Ornstein-Uhlenbeck, but just as democracy is the
14 worst method of organizing a society “except for all the others”, so these two models are all we’ve
15 really got that is tractable. Critics will be admitted to the event, but only if they carry with them
16 another tractable model.” - J. Felsenstein, r-sig-phylo email list, 8th April 2008.

17 The parametric estimation of phylogenies depends on having an appropriate model of character evolution
18 (Posada and Crandal 2001). Molecular systematists are spoiled for choice in this regard. For example, the
19 program jModelTest2 can fit 1624 models of DNA sequence evolution (Darriba et al. 2012). The situation for
20 the comparative analysis of continuous traits is quite different. Here, we have mainly two analytical models in
21 popular use: Brownian motion (BM) and the Ornstein-Uhlenbeck (OU) process. Other models such as “early
22 burst” are also sometimes used (e.g. Blomberg et al. 2003; Ingram et al. 2012) and there have been several
23 extensions to the OU model (see below). There are other approaches to phylogenetic comparative analyses
24 that do not use explicit models of evolution (in terms of being able to write down the appropriate equations).
25 Some non-analytical models can be used to estimate sampling distributions for regression parameters using
26 computer simulation (Garland et al. 1993), and the evolutionary model for continuous traits can also be altered
27 by applying branch-length transformations (e.g. Grafen 1989; Pagel 1999; Freckleton et al. 2002; Blomberg et al.
28 2003). We do not consider these approaches to phylogenetic comparative analyses here. Instead, we focus on
29 providing an approach to comparative analyses based on the theory of stochastic processes, which unites BM,
30 OU and other processes in a common statistical and probabilistic framework.

31 Starting with Bachelier (1900), the main application of stochastic processes has been in finance where models
32 have been developed for stock prices, derivatives, options and other financial products. In that domain, the
33 model of Black and Scholes (1973) has been particularly successful (in terms of citations), but research into the
34 theory of stochastic processes is still thriving across a wide range of disciplines, especially the physical sciences
35 (e.g. Uhlenbeck and Ornstein 1930; Einstein 1956; Freund and Pöschel 2000; Gardiner 2009). Although diffusion
36 models are common in epidemiology and other life sciences (Fuchs 2013), applications in evolutionary biology are
37 rare. The Wright-Fisher model and the Moran model in population genetics are well-known exceptions (Fisher
38 1922; Wright 1931; Feller 1951; Moran 1958; Ewens 2004). Population geneticists have used these stochastic
39 processes to model microevolution. Here we examine the possible uses of stochastic processes in studies of
40 macroevolution, i.e. evolution above the species level (Simpson 1953; Rensch 1959; Stanley 1975; Benton 2015;
41 Serrelli and Gontier 2015), with the aim to provide new models and methods for the phylogenetic comparative
42 analysis of non-Gaussian traits. Such models are necessary because current evolutionary models for quantitative
43 traits can have poor performance (Pennell et al. 2015).

44 MATHEMATICAL BACKGROUND

45 In order to fully understand the mathematics of stochastic processes, some background is required. At least,
46 some knowledge of Riemann-Stieltjes integrals, as well as some understanding of measure-theoretic probability

47 theory is necessary. Introductory books such as Øksendal (2007) or Klebaner (2012) can be helpful. Gardiner
48 (2009) provides an excellent practical approach which largely ignores the measure-theoretic foundations, but
49 concentrates mainly on applications in the physical sciences.

Consider a sample space Ω consisting of discrete, elementary events ω , occurring over time such that:

$$\Omega = \{\omega : \omega = (x_1, x_2, x_3, \dots, x_T)\}$$

where x_1, \dots, x_T are values of a (univariate) trait x at time $= 1, \dots, T$. Our trait may come from a good palaeontological sequence, for example. Our knowledge about the evolution of the trait increases as we observe more and more values of x as T increases. However, in general we only observe one possible x at each time step. There could have been many other outcomes for the trait at each time, so we only have information on the observed values A , a subset of Ω . We therefore know that the “true” state of the trait over all time must be in A and not in that part of Ω that is not A . In set notation, $\Omega \setminus A = \bar{A}$. Now define \mathcal{F}_t as the information available about the trait (ie the trait values) at all times up to time t , ie A . At $t = 0$ we have no information about the trait so $\mathcal{F}_0 = \{\emptyset, \Omega\}$ where \emptyset is the empty set. At $t = 1$ we know x_1 , at $t = 2$ we know x_1 and x_2 , etc. We do not forget the previously gained information. Therefore each \mathcal{F}_t contains the trait value at time t plus all the \mathcal{F}_t that have gone before. ie. $\mathcal{F}_0 \subset \mathcal{F}_1 \subset \mathcal{F}_2 \subset \dots \subset \mathcal{F}_T$. Each \mathcal{F}_t is called a *field* or *algebra*. The collection of all fields is called a *filtration*. ie.

$$\mathbb{F} = \{\mathcal{F}_0, \mathcal{F}_1, \dots, \mathcal{F}_t, \dots, \mathcal{F}_T\} \quad \mathcal{F}_t \subset \mathcal{F}_{t+1}$$

50 The above explanation of fields is limited to the discrete time case. We would also like to model probability
51 as a continuous function of time. The definition of fields in the continuous time case is more tiresome but
52 can be found in any textbook on measure-theoretic probability (e.g. Pollard 2002). The most important field
53 in measure-theoretic probability theory is the Borel σ -field (\mathfrak{B}). A probability (Lebesgue) measure, \mathbb{P} can be
54 defined for a process that generates a σ -field. Hence, a probability space is defined as the triple $(\Omega, \mathcal{F}, \mathbb{P})$. A
55 *random variable* X on $\{\Omega, \mathcal{F}\}$ is a measurable function from (Ω, \mathcal{F}) to $(\mathbb{R}, \mathfrak{B})$, where \mathfrak{B} is the Borel σ -field on
56 the real number line. A *stochastic process* is a collection of random variables $\{X(t)\}$. A stochastic process is
57 said to be *adapted* to a filtration \mathbb{F} if for all t , $X(t)$ is a random variable on \mathcal{F}_t . We will only be considering
58 stochastic processes that are adapted to a filtration. This is not really a limitation, as a major property of
59 adapted processes is that they are unable to anticipate the future, which does not appear to be a very limiting
60 assumption for a macroevolutionary model.

61 BROWNIAN MOTION

62 Brownian motion (BM) is named for the movement of pollen grains suspended in water, as first observed by
63 the botanist Robert Brown in 1837, but it is observed in many other multi-particle settings. The mathematics
64 of BM were first analysed by Bachelier (1900), who anticipated almost all the mathematical results of Einstein’s
65 work in 1905 in the context of molecular movement (see Einstein 1956). Wiener (1923) was the first to rigorously

66 characterise BM as a stochastic process, and hence BM is sometimes also known as the Wiener process. BM
67 was first proposed as a model of character evolution for phylogeny estimation by Felsenstein (1973), who also
68 introduced this model into phylogenetic comparative regression analyses (Felsenstein 1985).

69 Let $B(t)$ be the trait value of a BM process at time t . BM has the following defining properties (e.g. Klebaner
70 2012). BM has independent increments. $B(t) - B(s)$ for $t > s$ is independent of the past $B(u)$ where $0 \leq u \leq s$.
71 The increments are also Gaussian. $B(t) - B(s)$ has a Normal (Gaussian) distribution with a mean $\mu = 0$ and
72 variance $\sigma^2 = t - s$. This means we can use all the powerful mathematical machinery appropriate to Gaussian
73 distributions.

74 Further, the sample paths of a BM process $B(t)$ have the following properties, for almost every sample path
75 (i.e. other than those of Lebesgue measure zero): $B(t)$ is a continuous function of t . Hence, BM can be used to
76 model continuous traits in continuous time. $B(t)$ is not monotone in any time interval, no matter how small the
77 interval. BM paths are jagged at all time scales. Despite being continuous, $B(t)$ is nowhere differentiable. This
78 property makes it difficult to estimate rates of evolution from sample paths, although σ^2 is usually associated
79 with the rate of evolution. The quadratic variation of $B(t) = t$. That is, the variance of $B(t)$ increases linearly
80 with t . There doesn't seem to be any biological reason why the variance of a trait should increase linearly with
81 time. Further, this property implies that there are no bounds to evolution and that traits have no physical
82 limits. This is unlikely to be true for any trait (e.g. McGhee 2015) but see Conway Morris et al. (2015); Vermeij
83 (2015, *ibid.*).

84 BM is useful as a simple model of trait evolution. Its simplicity is due to the above properties, as well as to
85 the fact that it has the Markov property. Further, BM is a martingale, which means that the expectation of
86 the process at time $t + s$ is the value of the process at time t . That is, $E(B(t + s)|\mathcal{F}_t) = B(t)$. The Markov
87 and martingale properties simplify the mathematics of working with BM processes. BM lends itself to two
88 evolutionary interpretations. Either it is a model implying no selection and evolution occurs just by random
89 drift, or it can be viewed as a model of very strong selection in a randomly varying environment (see Hansen
90 and Martins 1996). These interpretations cannot be simultaneously correct, and both are likely to be wrong for
91 any real quantitative trait.

92 THE ORNSTEIN-UHLENBECK PROCESS

93 The OU process was introduced as an improved model for physical Brownian motion, which incorporates the
94 effect of friction (Uhlenbeck and Ornstein 1930). It also has a long history in evolutionary biology. It can be
95 derived from the consideration of stabilising selection and genetic drift (Lande 1976). Its use in phylogenetic
96 comparative methods has been promoted by many authors (Felsenstein 1988; Hansen and Martins 1996; Hansen
97 1997; Martins and Hansen 1997; Butler and King 2004; Hansen et al. 2008; Beaulieu et al. 2012). It has the

98 following form:

$$X(t) = \mu + e^{-\alpha t} \left(X(0) - \mu + \sigma \int_0^t e^{\alpha s} dB(s) \right) \quad (1)$$

99 where μ is the mean of the process. Note that $X(t)$ in (1) depends on $B(s)$. That is, BM is one building
100 block of the OU process. The biological interpretation of the OU process is controversial. Most authors have
101 interpreted α as the strength of a restraining force corresponding to stabilizing selection, and the sample paths
102 as trajectories of evolution of organisms' traits (e.g. Beaulieu et al. 2012; Butler and King 2004). However,
103 Hansen et al. (2008) interpret the sample paths as paths of an evolutionary optimum itself, subject to an overall
104 central tendency with strength α and stochastic perturbations.

105 The properties of OU are well known (e.g. Insua et al. 2012; Klebaner 2012). The OU process is a Gaussian
106 process with continuous paths. It has the Markov property and it is stationary, provided the initial distribution
107 is the stationary distribution $N(\mu, \frac{\sigma^2}{2\alpha})$. It is the *only* stochastic process which has all three properties (Gaussian,
108 Markov, stationarity) (Breiman 1968; Klebaner 2012). OU is *not* a martingale. The Gaussian property of both
109 BM and OU makes them relatively simple to work with, for example, (Hansen 1997; Butler and King 2004)
110 used likelihood methods to fit models with different α values on different branches of the phylogeny. Beaulieu
111 et al. (2012) extend this idea by allowing σ to vary with time.

112 Note that the stochastic integral in (1) is with respect to “white noise”, implying that $B(t)$ is differentiable,
113 whereas one of the properties of BM is that it is *not* differentiable. The meaning of such integrals is therefore
114 not straight forward. In fact, it requires a new definition for integration. The definition adopted here is that of
115 Itô (1944, 1946). There are other approaches to stochastic integration, most notably the Stratonovich integral
116 (e.g. Gardiner 2009). Turelli (1977) has discussed situations in which one definition may be preferred over the
117 other. In practice, the Itô integral is the most widely used:

$$\int_{t_0}^t f(s) dB_s = \text{ms-lim}_{n \rightarrow \infty} \left\{ \sum_{i=1}^n f(t_{i-1}) [B(t_i) - B(t_{i-1})] \right\} \quad (2)$$

118 where ms-lim means the mean square limit (Gardiner 2009, p. 41).

119 The main drawback of both BM and OU that we wish to highlight is the Gaussian nature of both stochastic
120 processes. While analytically and computationally useful, this assumption limits the application of the models
121 to traits that are Normally-distributed. Of course, one could transform the response variable so that it is then
122 approximately Gaussian, such as using the *logit(x)* *probit(x)*, or $\text{Sin}^{-1}\sqrt{x}$ transformations for proportions, or
123 the $\log(x)$ transformation for counts, and then use Gaussian process models (Ives 2015; Warton et al. 2016).
124 However, shoe-horning data using transformations can make interpretation of model outputs more difficult.
125 Instead, we suggest that the direct modelling of non-Gaussian evolutionary processes provides a much more
126 elegant view of the evolutionary process. There is a strong analogy with the development of Generalized Linear

127 Models, which greatly extended the analysis of non-Gaussian linear models (McCullagh and Nelder 1989). Here
128 we outline a generalized method of constructing new stochastic process models for continuous trait evolution.

129 DIFFUSIONS AS MODELS OF TRAIT EVOLUTION

130 Consider the stochastic differential equation (SDE):

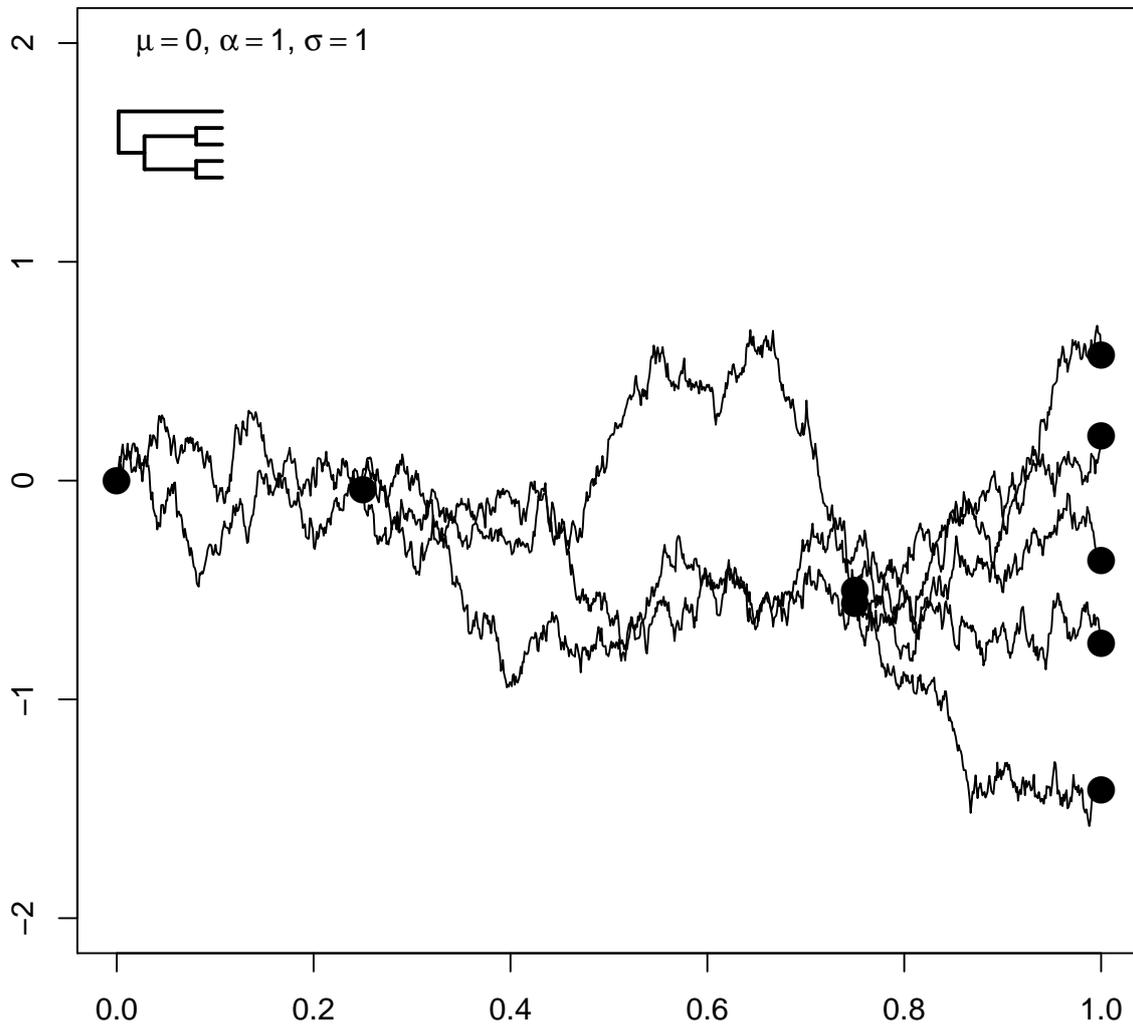

$$dX_t = b(X_t, t)dt + \sigma(X_t, t)dB_t \quad (3)$$

131 Such SDEs are termed “diffusion” equations and arise as solutions to the Fokker-Planck equation (Gardiner
132 2009). The left-hand side of the equation represents a small change in trait variable X_t at time t . The right-
133 hand side has two terms. The first term is the deterministic part of the model. $b(X_t, t)$ is termed the *drift*
134 *coefficient*. The differential of the first term is dt , which denotes a differential with respect to (continuous)
135 time. Note the difference in usage of the term compared to its use in population genetics, where drift implies
136 a stochastic process. We will retain the traditional mathematical terminology. The second term is stochastic,
137 as the differential is $dB(t)$, “white noise”. $\sigma(X_t, t)$ is termed the *diffusion coefficient*. In financial statistics,
138 $\sigma(X_t, t)$ is termed the “volatility” (Mikosch 1998). Note that both b and σ can depend on both X_t and t in some
139 arbitrary way. It is important that the only meaning of (3) is with respect to the Itô definition of the integral
140 (2). Stochastic processes of this type are termed “Itô diffusions.”

141 The Ornstein-Uhlenbeck diffusion process can be defined by the following SDE:

$$dX_t = \alpha(\mu - X_t)dt + \sigma dB_t \quad (4)$$

142 for α , μ and σ as real, positive constants. Here, α represents the restraining force of stabilising selection. μ
143 represents the mean trait value (at stationarity). The drift coefficient here is a linear function of X_t . The form
144 of the drift is significant, as it is this expression that controls the forcing of the trait X_t back towards μ . OU is
145 thus said to be “mean-reverting”: X_t tends to return to μ over time. However, the property of mean reversion
146 is not limited to the OU process. Any simple diffusion model with a drift coefficient of the form in (4) will
147 exhibit mean reversion. It is also clear that (4) is time-homogeneous since neither b nor σ depend on t . The
148 process is also ergodic. That is, given enough time, the time average for any particular species’ trait is equal to
149 the average trait value across species (Lebowitz and Penrose 1973). These properties suggest that a stationary
150 distribution exists for this process. Figure 1 shows a sample evolution along a 5-species tree for the OU model.

151

Figure 1: Ornstein-Uhlenbeck evolution along a 5-species tree. μ is the mean of the process, α is the strength of the restraining force, and σ is the diffusion coefficient. Large dots are nodes and tips.

152

NEW EVOLUTIONARY MODELS

153 The key to the construction of new models for evolution is the solution of the Fokker-Planck (Kolmogorov
154 Forward) equation (Risken 1996). In one dimension it takes the form:

$$\frac{\partial f(x,t)}{\partial t} = -\frac{\partial}{\partial x}[b(x,t)f(x,t)] + \frac{1}{2}\frac{\partial^2}{\partial x^2}[\sigma^2(x,t)f(x,t)] \quad (5)$$

155 (5) governs the time evolution of the underlying probability law $f(x,t)$. It is a partial differential equation in
156 x and t . Note that it is *not* stochastic. If the stochastic process is time-homogeneous, (5) can be written as:

$$\frac{d}{dx}[b(x)f(x)] - \frac{1}{2}\frac{d^2}{dx^2}[\sigma^2(x)f(x)] = 0 \quad (6)$$

157 Solving for $f(x)$ gives the following formula for the construction of the stationary distribution (Appendix 1):

$$f(x) = \frac{C}{\sigma^2(x)} \exp\left(\int_{x_0}^x \frac{2b(y)}{\sigma^2(y)} dy\right) \quad (7)$$

158 where C is a constant of integration found by solving $\int f(x)dx = 1$. (7) is sometimes known as Wright's
159 equation (Wright 1938; Cobb 1998).

Consider the following diffusion equations:

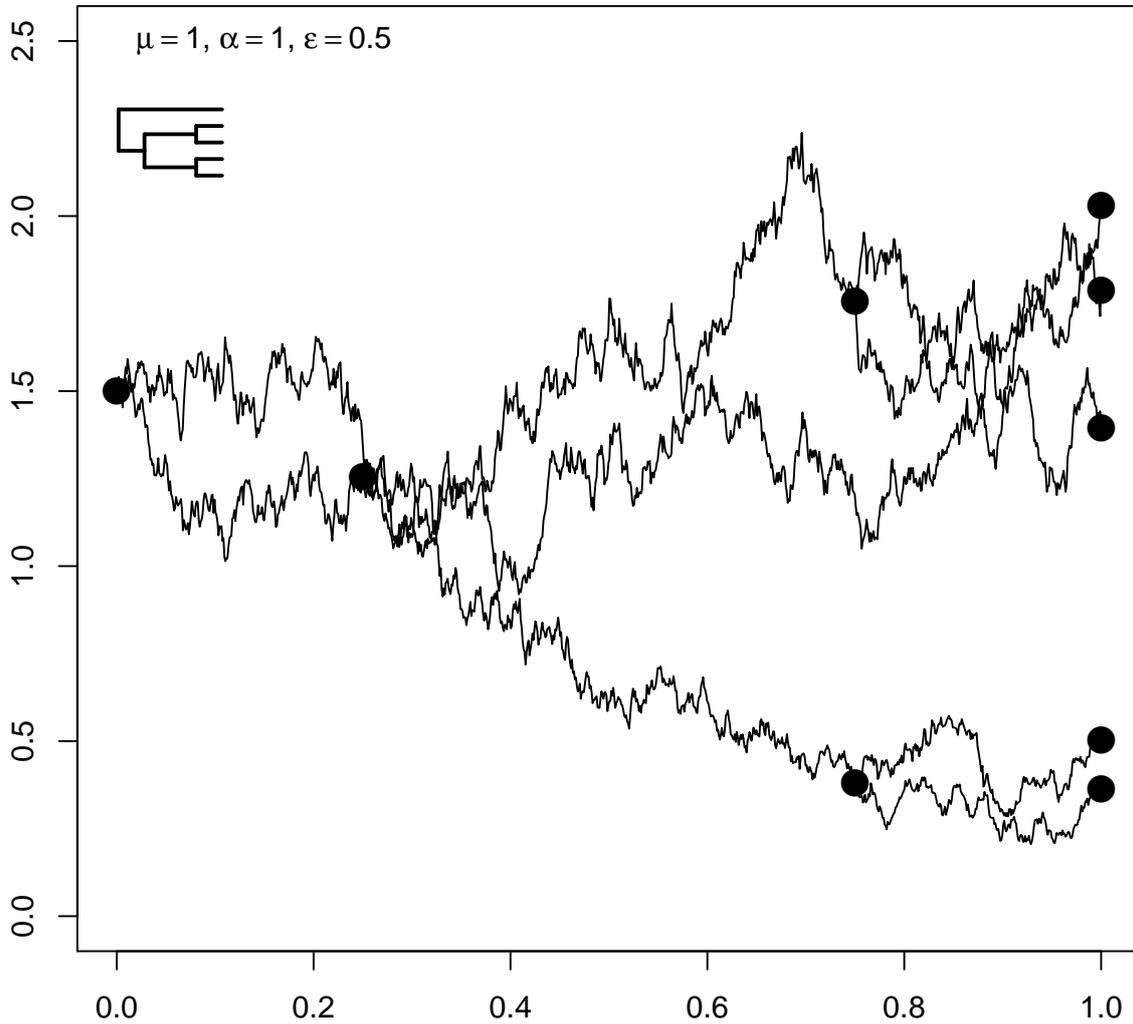

$$dX_t = \alpha(\mu - X_t)dt + \sqrt{\epsilon X_t}dB_t \quad (8)$$

$$dX_t = \alpha(\mu - X_t)dt + \sqrt{\epsilon X_t(1 - X_t)}dB_t \quad (9)$$

The drift terms in (8) and (9) are of the same form as in (4). Hence, these processes are both mean-reverting, and will be driven by a central tendency towards μ , with a restraining force α . The difference between these two processes and OU is in the diffusion coefficient. With a mean-reverting process, the form of the diffusion coefficient determines the distribution of the stationary distribution. The stationary distributions for each process described by (8) and (9) are derived in Appendix 2. While the notation for calculating with diffusion models is powerful and elegant, stochastic processes come alive when visualised using simulation. We provide example plots of paths mapped onto a phylogeny with five species (Figs.2 and 3). (8) has as its stationary distribution:

$$f(x|\mu, \delta) = \left(\frac{x}{\delta}\right)^{-1+\frac{\mu}{\delta}} \frac{e^{-\frac{x}{\delta}}}{\Gamma(\frac{\mu}{\delta})}, \quad \delta = \frac{\epsilon}{\alpha}.$$

160 Γ is the Gamma function. That is, $f(x|\mu, \delta)$ is a density of a Gamma distribution with mean = μ , mode = $\mu - \delta$,
161 and variance = $\delta\mu$: $x \sim \text{Gamma}(\frac{\mu}{\delta}, \frac{1}{\delta})$. In fact, (8) is the Cox, Ingersoll and Ross (CIR) model commonly used
162 in finance (Cox et al. 1985). See Figure 2.

163

Figure 2: Cox-Ingersoll-Ross evolution along a 5-species tree. Large dots are nodes and tips. μ is the mean of the process, α is the strength of the restraining force, and ϵ is the scaling constant for the diffusion coefficient. Large dots are nodes and tips.

The stationary distribution of the process described by(9) is:

$$f(x) = \frac{1}{B(\frac{\mu}{\delta}, \frac{(1-\mu)}{\delta})} x^{\frac{\mu}{\delta}-1} (1-x)^{\frac{(1-\mu)}{\delta}-1}, \delta = \frac{\epsilon}{\alpha}$$

164 B is the Beta function. That is, $f(x|\mu, \delta)$ is the density of a Beta distribution with $x \sim Beta(\frac{\mu}{\delta}, \frac{(1-\mu)}{\delta})$ (Fig 2).

165 The analysis of (8) and (9) and several other examples have been provided by Cobb (1998). It is interesting

166 that in both cases, the substitution $\delta = \frac{\epsilon}{\alpha}$ was necessary in order to correctly recognise the distributions as

167 Gamma or Beta. This suggests that the separate estimation of ϵ and α is difficult if estimation is based solely

168 on the stationary distribution. The same stationary distributions occur for arbitrary α and ϵ , so long as their

169 ratio (δ) remains constant. A sample evolutionary path from this Beta process is presented in Figure 3.

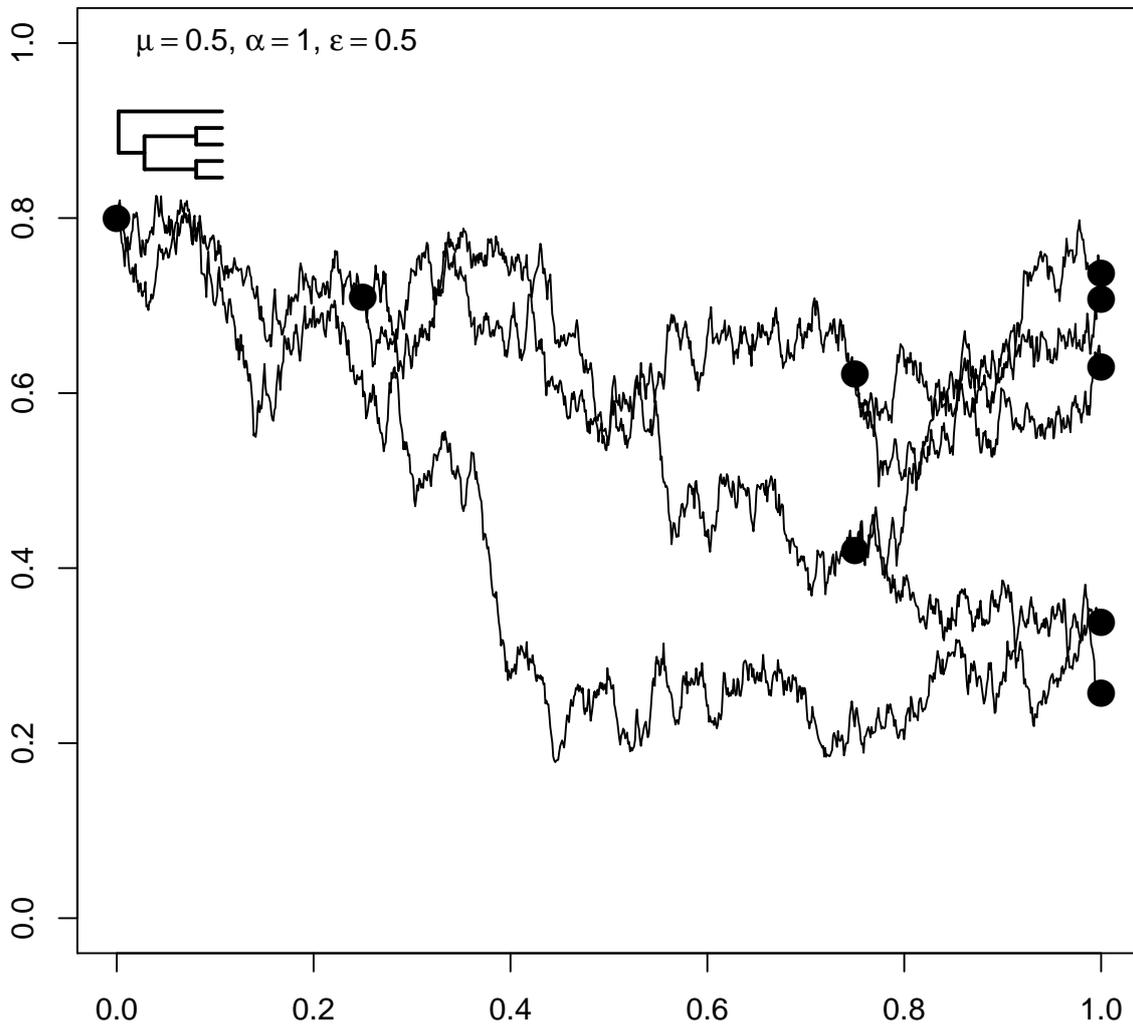

Figure 3: Beta evolution along a 5-species tree. μ is the mean of the process, α is the strength of the restraining force, and ϵ is the scaling constant for the diffusion coefficient. Large dots are nodes and tips.

STOCHASTIC DIFFERENTIAL EQUATIONS FROM STATIONARY DISTRIBUTIONS

Reversing the procedure, that is deriving an SDE given a stationary distribution, is more difficult since the correspondence between SDEs and their stationary distribution (if it exists) is not unique. The problem has been addressed by Cai and Lin (1996). Extra information is needed, specifically the form of the spectral density of the process, which affects the structure of the drift coefficient in the SDE. Unfortunately for models of trait evolution, we rarely have detailed information on the evolutionary trajectory of a trait (ie the true historical realisation of the process) and hence we cannot analyse the spectral density of the trajectory in order to infer

179 a good model for the drift coefficient. We need to make extra assumptions. Fortunately, if we assume that the
180 spectral density is of the low-pass filter type:

$$\Phi_{XX}(\omega) = \frac{\alpha\delta^2}{\pi(\omega^2 + \alpha^2)} \quad (10)$$

181 where Φ_{XX} is the spectral density at frequency ω , δ^2 is the mean-square value of the process $X(t)$, then the
182 drift coefficient will be of the mean-reverting OU type in (4), with α in (10) being identical to α in (4). The
183 low-pass filter assumption implies that the drift coefficient is determined mainly by the low frequency (long
184 wavelength) characteristics of the evolutionary trajectory. That is, the form of the drift is mainly determined
185 by long-lasting, slow deviations from μ and short-term (high-frequency) excursions are less important. To our
186 knowledge, this assumption has never been made explicit in the literature on the application of the OU model
187 in phylogenetic comparative methods.

Calculation of the diffusion coefficient comes directly from the application of the time-homogeneous Fokker-Planck equation (6), except instead of solving for $f(x)$, we now solve for $\sigma(x)$ (Cai and Lin 1996). The expression for $\sigma^2(x)$ becomes:

$$\sigma^2(x) = -\frac{2\alpha}{f(x)} \int^x yf(y)dy.$$

188

189 TRANSITION DISTRIBUTIONS

190 The stationary distribution is not the only distribution associated with a Markov diffusion process. The transi-
191 tion, or conditional, distribution is important for simulation and likelihood calculations (Iacus 2008). It can be
192 found as a solution to the Fokker-Planck equation (Klebaner 2012) and is defined as:

$$P(y, t, x, s) = P(X(t) \leq y | X(s) = x). \quad (11)$$

193 Equation (11) defines the probability distribution of y , the value of X occurring at time t , given that the process
194 X has reached x at time s , where $s < t$. Unfortunately, for most processes the transition distribution is unknown
195 or intractable. For Gaussian processes, the conditional density is usually straightforward. Brownian motion
196 has as its transition distribution the Normal distribution with mean $\mu = \mathbb{E}(X_t | X_s = x) = x$, by the martingale
197 property. The conditional variance of BM is $\text{Var}(X_t | X_s = x) = \sigma^2 t$. That is, the variance is independent of the
198 trait value and depends only on t .

For the OU process (4) and $t > s \geq 0$ the transition density is Gaussian with mean $\mathbb{E}(X_t | X_s = x) = xe^{-\alpha(t-s)} + \mu(1 - e^{-\alpha(t-s)})$ and variance $\text{Var}(X_t | X_s = x) = \frac{\sigma^2}{2\alpha}(1 - e^{-2\alpha(t-s)})$. The complexity of transition distributions increases quickly with the complexity of the corresponding SDE. Equation (8), the CIR model, has the the following transition density (Cox et al. 1985):

$$f(s, x, t, y) = c \left(\frac{u}{v}\right)^{\frac{\nu}{2}} \exp(-(u+v)) I_{\nu}(2\sqrt{uv})$$

for $t > s \geq 0$ where

$$c = \frac{2\alpha}{\epsilon^2(1 - e^{-\alpha(t-s)})}, u = cx^{-\alpha(t-s)}, v = cy, \nu = \frac{2\alpha\mu}{\epsilon^2} - 1.$$

I_ν is the modified Bessel function of the first kind of order ν :

$$I_\nu(z) = \sum_{k=0}^{\infty} \left(\frac{z}{2}\right)^{2k+\nu} \frac{1}{k! \Gamma(k + \nu + 1)}$$

where $z \in \mathbb{R}^+$ and $\Gamma(\cdot)$ is the Gamma function. The expectation and variance of this distribution are:

$$\begin{aligned} \mathbb{E}(X_t|X_s = x) &= 2\frac{\alpha\mu}{c\epsilon^2} + xe^{-\alpha(t-s)} \\ \mathbb{V}\text{ar}(X_t|X_s = x) &= \frac{2}{c} \left(\frac{\alpha\mu}{c\epsilon^2} + xe^{-\alpha(t-s)} \right) \end{aligned}$$

199 respectively. The transition density of equation (9) is even more complicated and involves infinite sums of
200 hypergeometric functions (Abundo 1997). Transition densities are of extreme importance for phylogenetic
201 comparative methods, as they determine the structure of the evolutionary covariance matrix and the relationship
202 between branch lengths and covariances. Hence, approaches such as PGLS (Grafen 1989; Martins and Hansen
203 1997; Blomberg et al. 2012) are intimately dependent on knowing transition densities. However, even quite
204 simple models like the non-Gaussian models presented here are likely to present formidable problems with
205 calculating evolutionary covariances, as the formulae for the transition densities for these models are extremely
206 difficult to work with, if they are known at all.

207 DISCUSSION

208 *Fitting Models to Data*

209 To be useful, theory must be confronted with data (Hilborn and Mangel 2013). The evolutionary models
210 discussed here (of which BM and OU are special cases) therefore require methods to fit them to comparative
211 data in order to estimate parameters and test hypotheses about those parameters. For BM, OU and other
212 Gaussian processes, we can use the machinery developed for Normal distributions. In particular, there are simple
213 relationships between branch lengths on a phylogeny and covariances for linear, Gaussian processes (Hansen and
214 Martins 1996). There are no such relationships for non-linear processes that have stationary and/or transition
215 distributions that are non-Gaussian so we cannot use inference methods that rely on expected covariances among
216 species. Methods have recently been proposed for the calculation of likelihoods for continuous characters on
217 a tree, if the transition density of the evolutionary model is known (Hiscott et al. 2015). However, often the
218 transition density is not known in closed form, or not known at all. If there was no phylogenetic dependence
219 (that is, a star phylogeny), we could estimate model parameters, as the existence of a stationary distribution
220 implies that at any time point independent samples will follow the stationary distribution. Unfortunately in
221 the case of comparative data with “phylogenetic signal”, the data are not independent. We cannot make use of
222 this result.

Simulation is currently the only option when the transition density of the process is intractable. Simulation based methods for estimating parameters for stochastic processes are widely available, largely based on theory developed for use in statistical finance (Iacus 2008). For example, stock prices may be observed every fraction of a second, resulting in a large amount of high-frequency data with which to make inferences. Methods to deal with missing data in the high-frequency setting have been developed (e.g Roberts and Stramer 2001). In this context the formidable problem is that data in comparative studies are only observed at the tips of the phylogeny. Rarely, internal branches may be calibrated with fossils. The entire evolutionary history of the trait for each species is thus missing and unknown. This is worse than “low-frequency” data (addressed by Fuchs 2013): it is almost “no-frequency” data. The simulation of the entire evolutionary history, except for the tip and fossil data, is necessary. However, we may be able to combine simulated and real data using data augmentation in a Bayesian framework which might permit the approximate estimation of model parameters (Tanner and Wong 1987; Papaspiliopoulos et al. 2013). An MCMC scheme that alternates between the update of simulated paths, and the sampling of parameters via data augmentation appears to be the most promising method (Fuchs 2013). Such an approach would require the use of bridge processes (e.g. Beskos et al. 2008; Bladt and Sørensen 2010; Lin et al. 2010) both to ensure that observed trait values are always part of the simulated trait evolutionary history and to iteratively update small sections of the simulated trait history at each iteration of an MCMC procedure. Acceptance rates during MCMC are higher when only small parts of the tree are updated at a time (Elerian 1999; Elerian et al. 2001; Roberts and Stramer 2001; Kalogeropoulos 2007). Methods exist for the updating of bridge processes in MCMC algorithms (Beskos et al. 2006, 2008, 2013).

The notion of using fossil phenotypes and dates to fix points in the trait-time space is attractive, but may contain grave difficulties. Cladistic criticisms of the use of fossils to establish ancestor-descendent relationships have never been refuted (Engelmann and Wiley 1977; Patterson 1981). The recent development of “tip dating” methods may avoid such criticism (Ronquist et al. 2012; O’Reilly et al. 2015). Instead we may have to be content to build quantitative trait models that incorporate ancestor-descendent relationships as ancilliary hypotheses, recognising that tests of such hypotheses may be impossible for any real dataset. However, simulation studies may be valuable in assessing the sensitivity of trait model parameter estimation to fossil placement (as an ancestor or as a sister taxon). It may be that inferring a fossil as a direct ancestor rather than as a close sister taxon will make little difference to parameter estimates for models of quantitative trait evolution. However, this has yet to be established.

The Lamperti transformation may be used to improve the simulation of trait trajectories by transforming to a unit diffusion coefficient (Lamperti 1962; Burnecki et al. 1997; Møller and Madsen 2010; Fuchs 2013). Consider equation (3). The Lamperti transformation is $Y = (Y_t)_{t \geq 0}$ where:

$$Y_t = g(X_t) = \int^{X_t} \frac{du}{\sigma(u)}$$

Provided the transformation $g(\cdot)$ exists and is invertible, Y fulfils the diffusion equation:

$$dY_t = \left(\frac{b(g^{-1}(Y_t), t)}{\sigma(g^{-1}(Y_t))} - \frac{1}{2} \frac{\partial \sigma}{\partial x}(g^{-1}(Y_t)) \right) dt + dB_t,$$

with $Y_{t_0} = g(x_0)$.

Transforming the model to remove any dependence of the diffusion coefficient on $X(t)$ and on t makes the transformed process “more Gaussian” but at the cost of increasing the complexity of the drift coefficient (Iacus 2008). However, there are grave difficulties even with fitting Gaussian models, where the transition density is known in closed form. OU has significant problems (Cooper et al. 2015), including problems with the identifiability of parameters (Ho and Ané 2014). Many simulated likelihood methods have been proposed for fitting models where the transition density is unknown (Brandt and Santa-Clara 2002; Durham and Gallant 2002; Sørensen 2004; Cano et al. 2006; Hurn et al. 2007; Kalogeropoulos 2007), including phylogenetic comparative methods (Kutsukake and Innan 2012). These methods often include a discretised, “locally Gaussian” approximation method such as the Euler scheme or the Milstein scheme (Elerian 1998; Iacus 2008). Bayesian simulation methods for parameter estimation in non-Gaussian stochastic process models of evolution is a current topic of research.

Stationarity

The notions of stationarity and stationary distributions have been central to this study. In the absence of an excellent fossil record of trait evolution for most traits and most taxa, it seems to be a necessary assumption for evolutionary stochastic process models that are more complicated than BM. Indeed, the success of the OU process in evolutionary studies is almost as much based on its stationarity as its Gaussian properties. Several authors have constructed non-stationary evolutionary models based on OU (e.g. Bartoszek 2012; Beaulieu et al. 2012; Jhwueng and Maroulas 2014). Non-stationarity can arise because of time dependence in the drift coefficient, time dependence in the diffusion coefficient, or both. For mean-reverting processes, the mean of the process μ and/or the strength of the restraining force α may be time dependent (Beaulieu et al. 2012). σ might vary with time smoothly over the tree (Bartoszek 2012).

Aside from the problem of overparameterisation (Bartoszek 2012), different parameters on different clades of the tree imply at least a short period of non-stationarity as species evolve from an ancestral evolutionary regime to the new conditions. Currently, OU based models assume immediate stationarity after the change in evolutionary regime (e.g. Beaulieu et al. 2012). If the old regime is almost the same as the new conditions, then stationarity in the new conditions may be achieved relatively quickly. However, if the old regime is very different from the new one, the length of the non-stationary period may be considerable and the underlying “instantaneous” stationary model will be wrong. Only fossil evidence can help in this regard because fossils can provide fixed points in the morphospace-time that can anchor the model, and provide evidence of non-stationary trait evolution or stasis. Of course, if the ancestral and derived stationary distributions are very similar so that stationarity is achieved quickly, it will be difficult to tell these two scenarios apart.

284

Model Extensions

285 An obvious extension of univariate stochastic processes is to re-cast them in a multivariate or multidimensional
286 framework. There has been some research into multivariate phylogenetic comparative methods, including several
287 software packages, largely based on BM, OU, and early-burst models (Zheng et al. 2009; Klingenberg 2011;
288 Bartoszek 2011; Bartoszek et al. 2012; Klingenberg and Marugn-Lobn 2013; Adams 2014a,b,c; Clavel et al. 2015).
289 Certainly, multivariate diffusions are necessary to understand the correlation among characters (Bartoszek et al.
290 2012). However, the properties of univariate diffusion models do not always carry over to the multivariate setting.
291 In particular, there are well-known differences between the recurrence and transience properties of Brownian
292 motion in multiple dimensions (Mörters and Peres 2010). The analysis of the properties of multivariate diffusion
293 models for phylogenetically-correlated data is a topic of current research (Sherratt and Blomberg, in prep.).

A further extension of diffusion models is to the case where evolution is not strictly continuous, but consists of continuous evolution punctuated by “jumps” using Lèvy processes Landis et al. (2012). Lèvy processes are stochastic processes with independent, stationary increments. They can be thought of as consisting of three superimposed processes:

$$X_t = \sigma B_t + J_t + M_t$$

294 where B_t is a BM (possibly with drift), J_t is a compound Poisson point process, and M_t is a (square-integrable)
295 martingale with jumps. Hence, simple BM is a special case of a Lèvy process with no discrete jumps. Note
296 that OU is not a Lèvy process. Landis et al. (2012) estimate parameters for a Lèvy process fitted to data for
297 body mass and brain volume in primates, and found evidence for some jumps in each trait, rejecting a simple
298 BM model. The application of Lèvy processes to phylogenetic comparative data is promising, but given the
299 difficulties and complexities of fitting Itô diffusions, it may pay to be wary of hidden pitfalls. Certainly the
300 *post hoc* identification of jumps may not be of much use without a working hypothesis for *why* we may expect
301 jumps at certain nodes on the tree, and models already exist for postulating *a priori* different rates of evolution
302 in different parts of the tree (e.g. Butler and King 2004; O’Meara et al. 2006). It may be difficult to choose
303 between “jump” models and models that estimate rapid changes of evolutionary rate (large differences in σ) for
304 particular clades (e.g. Alfaro et al. 2009; Rabosky et al. 2013, 2014; Shi and Rabosky 2015). One may also object
305 to “jump” models on theoretical grounds. Itô diffusions are continuous processes (although not differentiable),
306 and as such represent the dictum, “*Natura non facit saltus*”. If we are to allow jumps in evolutionary history,
307 we should be able to provide a mechanistic (genetic) explanation of how and why jumps occur, and how to
308 distinguish jumps from rapid, continuous evolution.

309

Evolutionary models for phylogenetic comparative analyses

310 Scientific models may be developed with several different motivations. The scientist may build models to make
311 a decision (e.g. to reject a null hypothesis), summarise evidence (e.g. calculate the likelihood of observing

312 the data, given a model) or quantify their beliefs (using Bayes Theorem). Another important property of a
313 model is its predictive ability, and predictive models have long been the favourite approach in the physical
314 sciences: models predict future observations which then test the validity of the model. Biologists, and especially
315 evolutionary biologists, have never put much faith in predictive models (Hillis 1993). So many factors affect
316 the evolution of organisms, and over such a long timespan, that one is tempted to give up hope of developing
317 mathematical models that have any predictive value in the real world. And it is true that it would be foolish to
318 make predictions of where in the phylomorphospace *sensu* Sidlauskas (2008) species will evolve to in some future
319 deep time. We have no hope of making the necessary observations. Although we may not be able to predict the
320 precise evolutionary trajectory of any particular species, we can perhaps predict (or postdict) the probability
321 distribution of traits across species. Given the traits from a newly discovered species (fossil or extant), we can
322 predict that the new trait values fit well within the distribution of the known species' trait values, where the
323 parameters of the distribution are estimated from extant species. If the values for the new species' traits are
324 more extreme so that they fall into the tails of the stationary distribution, we may reject our model of evolution
325 for that set of species and traits. This “grey box” approach to model identification (Kristensen et al. 2004) gives
326 up the possibility of knowledge of the microevolutionary processes leading to species diversification and trait
327 evolution, and replaces it with a tractable stochastic process that summarises the evolution of the statistical
328 distribution of trait values over deep time. Given the quality of most comparative data sets, this may be the
329 best that can be achieved.

330 The modelling approach and the new models described here involve a considerable amount of mathematical
331 sophistication in their derivation and in the analysis of their properties. Computational skill is necessary
332 in developing algorithms to fit the models to data. Critics may object that the approach outlined here is
333 too complex or unnecessary, given the quality of data in most phylogenetic comparative analyses. However,
334 diffusions are already the most popular model for phylogenetic comparative studies, in the form of BM and
335 OU. The present author hopes simply to widen horizons and provide a unifying framework. It is true that,
336 “All models are wrong, but some are useful” (Box 1976). Nevertheless, mathematics (and its sister taxon,
337 computation) are the best tools we have in order to precisely describe both the nature of macroevolutionary
338 phenomena and our assumptions about them. A small amount of precise mathematics can sometimes cut
339 through imprecise verbal arguments. For example, the microevolutionary genetic theory developed by Fisher,
340 Haldane and Wright effectively silenced the arguments between naturalists and Mendelians on the importance of
341 natural selection and the nature of genetic variation, leading to the Evolutionary Synthesis (Mayr and Provine
342 1998). A mathematical theory of macroevolution which unites stochastic models of trait evolution with models
343 of phylogenesis, speciation and extinction may allow us to better statistically model the course of phenotypic
344 evolution (e.g. Maddison et al. 2007; FitzJohn 2010; Goldberg et al. 2011), although estimating parameters for
345 these models may be difficult without fossil trait data. Recent applications of trait-mediated diversification
346 models based only on extant trait data may be misleading (Rabosky and Goldberg 2015). A more sophisticated
347 understanding of the mathematics of diffusions and other stochastic processes may allow the critical appraisal

348 of macroevolutionary models for biological phenomena in deep time.

349 *Conclusion*

350 Currently popular models of trait evolution rely heavily on Gaussian processes and their useful mathematical
351 properties. However, non-Gaussian models are possible and may have some advantages over Gaussian models in
352 certain situations where the data are likely to be non-Normal. The present study describes new, non-Gaussian
353 models of trait evolution, together with methods for building new models, and a discussion of the mathematical
354 and computational difficulties in working with diffusion models in a more generalised setting. Several new
355 avenues for investigation are suggested. In particular, the role of fossils in improving the identifiability of
356 models and the extension of models to multivariate trait space seem especially timely. These areas are not
357 without challenges. Including fossils as ancestors, rather than as sister taxa has been a difficult problem for
358 many years, as the early cladists were well aware. The extension of univariate models to multivariate trait
359 space is likely to be more difficult than expected, as even the simplest evolutionary model, BM, has different
360 properties in multiple dimensions. Another important research direction is to establish the expected covariances
361 for traits in terms of the transition distributions for non-Gaussian models. This is likely to be difficult but would
362 pay off immensely, allowing the the construction of a new Generalized Phylogenetic Model, by analogy with
363 Generalized Linear Models. Nevertheless, research into the application of stochastic process (diffusion) models
364 to the evolution of quantitative traits appears to hold great promise. Critics may now be admitted to the event.

APPENDIX 1: DERIVATION OF WRIGHT'S EQUATION

592

593 Consider the Fokker-Planck equation for an Itô diffusion X_t (5). Alternatively, (5) can be re-written as (Risken
594 1996):

$$\begin{aligned} \frac{\partial}{\partial t} f(x, t) &= L_{FP} f(X_t, t), \\ L_{FP} &= -\frac{\partial}{\partial x} b(X_t, t) + \frac{1}{2} \frac{\partial^2}{\partial x^2} \sigma(X_t, t) \end{aligned} \quad (\text{A1.1})$$

595 Further, equations (A1.1) can be written as:

$$\begin{aligned} \frac{\partial f(X_t, t)}{\partial t} + \frac{\partial S}{\partial x} &= 0, \\ S(X_t, t) &= \left[b(X_t, t) - \frac{1}{2} \frac{\partial}{\partial x} \sigma(X_t, t) \right] f(X_t, t) \end{aligned} \quad (\text{A1.2})$$

$S(X_t, t)$ can be interpreted as a probability flow. For natural boundary conditions $\min x = -\infty$ and $\max x = \infty$, and assuming time-homogeneity, $S(X_t, t) = S(X_t) = 0$. Letting $x = X_t$ we have the following first-order linear differential equation:

$$\frac{1}{2} \frac{d}{dx} [\sigma^2(x) f(x)] - b(x) f(x) = 0$$

596 Let $m(x) = \sigma^2(x) f(x)$, implying $f(x) = \frac{m(x)}{\sigma^2(x)}$ then

$$\frac{dm(x)}{dx} - 2 \frac{b(x)m(x)}{\sigma^2(x)} = 0 \quad (\text{A1.3})$$

Equation (A1.3) can be solved using the method of integrating factors. Let $I = e^{-2 \int^x \frac{b(y)}{\sigma^2(y)} dy}$. Multiplying both sides of equation (A1.3) by I :

$$e^{-2 \int^x \frac{b(y)}{\sigma^2(y)} dy} \frac{dm}{dx} - 2 \frac{b(x)m(x)}{\sigma^2(x)} e^{-2 \int^x \frac{b(y)}{\sigma^2(y)} dy} = 0$$

597 Integrating both sides and using the product rule on the LHS,

$$e^{-2 \int^x \frac{b(y)}{\sigma^2(y)} dy} m(x) = C \quad (\text{A1.4})$$

598 where C is a constant of integration. Substituting $m(x) = \sigma^2(x) f(x)$ and rearranging, we have:

$$f(x) = \frac{C}{\sigma^2(x)} e^{2 \int^x \frac{b(y)}{\sigma^2(y)} dy} \quad (\text{A1.5})$$

599 which is Wright's formula.

APPENDIX 2: DERIVATION OF STATIONARY DISTRIBUTIONS

600

CIR model

601

Let $b(x) = \alpha(\mu - x)$, $\sigma = \sqrt{\epsilon x}$. Substituting into Wright's formula (7):

$$\begin{aligned} f(x) &= \frac{C}{\epsilon x} \exp \left[\int_{-\infty}^x \frac{2\alpha(\mu - s)}{\epsilon s} ds \right] \\ &= \frac{C}{\epsilon x} \exp \left[\frac{\mu \log(x) - x}{\epsilon/\alpha} \right] \end{aligned}$$

602 Let $\delta = \frac{\epsilon}{\alpha}$. Then:

$$\begin{aligned} f(x) &= Cx^{-1}x^{\frac{\mu}{\delta}}e^{-\frac{x}{\delta}} \\ &= Cx^{\frac{\mu}{\delta}-1}e^{-\frac{x}{\delta}} \end{aligned} \tag{A2.1}$$

Equation (A2.1) can be recognised as the kernel of a Gamma density, with shape $\frac{\mu}{\delta}$ and scale δ , and with normalising constant C . Therefore,

$$C = \frac{1}{\Gamma(\frac{\mu}{\alpha})\delta^{\frac{\mu}{\delta}}}$$

where $\Gamma(\cdot)$ is the Gamma function. i.e.

$$f(x|\mu, \delta) = \frac{1}{\Gamma(\frac{\mu}{\alpha})\delta^{\frac{\mu}{\delta}}}x^{\frac{\mu}{\delta}-1}e^{-\frac{x}{\delta}}$$

603 or $x|\mu, \delta \sim \text{Gamma}(\frac{\mu}{\delta}, \delta)$.

604

Beta model

Let $b(x) = \alpha(\mu - x)$, $\sigma = \sqrt{\epsilon x(1-x)}$. Substituting into Wright's formula (7):

$$\begin{aligned} f(x) &= \frac{C}{\epsilon x(1-x)} \exp \left[\int_{-\infty}^x \frac{2\alpha(\mu-s)}{\epsilon s(1-s)} ds \right] \\ &= \frac{C}{\epsilon x(1-x)} e^{(\frac{\alpha}{\epsilon}\mu \log x + \frac{\alpha}{\epsilon}(1-\mu) \log(1-x))} \\ &= \frac{C}{\epsilon x(1-x)} x^{\frac{\alpha\mu}{\epsilon}} (1-x)^{\frac{\alpha(1-\mu)}{\epsilon}} \end{aligned}$$

605 Setting $\delta = \frac{\epsilon}{\alpha}$ and simplifying further, we have:

$$f(x) = Cx^{\frac{\mu}{\delta}-1}(1-x)^{\frac{1-\mu}{\delta}-1} \tag{A2.2}$$

Equation (A2.2) is the kernel of a Beta distribution with shape parameters $\frac{\mu}{\delta}$ and $\frac{(1-\mu)}{\delta}$, and normalising constant C . Hence, the density can be written as:

$$f(x|\mu, \delta) = \frac{1}{\text{B}(\frac{\mu}{\delta}, \frac{(1-\mu)}{\delta})}x^{\frac{\mu}{\delta}-1}(1-x)^{\frac{(1-\mu)}{\delta}-1}$$

606 where $\text{B}(\cdot, \cdot)$ is the Beta function. More succinctly, $x|\mu, \delta \sim \text{Beta}(\frac{\mu}{\delta}, \frac{(1-\mu)}{\delta})$.
