44 **Abstract**

45 *Plasmodium vivax* malaria is much less common in Africa than the rest of the world
46 because the parasite relies primarily on the Duffy antigen/chemokine receptor (*DARC*)
47 to invade human erythrocytes, and the majority of Africans are Duffy negative. Recently,
48 there has been a dramatic increase in the reporting of *P. vivax* cases in Africa, with a
49 high number of them being in Duffy negative individuals, potentially indicating *P. vivax*
50 has evolved an alternative invasion mechanism that can overcome Duffy negativity.
51 Here, we analyzed single nucleotide polymorphism (SNP) and copy number variation
52 (CNV) in Whole Genome Sequence (WGS) data from 44 *P. vivax* samples isolated from
53 symptomatic malaria patients in southwestern Ethiopia, where both Duffy positive and
54 Duffy negative individuals are found. A total of 236,351 SNPs were detected, of which
55 21.9% was nonsynonymous and 78.1% was synonymous mutations. The largest
56 number of SNPs were detected on chromosomes 9 (33,478 SNPs; 14% of total) and 10
57 (28,133 SNPs; 11.9%). There were particularly high levels of polymorphism in
58 erythrocyte binding gene candidates including reticulocyte binding protein 2c (*RBP2c*),
59 merozoite surface protein 1 (*MSP1*), and merozoite surface protein 3 (*MSP3.5*,
60 *MSP3.85* and *MSP3.9*). Thirteen genes related to immunogenicity and erythrocyte
61 binding function were detected with significant signals of positive selection. Variation in
62 gene copy number was also concentrated in genes involved in host-parasite
63 interactions, including the expansion of the Duffy binding protein gene (*PvDBP*) on
64 chromosome 6 and several *PIR* genes. Based on the phylogeny constructed from the
65 whole genome sequences, the expansion of these genes was an independent process
66 among the *P. vivax* lineages in Ethiopia. We further inferred transmission patterns of *P.*

67 *vivax* infections among study sites and showed various levels of gene flow at a small
68 geographical scale. The genomic features of *P. vivax* provided baseline data for future
69 comparison with those in Duffy-negative individuals, and allowed us to develop a panel
70 of informative Single Nucleotide Polymorphic markers diagnostic at a micro-
71 geographical scale.

89 **Introduction**

90 Vivax malaria is the most geographically widespread human malaria, causing over 130
91 million clinical cases per year worldwide [1]. *Plasmodium vivax* can produce dormant
92 liver-stage hypnozoites within infected hosts, giving rise to relapse infections from
93 months to years. This unique feature of *P. vivax* contributes to an increase in
94 transmission potential and increases the challenge of elimination [2]. Understanding *P.*
95 *vivax* genome variation will advance our knowledge of parasite biology and host-
96 parasite interactions, as well as identify potential drug resistance mechanisms [3, 4].
97 Such data will also help identify molecular targets for vaccine development [5-7], and
98 provide new means to track the transmission and spread of drug resistant parasites [8-
99 9].

100 Compared to *P. falciparum*, *P. vivax* isolates from Southeast Asia (e.g., Thailand
101 and Myanmar), Pacific Oceania (Papua New Guinea), and South America (Mexico,
102 Peru, and Colombia) have significantly higher nucleotide diversity at the genome level
103 [2]. This could be the result of frequent gene flow via human movement, intense
104 transmission, and/or variation in host susceptibility [10-14]. *P. vivax* infections are also
105 much more likely to contain multiple parasite strains in areas where transmission is
106 intense and/or relapse is common [10, 15-18]. In Papua New Guinea, for example, *P.*
107 *vivax* infections had an approximately 3.5-fold higher rate of polyclonality and nearly
108 double the multiplicity of infection (MOI) than the *P. falciparum* infections [16]. Similar
109 rates of polyclonality and MOI have also been reported in *P. vivax* in Cambodia [6]. It is
110 possible intense transmission has sustained a large and stable parasite population in
111 these regions [17,18]. By contrast, geographical differentiation and selection pressure

112 over generations can lead to fixation of parasite genotypes in local populations. In the
113 Asia-Pacific region, *P. vivax* showed a high level of genetic relatedness through
114 inbreeding among the dominant clones, in addition to strong selection imposed in a
115 number of antimalarial drug resistance genes [19]. In Ethiopia, the chloroquine
116 resistance transporter gene (*Pvcrt*) of *P. vivax* on chromosome 14 had been shown with
117 significant selection in a region upstream of the promoter, highlighting the ability of *P.*
118 *vivax* to rapidly evolve in response to control measures [20]. Apart from mutations, high
119 copy number observed in *Pvcrt* and multidrug resistant gene (*Pvmdr1*) has also been
120 shown to be associated with increased antimalaria drug resistance [21,22].

121 Recent genomic studies have indicated that some highly polymorphic genes in
122 the *P. vivax* genome are associated with red blood cell invasion and immune evasion
123 [10, 12, 19, 23]. They include the merozoite surface protein genes *MSP1*
124 (*PVP01_0728900*) and *MSP7* (*PVX_082665*), *Pv-fam-b* (*PVX_002525*), *Pv-fam-e*
125 (*PVX_089875*), the reticulocyte binding protein gene *RBP2c* (*PVP01_0534300*), serine-
126 repeat antigen 3 (*SERA*; *PVX_003840*), as well as virulent genes (*VIR*) such as *VIR22*
127 (*PVX_097530*) and *VIR12* (*PVX_083590*) [23-29]. Polymorphisms in genes associated
128 with immune evasion and reticulocyte invasion have important implications for the
129 invasion efficiency and severity of *P. vivax* infections. Members of the erythrocyte
130 binding gene family, including reticulocyte binding proteins (*RBPs*), Duffy-binding
131 proteins (*DBPs*), and merozoite surface proteins (*MSP3* and *MSP7*) have been
132 previously shown to exhibit high sequence variation in *P. vivax* [20, 30]. The
133 polymorphisms in *RBP1* and *RBP2* genes may relate to an increased capability of
134 erythrocyte invasion by *P. vivax* [31-33]. It has been suggested that *PvRBP2b-TfR1*

135 interaction is vital for the initial recognition and invasion of host reticulocytes [34], prior
136 to the engagement of *PvDBP1* and Duffy antigen chemokine receptor (*DARC*) and
137 formation of a tight junction between parasite and erythrocyte [35]. Apart from *PvRBP*,
138 Reticulocyte Binding Surface Antigen (*PvRBSA*) [36], an antigenic adhesin, may also
139 play a key role in *P. vivax* parasites binding to target cells, possessing the capability of
140 binding to a population of reticulocytes with a different Duffy phenotype [37, 38].
141 Another erythrocyte binding protein gene (*PvEBP*), a paralog of *PvDBP1*, which harbors
142 all the hallmarks of a *Plasmodium* red blood cell invasion protein, including conserved
143 Duffy-binding like and C-terminal cysteine-rich domains [39], has been recently shown
144 to be variable in copy number in the Malagasy *P. vivax* [39]. Functional analyses
145 indicated that region II of this gene bound to both Duffy-positive and Duffy-negative
146 reticulocytes, although at a lower frequency compared to *PvDBP*, suggestive of its role
147 in erythrocyte invasion [40]. Both *PvEBP1* and *PvEBP2* genes exhibit high genetic
148 diversity and are common antibody binding targets associated with clinical protection
149 [41, 42]. Other proteins such as tryptophan-rich antigen gene (*TRAg*), anchored
150 micronemal antigen (*GAMA*), and Rhoptry neck protein (*RON*) have also been
151 suggested to play a role in red cell invasion, especially in low-density infections [43-47].
152 Information of the polymorphisms in these genes will have important implications on the
153 dynamics of host-parasite interactions.

154 Compared to Southeast Asia and South America where *P. vivax* is highly
155 endemic, data on polymorphisms in erythrocyte binding gene candidates of *P. vivax*
156 from Africa is limited. Filling the gap is critical for identifying functional genes in
157 erythrocyte invasion, biomarkers for tracking the African *P. vivax* isolates, as well as

158 potential gene targets for vaccine development. It was previously thought that most
159 African populations were immune to *P. vivax* infections due to the absence of *DARC*
160 gene expression required for erythrocyte invasion. However, several recent reports
161 have indicated the emergence and potential spread of *P. vivax* across Africa [32, 48-
162 50]. The objective of this study was to describe genomic variation of *P. vivax* from
163 Ethiopia. Specifically, we examined the level of genetic polymorphisms in a panel of 64
164 potential erythrocyte binding protein genes that have been suggested to play a role in
165 the parasite-host invasion process. In addition, we inferred transmission patterns of *P.*
166 *vivax* infections from different study sites based on the genetic variants. A recent study
167 by Auburn *et al.* [20] has compared the genetic variants of *P. vivax* from Ethiopia with
168 other geographical isolates. In the present study, we focus on the genomic
169 characteristics of *P. vivax* among different study sites in Ethiopia with the goals to
170 establish a baseline for genome comparison with the Duffy-negative *P. vivax* in our
171 ongoing investigation, as well as to develop a panel of informative Single Nucleotide
172 Polymorphic (SNP) markers diagnostic at a micro-geographical scale.

173

174 **Materials and Methods**

175 **Ethics statement**

176 Scientific and ethical clearance was obtained from the Institutional Scientific and Ethical
177 Review Boards of Jimma and Addis Ababa Universities in Ethiopia, and The University
178 of North Carolina, Charlotte, USA. Written informed consent/assent for study
179 participation was obtained from all consenting heads of households, parents/guardians

180 (for minors under age of 18), and each individual who was willing to participate in the
181 study.

182

183 **Study area and sample collection**

184 Genomic DNA was extracted from 22 clinical samples collected in Jimma, southwestern
185 Ethiopia during peak transmission season (September – November, 2016; Figure 1).

186 Finger-pricked blood samples were collected from malaria symptomatic (who has fever
187 with axillary body temperature > 37.5°C and with confirmed asexual stages of malaria
188 parasite based on microscopy) or febrile patients visiting the health centers or hospitals
189 at each of the study sites. Thick and thin blood smears were prepared for microscopic

190 examination, and 4-6 ml of venous blood were collected from each *P. vivax*-confirmed

191 patient in K2 EDTA blood collection tubes. For the whole blood samples, we used the

192 Lymphoprep/Plasmodpur-based protocol to deplete the white blood cells and enrich the

193 red blood cell pellets [51]. DNA was then extracted from approximately 1 ml of the red

194 blood cell pellets using Zymo Bead Genomic DNA kit (Zymo Research) following the

195 manufacturer's procedures. The extracted DNA were first assessed by nested and

196 quantitative PCR methods to confirm and quantify *P. vivax* of the infected samples [52].

197 From a larger set of samples, we then performed microsatellite analyses using seven

198 different loci [53]. Only monoclonal samples were selected and proceeded for

199 sequencing. Whole genome sequencing was conducted on the Illumina HiSeq 3000

200 Sequencing Platform at the Wellcome Sanger Institute (European Nucleotide Archive

201 [ENA] accession number of each sample in Table 1). The generated sequence reads

202 were mapped individually to the publicly available reference genome PvP01 from Gene

203 DB using Bowtie version 2 [54]. The original 22 samples were processed to remove
204 reads other than *P. vivax*. The percentage coverage of the *P. vivax* reads in our
205 samples were high enough to not affect the results. An additional 24 sample sequence
206 data were obtained as FASTQ files from the ENA. These samples were collected from
207 Arbaminch, Badowacho, Halaba, and Hawassa in southwestern Ethiopia (Figure 1), the
208 Duffy status of each of these 24 samples is unknown. They were then aligned to the
209 PVP01 reference genome using BWA-MEMv.2 with default settings [55, 56]. The overall
210 quality of each resulting BAM was assessed using FASTQC. Similarly, we concluded
211 that the percentage of the *P. vivax* reads covered in the additional 24 samples were
212 high enough to reflect the dominant signal of the variants and negate polyclonal
213 influences. Two of our samples displayed a significant decline in average quality in read
214 mapping and were therefore removed from further SNP variant and copy number
215 variation analyses.

216

217 **SNP discovery, annotation, and filtering**

218 Potential SNPs were identified by SAM tools v.1.6 mpileup procedure [57] in conjunction
219 with BCF tools v.1.6 [57] across all 44 sample BAM files using the PVP01 reference
220 genome. Compared to the Salvador-I, the PVP01 reference genome consists of 14
221 major chromosomal sequences, and provides a greater level of gene annotation power
222 and improved assembly of the subtelomeres [56]. We analyzed only sequence reads
223 that were mapped to these 14 major chromosomal sequences. The hypervariable and
224 subtelomeric regions in our samples were retained during the variant calling procedure
225 and each sample BAM file had duplicates marked using SAMtools 1.6 markdup

226 procedure. For the mpileup procedure, the maximum depth threshold, which determines
227 the number of maximum reads per file at a position, was set to 3,000 million to ensure
228 that the maximum amount of reads for each position was not reached. Samples were
229 pooled together using a multisampling variant calling approach. The SNPs were then
230 annotated with SnpEff v.4.3T [58] based on the annotated gene information in GeneDB.
231 Filtering was done using the following standard metrics, including Read Position Bias,
232 Mapping Quality vs Strand Bias, Raw read depth, Mapping Quality Bias, Base Quality
233 Bias, and Variant Distant Bias produced by SAM tools and BCF tools during the variant
234 calling procedure. In Snp Sift, data was filtered by choosing SNPs that had a Phred
235 Quality score ≥ 40 , a raw read depth (DP) ≥ 30 , and a base quality bias >0.1 [59]. We
236 then calculated the allele frequency for each SNP position for all 44 samples using the
237 frequency procedure in VCF tools v.0.1.15 [60]. The total number of SNPs across all
238 samples, as well as the number of nonsynonymous and synonymous mutations were
239 recorded. Mutations were compared among the 14 chromosomes in addition to a panel
240 of 64 erythrocyte binding genes.

241

242 **Copy number variation analyses**

243 Copy number variation of gene regions was assessed with CNVnator [61]. CNVnator
244 uses mean-shift theory, a partitioning procedure based on an image processing
245 technique and additional refinements including multiple bandwidth partitioning and GC
246 correction [61]. We first calculated the read depth for each bin and correct GC-bias. This
247 was followed by mean-shift based segment partition and signal merging, which
248 employed an image processing technique. We then performed CNV calling, of which

249 segments with a mean RD signal deviating by at least a quarter from genomic average
250 read depth signal were selected and regions with a P -value less than 0.05 were called.
251 A one-sided test was then performed to call additional copy number variants. SAM tools
252 v.1.6 was utilized in our data preprocessing step to mark potential duplicates in the BAM
253 files and followed the CNV detection pipeline [62]. We extracted the read mappings
254 from each of BAM files for all chromosomes. Once the root file was constructed using
255 the extracted reads, we generated histograms of the read depths using a bin size of
256 100. The statistical significance for the windows that showed unusual read depth was
257 calculated and the chromosomes were partitioned into long regions that have similar
258 read depth.

259 To validate the results from CNVnator, we used the GATK4 copy number
260 detection pipeline to further examine gene copy number [63-65]. The read coverage
261 counts were first obtained from pre-processed genomic intervals of a 1000-bp window
262 length based on the PvP01 reference genome. The read fragment counts were then
263 standardized using the Denoise Read Counts that involved two transformations. The
264 first transformation was based on median counts, including the \log_2 transformation, and
265 the counts were normalized to center around one. In the second transformation, the tool
266 denoises was used to standardized copy ratios using principal component analysis.

267

268 **Test for positive selection**

269 Regions of positive selection were examined among the 44 Ethiopian *P. vivax* isolates
270 using the integrated haplotype score approach, specifically the SciKit-Allel for python, a
271 package used for analysis of large scale genetic variation data [66]. Before the samples

272 were run through Scikit-allel, genotypes for each of the samples were phased using
273 BEAGLE [67]. Genes that were detected with signals of positive selection by SciKit-
274 Allel, as well as a panel of 64 potential erythrocyte binding genes were further evaluated
275 using the PAML package (Phylogenetic Analysis by Maximum Likelihood) [68]. Using
276 the codeml procedure in PAML, DNA sequences were analyzed with the maximum
277 likelihood approach in a phylogenetic framework. The synonymous and
278 nonsynonymous mutation rates between protein-coding DNA sequences were then
279 estimated in order to identify potential regions of positive selection. We created two
280 models, the neutral model M1 and the selection model M2. The average d_N/d_S values
281 were estimated across all branches in both M1 and M2 models and the average d_N/d_S
282 values across all sites in the M2 model. The d_N/d_S values were compared between the
283 two models using a likelihood ratio test for significant positive selection.

284

285 **Comparison of nucleotide diversity among EBP gene regions**

286 Based on the literature [23-33], we identified 64 gene regions that are potentially related
287 to erythrocyte binding in *P. vivax* (Supplementary Table 1). These included the *DBP*
288 (duffy binding protein), *EBP* (erythrocyte binding protein), *MSP* (merozoite surface
289 protein), and *RBP* (reticulocyte binding protein) multigene families, the tryptophan rich
290 antigen gene family (*TRAg*), GPI-anchored microanemal antigen (*GAMA*), microneme
291 associated antigen (*MA*), rhoptry associated adhesin (*RA*), high molecular weight
292 rhoptry protein 3 (*RHOP3*), and rhoptry neck protein (*RON*) genes. Previous study has
293 shown that the transcriptome profiles of the *TRAg* genes were differentially transcribed
294 at the erythrocytic stages, indicating that these genes may play specific roles in blood-

295 stage development [43]. The reticulocyte binding protein multigene family encodes
296 genes that each have a receptor on the surface that is essential for the host-invasion
297 stage of *P. vivax* [69]. The *MSP* multigene family, currently assumed to be a candidate
298 for vaccine generation, also plays a role in the invasion stage of *P. vivax* and is also
299 immunogenic [26]. The nucleotide diversity of 64 potential erythrocyte binding genes
300 were compared among the 44 *P. vivax* sample consensus sequences using DnaSP
301 [70]. The Pairwise-Deletion method where gaps were ignored in each pairwise
302 comparison was used for this calculation.

303

304 **Genetic relatedness and transmission network analyses**

305 Phylogenetic analyses were performed to infer the genetic relatedness among the 44
306 Ethiopian isolates. Sequence alignment was first conducted using a multiple sequence
307 alignment program in MAFFT v. 7 [71]. The alignment was then trimmed to remove
308 gaps using trimal (the *gappyout* option) that trimmed the alignments based on the gap
309 percentage count over the whole alignment. After sequence editing, we concatenated
310 all alignment files using FASconCAT-G [72], a perl program that allows for
311 concatenation and translation (nucleotide to amino acid states) of multiple alignment
312 files for phylogenetic analysis. We used the maximum likelihood method implemented in
313 the Randomized Accelerated Maximum Likelihood (RAxML) v8 to construct
314 phylogenetic trees [73]. The GTRGAMMA model was used for the best-scoring
315 maximum likelihood tree. The GTR model incorporates the optimization of substitution
316 rates and the GAMMA model accounts for rate heterogeneity. A total of 100 rapid
317 bootstrap runs were conducted to evaluate the confidence of genetic relationships. In

318 addition, we performed principal component analyses using the glPCA function in R, a
319 subset of the adegenet package [74], to determine the genetic relatedness of the
320 samples among the different study sites in Ethiopia. A transmission network was
321 created using StrainHub, a tool for generating transmission networks using phylogenetic
322 information along with isolate metadata [75]. The transmission network was generated
323 using the locations of the samples as the nodes and calculating the source hub ratio
324 between each location. The source hub ratio was calculated by the number of
325 transitions originating from a node over the total number of transitions related to that
326 node. A node with a ratio close to 1 indicates a source, a ratio close to 0.5 indicates a
327 hub, and a ratio close to 0 indicates a sink for the *P. vivax* infections.

328

329 **Results**

330 **Distribution of SNPs among the chromosomes and EBP genes**

331 A total of 252,973 SNPs were detected among the 44 Ethiopian *P. vivax* samples
332 (Figure 2), with 21.5% (54,336 out of 252,973) nonsynonymous and 78.5% (198,637 out
333 of 252,973) synonymous mutations (Figure 3A). The highest number of SNPs were
334 observed on chromosomes 7 (28,856 SNPs; 11.4%), 9 (28,308 SNPs; 11.2%), and 12
335 (28,190 SNPs; 11.1%); whereas the lowest number of SNPs were observed on
336 chromosomes 3 (6,803 SNPs; 2.7%), 6 (5,044 SNPs; ~2%), and 13 (8,809 SNPs; 3.5%;
337 Figure 3A; Supplementary Table 2).

338

339 The 64 erythrocyte binding genes accounted for 3,607 of the total SNPs, with 1685
340 (46.7%) identified as nonsynonymous and 1922 (53.3%) as synonymous mutations

341 (Figure 3B). Among these genes, the highest number of SNPs were observed in
342 reticulocyte binding protein gene (*RBP2c*) on chromosome 5, followed by the *MSP3*
343 multigene family (*MSP3.5*, *MSP3.9* and *MSP3.8*) on chromosome 10. Nucleotide
344 diversity also showed to be highest in the *RBP* and *MSP3* multigene families, with an
345 average nucleotide diversity of 1.3% and 2.8%, respectively, among our samples
346 (Figure 3B). By contrast, the lowest number of SNPs were observed in the Duffy
347 binding protein gene (*DBP1*) on chromosome 6 with a total of 13 SNPs, of which 12
348 were identified as nonsynonymous and one as synonymous mutations (Figure 3B).
349 Likewise, another erythrocyte binding protein (*EBP2*), located also on chromosome 6,
350 was one of the least variable genes with only one nonsynonymous mutation. The *TRAg*
351 gene family also showed a low level of nucleotide diversity when compared to the other
352 *EBP* gene families with an average nucleotide diversity of 0.2% (Figure 3B).

353

354 **Gene regions under positive selection**

355 Based on the integrated haplotype scores, positive selection was detected in 13 gene
356 regions (Figure 4). These included the sub-telomeric protein 1 (*STP1*) on chromosome
357 5, the membrane associated erythrocyte binding-like protein (*MAEBL*) on chromosome
358 9, *MSP3.8* on chromosome 10, as well as various plasmodium interspersed repeats
359 (*PIR*) protein genes on chromosomes 3, 5, 7, 10, 11, and 12 (Figure 4). Based on
360 PAML, 25 out of the 64 erythrocyte binding genes showed evidence of positive selection
361 (Table 2; Supplementary Table 3). The majority of these genes belong to the *TRAg*
362 multigene family. The *TRAg* genes had an average d_N/d_S ratio of 2.75 across all
363 branches and an average of 5.75 across all sites for the M2 model tested for selection

364 (Table 2). Compared to the other *TRAg* genes, *TRAg15* had more sites detected under
365 positive selection, with 50 of the sites showing a posterior probability greater than 50%
366 and 43 showing a posterior probability greater than 95% (Table 2). While the *TRAg4*
367 gene had the highest d_N/d_S ratio across all sites among other *TRAg* genes, only six sites
368 were shown under positive selection with a posterior probability greater than 50% and
369 one with a posterior probability greater than 95%.

370 All *RBP* genes, except for *RBP2c*, showed regions with significant signals of
371 positive selection (average d_N/d_S ratio across all sites: 5.11; Table 2). Among them,
372 *RBP2p1* had the largest number of sites with posterior probabilities greater than 95%
373 (Table 2). Among all the *MSP* genes, only *MSP5*, *MSP9*, and *MSP10* indicated regions
374 under positive selection. The *MSP5* and *MSP9* genes had an average d_N/d_S ratio of
375 3.85 across all sites and 1.11 across branches (Table 2). While *MSP10* had an average
376 d_N/d_S ratio of 1.16 across all branches and less than 1 across all sites, only seven sites
377 were indicated with posterior probabilities greater than 50% and 95% (Table 2).

378 Although *MSP3.8* showed potential positive selection based on the integrated haplotype
379 scores (Figure 4), PAML did not show significant evidence of positive selection. For the
380 *DBP* gene family, *DBP9* showed the highest d_N/d_S ratio across all sites and branches
381 (10.39 and 3.88, respectively; Table 2).

382

383 **Copy number variation and evolution of high-order copy variants**

384 According to CNVnator, 19 gene regions showed copy number variation among our
385 samples (Figure 5; Supplementary Table 4). Among them, 11 gene regions were
386 detected with up to 2-3 copies and 8 gene regions with 4 copies or higher. We observed

387 copy number variation in several *PIR* genes distributed across chromosomes 1, 2, 4, 5,
388 7, 10 and 12 (Figure 5; Supplementary Table 4). Specifically, for the *PIR* genes located
389 on chromosome 2 (including PVP01_0220700, PVP01_0200200, PVP01_0200300, and
390 PVP01_0200100; Figure 5), more than 20% of the samples had 2-3 copies and
391 approximately 2-4% of the samples had 4 copies or higher. Among the 64 erythrocyte
392 binding genes, duplications were observed in *DBP1* on chromosome 6 and *MSP3* on
393 chromosome 10. *DBP1* ranged from one to as high as five copies, and *MSP3* ranged
394 from one to as high as three copies among our samples (Figure 5), consistent with
395 previous findings [19, 20, 76]. The remaining erythrocyte binding genes were detected
396 with a single copy across our samples.

397 A maximum likelihood tree constructed based on the whole genome sequences
398 showed an admixture of *P. vivax* isolates with single and multiple *PvDBP* copy number
399 (Figure 6A). The Ethiopian *P. vivax* isolates were divided into six subclades. Subclade I
400 contained *P. vivax* samples mostly from Arbaminch and Badowacho with both one and
401 two *PvDBP* copies. Subclade II contained samples from Jimma and Hawassa with two
402 *PvDBP* copies. Subclade III contained a mixture of *P. vivax* samples from Arbaminch,
403 Halaba, Hawassa, and Jimma with single and high-order *PvDBP* copies. This clade was
404 sister to subclade IV that contained *P. vivax* samples mostly from Jimma (Figure 6A). In
405 subclade IV, no distinct clusters were detected between isolates with single and multiple
406 *PvDBP*. Subclade V contained samples from Jimma and subclade VI contained
407 samples from Arbaminch, Badowacho, Hawassa, and Halaba. Each of the subclades
408 had samples with both one and two *PvDBP* copies. Similar patterns were observed in
409 the *MSP3* and *PIR* genes where *P. vivax* isolates with single and multiple copies were

410 clustered together in separate subclades (Figures 6B-D), suggesting that these gene
411 regions could have expanded multiply among samples at different locations.

412

413 **Gene flow and transmission network of the Ethiopian *P. vivax***

414 The principal component analysis based on the SNP variants showed samples from
415 Arbaminch, Badowacho, Hawassa, and Halaba were genetically closely related but
416 differentiated from Jimma (Figure 7A). The transmission network indicated that
417 Arbaminch was the major source or hub of infections where the infections in Jimma,
418 Hawassa, Badowacho, and Halaba were originated from (Table 3; Figure 7B). On the
419 other hand, no transmission was originated from Halaba, making this location the
420 largest sink of transmissions. The greatest extent of gene flow was observed between
421 Arbaminch and Badowacho (Figure 7B). Hawassa and Jimma showed a source hub
422 ratio of 0.5, indicating that there are equally as many egress transmissions as ingress
423 transmissions (Table 3). Although Jimma and Badowacho/Halaba are in close
424 geographical proximity, no apparent gene flow was observed between these sites.

425

426 **Discussion**

427 Across the genome, the total number of SNPs observed among 44 *P. vivax* isolates in
428 Ethiopia were comparable to those previously reported in South American [77] and
429 Southeast Asian countries [19]. For instance, 303,616 high-quality SNPs were detected
430 in 228 *P. vivax* isolates from Southeast Asia and Oceania in a previous study, of which
431 Sal-I was used as the reference sequence and subtelomeric regions were discarded
432 [19]. Auburn *et al.* [20] found that the average nucleotide diversity in Ethiopia was lower

433 than in Thailand and Indonesia, but higher than in Malaysia. Chromosomes 3, 4, and 5
434 have been previously shown to contain the lowest proportion of synonymous SNPs than
435 the other parts of the genome [12]. In the present study, chromosomes 3 and 6 were
436 found to have the lowest number of both synonymous and nonsynonymous SNPs. This
437 follows observations made in other studies done with nucleotide diversity ranging from
438 0.8 SNPs per kb in North Korea to 0.59 SNPs per kb in Peru [78]. Among the 64
439 erythrocyte binding gene candidates, the MSP and RBP multigene families showed the
440 highest level of genetic variation. This agrees with previous studies that reported a
441 remarkably high diversity in *RBP2* than in *RBP1* and its homolog group in *P. falciparum*
442 [31]. In the Greater Mekong Subregion, the *MSP3* and *PIR* gene families also indicated
443 high levels of genetic diversity with 1.96% and 1.92% SNPs per base respectively,
444 confirming that members of multigene families are highly variable genetically [30, 79].
445 Such diversity suggested that the binding domains of these genes could be under
446 differential selection pressure. This pattern has been observed in previous studies and
447 is likely due to their critical role in reticulocyte invasion, immunogenic properties, and
448 human migration [26, 80-82].

449 Both CNVnator and GATK4 showed high order copies in several *PIR* gene
450 regions. In addition, the *PIR* and *STP1* genes were also indicated with significant
451 selection based on the iHS calculations. The *PIR* gene family, which includes *STP1*, are
452 located on the subtelomere regions and is a highly variable multigene family ranging
453 from 1,200 genes in the reference strain PvP01 to 346 genes in monkey-adapted strain
454 Salvador-I [56, 83]. Our analyses included only SNP variants that had a quality score of
455 40 or higher. Also, we used the PVP01 reference genome to map and annotate the

456 subtelomeric regions, with the goal to reflect variability and features across the entire
457 chromosome; whereas previous studies used the Sal-I reference genome with
458 hypervariable and subtelomeric regions removed to minimize mapping errors [19, 84].
459 A recent study in *P. chabaudi* suggested that polymorphisms in *PIR* genes could affect
460 the virulence of the parasites following passage from the mosquitoes [85]. Such a
461 variation in copy number of the *PIR* gene family has also been reported in *P. cynomolgi*
462 and *P. vivax* [86], suggesting that gene duplication could have been occurred
463 repeatedly in the ancestral lineages [86]. The *PIR* multigene family is one of the largest
464 gene families identified so far in *P. vivax* with several different potential functions.
465 Some *PIR* genes encode proteins on the surface of infected red blood cells, which could
466 confer to immune evasion; others encode proteins involved in signaling, trafficking and
467 adhesion functions [83]. Positive selection detected in the *PIR* genes among the
468 Ethiopian *P. vivax* isolates may have important implications on the susceptibility of the
469 mosquito hosts [87].

470 For the *P. vivax* isolates in Southeast Asia, copy number variation was observed
471 in nine gene regions including *DBP1*, *MDR1*, and *PVX_101445* (on chromosome 14)
472 with copy number ranging from 3 to 4 [19]. *DBP1* and *MSP3* showed higher order
473 copies when compared to other genomic regions. In this study, the highest and most
474 variable copy number variations were detected in the *DBP1*, with copy numbers ranging
475 from one to as high as five. Likewise, for the *MSP3*, copy numbers ranging from one to
476 as high as four. Based on the phylogeny, *DBP1* and *MSP3* expansion had occurred
477 multiple times as tandem copies. These findings were consistent with earlier studies
478 [19, 76] and suggested that gene expansion may play a key role in host cell invasion

479 [88]. For all other putative erythrocyte binding genes, only a single copy was detected
480 among all samples. A larger sample in future investigations would verify this
481 observation.

482 In the present study, we identified a panel of 64 putative erythrocyte binding gene
483 candidates based on the information from the literature and analyzed their
484 polymorphisms. However, we did validate the function for each of these genes. Among
485 these 64 putative erythrocyte binding gene candidates, *MAEBL* was shown to be highly
486 conserved in *Plasmodium* [89], had the highest signal for positive selection among the
487 *P. vivax* samples in Ethiopia. In *P. berghei*, *MAEBL* is a sporozoite attachment protein
488 that plays a role in binding and infecting the mosquito salivary gland [89]. In *P.*
489 *falciparum*, *MAEBL* is located in the rhoptries and on the surface of mature merozoites,
490 and expresses at the beginning of schizogony [89]. In *P. vivax*, *MAEBL* is a conserved
491 antigen expressed in blood stages, as well as in the mosquito midgut and salivary gland
492 sporozoites [89, 90]. The *MAEBL* antigen contains at least 25 predicted B-cell epitopes
493 that are likely to elicit antibody-dependent immune responses [91]. Positive selection
494 observed in this gene region among the Ethiopian *P. vivax* isolates could be associated
495 with the immunity-mediated selection pressure against blood-stage antigens. Though
496 *DBP1* had the highest and most diverse copy number variation, no significant signal of
497 positive selection was detected.

498 It is noteworthy that the calculation of integrated haplotype scores and the
499 accuracy of phasing genotypes using BEAGLE were dependent on the levels of linkage
500 disequilibrium of the whole genomes. The higher the levels of linkage disequilibrium, the
501 more accurate are the phased genotypes and thus the iHS score. Pearson *et al.* [19]

502 found that *P. vivax* experienced drops in linkage disequilibrium after correcting for
503 population structure and other confounders. Linkage disequilibrium of *P. vivax*
504 genomes has been previously shown to be associated with the rate of genetic
505 recombination and transmission intensity [92-94]. In high transmission sites of Papua
506 New Guinea and the Solomon Islands, no identical haplotypes and no significant
507 multilocus LD were observed, indicating limited inbreeding and random associations
508 between alleles in the parasite populations [95, 96]. However, when transmission
509 intensity declined, similar haplotypes and significant LD were observed possibly due to
510 self-fertilization, inbreeding and/or recombination of similar parasite strains
511 [92]. Multilocus LD is significantly associated with the genetic relatedness of the
512 parasite strains [97], but inversely associated with the proportion of polyclonal infections
513 [98]. In Southwestern Ethiopia, malaria transmission ranged from low to moderate, and
514 LD levels varied markedly among the study sites [53, 99]. To address this limitation in
515 BEAGLE, all genes that were detected with positive selection in BEAGLE were further
516 analyzed with PAML for verification. Future study should include broad samples to
517 thoroughly investigate selection pressure at the population level and the function
518 significance of polymorphisms in the *MAEBL* and *PIR* genes.

519 Previous studies have shown high levels of genetic diversity among *P. vivax*
520 isolates in endemic countries [16, 100, 101]. Such a diversity was directly related to high
521 transmission intensity and/or frequent gene exchange between parasite populations via
522 human movement [4, 12, 13, 53]. For example, previous studies using microsatellites
523 have demonstrated a consistently high level of intra-population diversity ($H_E = 0.83$) but
524 low between-population differentiation (F_{ST} ranged from 0.001-0.1] in broader regions of

525 Ethiopia [53, 99]. High heterozygosity was also observed in *P. vivax* populations from
526 Qatar, India, and Sudan (average $H_E = 0.78$; 62), with only slight differentiation from *P.*
527 *vivax* in Ethiopia ($F_{ST} = 0.19$) [102]. Frequent inbreeding among dominant clones [92,
528 95] and strong selective pressures especially in relapse infections [19, 20, 102, 103]
529 may also contribute to close genetic relatedness between and within populations. Thus,
530 in this study, it is not surprising to detect a high level of parasite gene flow among the
531 study sites at a small geographical scale, despite the limited number of samples. In the
532 present study, we successfully employed a transmission network model to identify
533 transmission paths, as well as the source and sink of infections in the region, beyond
534 simply indicating genetic relationships.

535 To conclude, this study elaborated on the genomic features of *P. vivax* in
536 Ethiopia, particularly focusing polymorphisms in erythrocyte binding genes that
537 potentially play a key role in local parasite invasion, a critical question given the mixed
538 Duffy positive and negative populations of Ethiopia. The findings provided baseline
539 information on the genomic variability of *P. vivax* infections in Ethiopia and allowed us to
540 compare the genomic variants of *P. vivax* between Duffy-positive and Duffy-negative
541 individuals as the next step of our ongoing investigation. Further, we are in progress of
542 developing a panel of informative SNP markers to track transmission at a micro-
543 geographical scale.

544

545 **Data Availability**

546 Additional information is provided as supplementary data accompanies this paper.

547 Sequence data of this study are deposited in the European Nucleotide Archive (ENA)

548 and the accession number of each sample is listed in Table 1.

549

550 **Acknowledgements**

551 We are greatly indebted to the staffs and technicians from Jimma University for field
552 sample collection, the communities and hospitals for their support and willingness to
553 participate in this research.

554

555 **Funding**

556 This research was funded by National Institutes of Health (NIH R15 AI138002 to EL;
557 NIH U19 AI129326 to GY; NIH R01 AI050243 to GY; D43 TW001505 to GY) and The
558 Wellcome Trust 206194/Z/17/Z to JR. The funders had no role in study design, data
559 collection and analysis, decision to publish, or preparation of the manuscript.

874

875

876 **Tables**

877 **Table 1.** Information of whole genome sequences of 44 *Plasmodium vivax* isolates from
878 Ethiopia. The European Nucleotide Archive (ENA) accession number for all files.

879

880 **Table 2.** A shortlist of 25 erythrocyte binding genes that showed signals of positive
881 selection based on the Likelihood Ratio Test of the M1 (neutral model) and M2 models
882 (selection model) in PAML.

883

884 **Table 3.** Transmission network metrics among study sites calculated by StrainHub.

885

886 **Figures**

887 **Figure 1.** An overview of the *P. vivax* sample collection locations including Arbaminch,
888 Badowacho, Hawassa, Halaba, and Jimma in southwestern Ethiopia.

889

890 **Figure 2.** A summary representation of the *P. vivax* genome, with the outer ring as an
891 ideogram representing the 14 nuclear chromosomes and sizes of each. The second
892 track represented the average coverage for each chromosome among the 44 Ethiopian
893 samples. The third track containing the gray vertical dashes represented the
894 distribution of genes across the 14 chromosomes. The fourth track that contained the
895 red vertical lines represented the 64 erythrocyte binding gene candidates. The fifth
896 inner track with the light blue background represented the d_N/d_S ratio calculated by
897 partitioning the chromosomes into genomic regions and d_N/d_S directly. The three
898 outliers (yellow dots) represented three unknown plasmodium protein genes that were

899 detected with significant positive selection. The sixth track indicated the overall copy
900 number variation calculated using CNVnator. Red dots represented genes with copy
901 number variation among the Ethiopian genomes.

902

903 **Figure 3.** (A) A distribution of the nonsynonymous and synonymous mutations of each
904 chromosome. A higher proportion of synonymous mutations was observed compared to
905 nonsynonymous mutations. Chromosomes 7, 9, and 12 have the most mutations
906 overall, with chromosomes 6 and 3 having the fewest number of mutations. (B) Number
907 of mutation sites and the nucleotide diversity of 64 erythrocyte binding genes. The
908 *PvRBP* and *PvMSP* multigene families have the highest number of polymorphic sites
909 when compared to the others, with *PvRBP2c* the highest number of nonsynonymous
910 and synonymous mutations, followed by *PvMSP3* and *PvMSP1*. Approximately 40% of
911 the mutations were nonsynonymous. These genes were also indicated with the highest
912 nucleotide diversity.

913

914 **Figure 4.** Signal of positive selection across the 14 chromosomes among all *P. vivax*
915 samples. Genes that showed significant signal of positive selection included *STP1*,
916 *MAEBL*, *MSP3.8*, and *PIR* gene regions. *PvMSP3.8* gene may play a role in the
917 erythrocyte invasion. *MAEBL* is a membrane associated erythrocyte binding like protein
918 that may have a function associated with erythrocyte invasion.

919

920 **Figure 5.** A total of 28 gene regions that were detected with copy number variation.
921 Annotation of these genes can be found in Supplementary Table 4. Among them,

922 *PvDBP1* (PVP01_0623800) and *PvMSP3* (PVP01_1030900) were associated with
923 erythrocyte invasion. Other genes that were found to have high-order copy number
924 were *PIR* protein genes or unknown exported plasmodium proteins.

925

926 **Figure 6.** An unrooted whole genome phylogenetic tree of the 44 Ethiopian samples
927 showing the evolution of (A) *PvDBP*; (B) *PvMSP3*; (C) *PIR* gene on chromosome 2; and
928 (D) *PIR* gene on chromosome 11. The Ethiopian isolates were divided into three
929 subclades. Subclade I contained samples mostly from the Arbaminch and Badowacho.
930 Subclade II contained a mixture of isolates from Arbaminch, Halaba, Hawassa and
931 Jimma. Subclade III contained samples from Jimma. No distinct clusters were observed
932 between isolates with single and multiple *PvDBP*, *PvMSP3*, and *PIR* genes. These
933 patterns suggest that these gene regions could have expanded multiply among samples
934 at different locations.

935

936 **Figure 7.** (A) Principal component analysis plot based on the SNP information from our
937 variant analysis. Samples obtained from Jimma were clustered together, whereas
938 samples from Arbaminch, Badowacho, Hawassa, and Halaba were mixed together with
939 the exception of two samples from Hawassa. This clustering pattern suggested that
940 there was considerable genetic variation among study sites even at a small
941 geographical scale. (B) The transmission network, created using the StrainHub
942 program, indicated that Arbaminch was the major source of infection in Jimma, Halaba,
943 Badowacho and Hawassa. The greatest extent of gene flow (indicated by the boldest
944 arrow) was observed between Arbaminch and Badowacho. Even though Jimma,

945 Badowacho and Halaba are geographically in close proximity, gene flow was not
946 intense among these sites.

947

948 **Supplementary files**

949 **Supplementary Table 1.** Distribution of SNP variants in the 64 *P. vivax* erythrocyte
950 binding gene candidates among the 44 Ethiopian genomes.

951

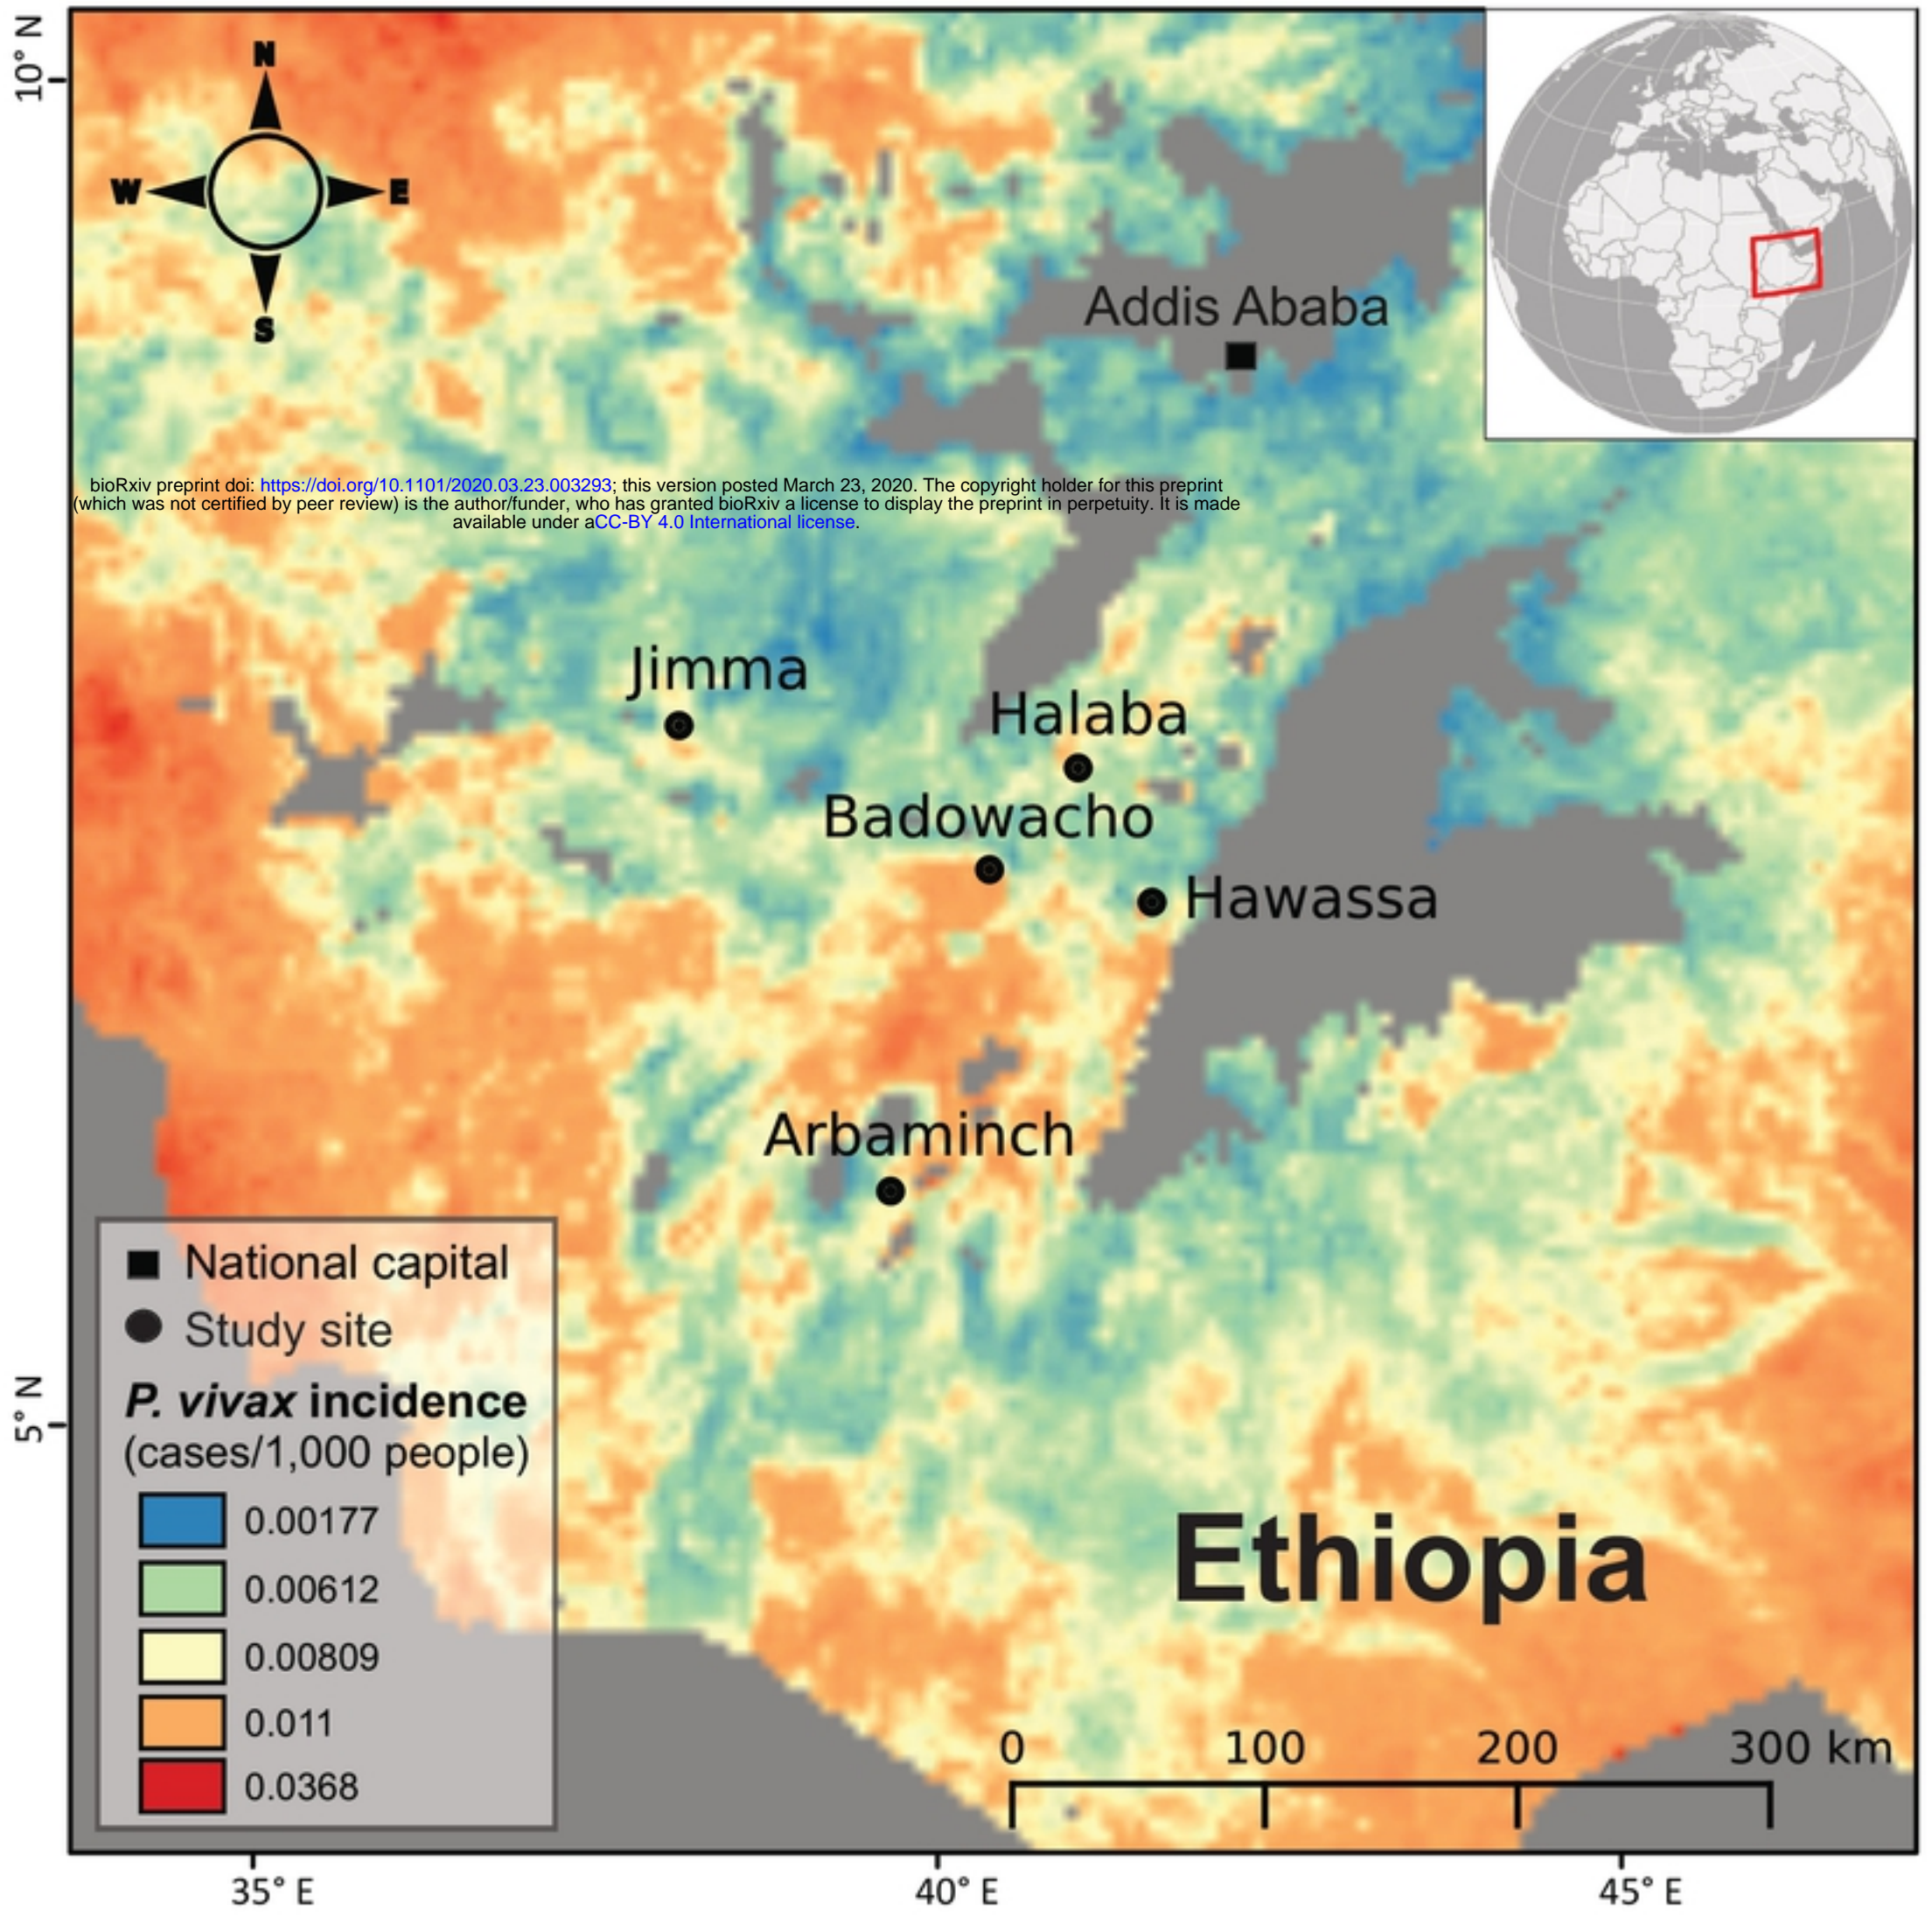

952 **Supplementary Table 2.** Distribution of single nucleotide polymorphism (SNP) variants
953 across *P. vivax* chromosomes of the 44 Ethiopian genomes.

954

955 **Supplementary Table 3.** Likelihood Ratio Test results of the M1 (neutral model) and
956 M2 models (selection model) in PAML of all the 64 erythrocyte binding gene candidates.

957

958 **Supplementary Table 4.** Gene regions that were detected with copy number variation
959 among the 44 Ethiopian *P. vivax* isolates based on CNVnator. Among them, only two
960 erythrocyte binding gene candidates *PvDBP1* and *PvMSP3* were detected with high-
961 order copies.
