10

11 **ABSTRACT**

12 As a first step toward the development of diagnostic and therapeutic tools to fight the Coronavirus
13 disease (COVID-19), we aim to characterize CD8+ T cell epitopes in the SARS-CoV-2 peptidome
14 that can trigger adaptive immune responses. Here, we use RosettaMHC, a comparative modeling
15 approach which leverages existing high-resolution X-ray structures from peptide/MHC complexes
16 available in the Protein Data Bank, to derive physically realistic 3D models for high-affinity
17 SARS-CoV-2 epitopes. We outline an application of our method to model 439 9mer and 279 10mer
18 predicted epitopes displayed by the common allele HLA-A*02:01, and we make our models
19 publicly available through an online database (<https://rosettamhc.chemistry.ucsc.edu>). As more
20 detailed studies on antigen-specific T cell repertoires become available, RosettaMHC models of
21 antigens from different strains and HLA alleles can be used as a basis to understand the link
22 between peptide/HLA complex structure and surface chemistry with immunogenicity, in the
23 context of SARS-CoV-2 infection.

24

25 An ongoing pandemic caused by the novel SARS coronavirus (SARS-CoV-2) has become the
26 focus of extensive efforts to develop vaccines and antiviral therapies (1). Immune modulatory
27 interferons, which promote a widespread antiviral reaction in infected cells, and inhibition of pro-
28 inflammatory cytokine function through anti-IL-6/IL-6R antibodies, have been proposed as
29 possible COVID-19 therapies (2, 3). However, stimulating a targeted T cell response against
30 specific viral antigens is hampered by a lack of detailed knowledge of the immunodominant
31 epitopes displayed by common Human Leukocyte Antigen (HLA) alleles across individuals
32 (“public” epitopes). The molecules of the class I major histocompatibility complex (MHC-I, or
33 HLA in humans) display on the cell surface a diverse pool of 8 to 15 amino acid peptides derived
34 from the endogenous processing of proteins expressed inside the cell (4). This MHC-I restriction
35 of peptide antigens provides jawed vertebrates with an essential mechanism for adaptive
36 immunity: surveillance of the displayed peptide/MHC-I (pMHC-I) molecules by CD8+ cytotoxic
37 T-lymphocytes allows detection of aberrant protein expression patterns, which signify viral
38 infection and can trigger an adaptive immune response (5). A Recent study has shown important
39 changes in T cell compartments during the acute phase of SARS-CoV-2 infection (6), suggesting
40 that the ability to quantify antigen-specific T cells would provide new avenues for understanding

41 the expansion and contraction of the TCR repertoire in different disease cohorts and clinical
42 settings. Given the reduction in breadth and functionality of the naïve T cell repertoire during aging
43 (7), identifying a minimal set of viral antigens that can elicit a protective response will enable the
44 design of diagnostic tools to monitor critical “gaps” in the T cell repertoire of high-risk cohorts,
45 which can be addressed using peptide or epitope string DNA vaccines (8).

46 Human MHC-I molecules are extremely polymorphic, with thousands of known alleles in the
47 classical HLA-A, -B and -C loci. Specific amino acid polymorphisms along the peptide-binding
48 groove (termed A-F pockets) define a repertoire of 10^4 - 10^6 peptide antigens that can be recognized
49 by each HLA allotype (9, 10). Several methods have been developed to predict the likelihood that
50 a target peptide will bind to a given allele (reviewed in (11)). Generally these methods make use
51 of available data sets in the Immune Epitope Database (12) to train artificial neural networks that
52 predict binding scores, and their performance varies depending on peptide length and HLA allele
53 representation in the database. Structure-based approaches have also been proposed to model the
54 bound peptide conformation *de novo* (reviewed in (13)). These approaches utilize various MCMC-
55 based schemes to optimize the backbone and side chain degrees of freedom of the peptide/MHC
56 structure according to an all-atom scoring function derived from physical principles (14–16), that
57 can be further enhanced using modified scoring terms (17) or mean field theory (18). While these
58 methods do not rely on large training data sets, their performance is affected by bottlenecks in
59 sampling of different backbone conformations, and any possible structural adaptations of the HLA
60 peptide-binding groove.

61 Predicting the bound peptide conformation whose N- and C- termini are anchored within a fixed-
62 length groove is a tractable modeling problem that can be addressed using standard comparative
63 modeling approaches (19). In previous work focusing on the HLA-B*15:01 and HLA-A*01:01
64 alleles in the context of neuroblastoma neoantigens, we have found that a side chain optimization
65 approach can yield accurate pMHC-I models for a pool of target peptides, provided that a reliable
66 template of the same allele and peptide length can be identified in the database (20). In this
67 approach (RosettaMHC), a local optimization of the backbone degrees of freedom is sufficient to
68 capture minor (within 0.5 Å heavy atom RMSD) structural adaptations of the target peptide
69 backbone relative to the conformation of the peptide in the template, used as a starting point. For
70 HLA-A*02:01, the most common HLA allele among disease-relevant population cohorts (21),
71 there is a large number of high-resolution X-ray structures available in the PDB (22), suggesting
72 that a similar principle can be applied to produce models of candidate epitopes directly from the
73 proteome of a pathogen of interest. Here, we apply RosettaMHC to derive structural models for
74 all predicted HLA-A*02:01 epitopes from the ~30 kbp SARS-CoV-2 genome, and make our
75 models publicly available through an online database. As detailed epitope mapping data from high-
76 throughput tetramer staining (23–25) and T cell functional screens (26) become available for
77 different clinical settings and disease cohorts, the models presented here can provide a toehold for
78 understanding links between pMHC-I antigen structure and immunogenicity, with actionable
79 value for the development of peptide vaccines to combat the disease.

80

81 **Materials and Methods**

82

83 *Identification of SARS-CoV-2 peptide epitopes*

84 The SARS-CoV-2 protein sequences were obtained from NCBI:

85 (https://www.ncbi.nlm.nih.gov/nucore/NC_045512.2). From these sequences, we generated all
86 possible peptides of lengths 9 and 10 (9,621 9mer and 9,611 10mer peptides). We applied
87 NetMHCpan4.0 (2018 version) to derive binding scores to HLA-A*02:01, and retained only
88 peptides classified as strong or weak binders (selected using the default percentile rank cut-off
89 values).

90

91 *Selection of PDB templates*

92 To model SARS-CoV-2 epitopes on HLA-A*02:01, we identified 3D structures from the PDB that
93 can be used as starting templates for comparative modeling. First, we selected all HLA-A*02:01
94 X-ray structures that are below 3.5 Å resolution and retained only those that have 100% identity
95 to the HLA-A*02:01 heavy chain sequence (residues 1-180). We found 241 template structures
96 bound to epitopes of lengths from 8 to 15 residues (of which 170 are 9mers and 61 are 10mers).
97 For each SARS-CoV-2 target peptide, we select a set of candidate templates of the same length by
98 matching the target peptide anchor positions (P2 and P9/P10) to peptides found in all template
99 structures. Then, we utilized the BLOSUM62 (27) substitution matrix to score all remaining
100 positions in the pairwise alignment of the target/template sequences, and the PDB template with
101 the top alignment score was selected for modeling. For target peptides with no templates with
102 matched peptide anchors in the database, we scored all positions in the pairwise alignment and
103 select the top scoring template for modeling.

104

105 *RosettaMHC modeling framework and database*

106 RosettaMHC (manuscript in preparation) is a comparative modeling protocol developed using
107 PyRosetta (28) to model pMHC-I complexes. The program accepts as input a list of peptide
108 sequences, an HLA allele definition and a template PDB file (selected as described in the previous
109 step). To minimize "noise" in the simulation from parts of the MHC-I fold that do not contribute
110 to peptide binding, only the α_1 and α_2 domains are considered in all steps. For each peptide, a full
111 alignment between the target and template peptide/MHC sequences is performed using clustal
112 omega (29). The alignment is used as input to Rosetta's threading protocol (*partial_thread.<ext>*).
113 From the threaded model, all residues in the MHC-I groove that are within a heavy-atom distance
114 of 3.5 Å from the peptide are subjected to 10 independent all-atom refinement simulations using
115 the FastRelax method (30) and a custom movemap file. Binding energies are extracted from the
116 refined structures using interface analyzer protocol (*InterfaceAnalyzer.<ext>*). The top three
117 models are selected based on the binding energies, and used to compute an average energy for
118 each peptide in the input list. RosettaMHC models of SARS-CoV-2/HLA-A*02:01 epitopes are
119 made available through an online database (see data availability). The website that hosts our
120 database is constructed using the Django web framework.

121 **Results and Discussion**

122

123 *Template identification for structure modeling using RosettaMHC*

124 Our full workflow for template identification and structure modeling is outlined in Figure 1a, with
125 a flowchart shown in Figure 1b. To identify all possible regular peptide binders to HLA-A*02:01
126 that are expressed by SARS-CoV-2, we used a recently annotated version of all open reading
127 frames (ORFs) in the viral genome (31) from NCBI which was made available through the UCSC
128 genome browser (32). We used 9- and 10- residue sliding windows to scan all protein sequences,
129 since these are the optimum peptide lengths for binding to the HLA-A*02:01 groove (33). While
130 spliced peptide epitopes (34) are not considered in the current study, this functionality can be added
131 to our method at a later stage. Using NetMHCpan4.0 (35), we identified all 439 9mer and 279
132 10mer epitopes that are predicted to yield positive (classified as both weak and strong) binders. To
133 further validate this peptide set and derive plausible 3D models of the peptide/HLA-A*02:01
134 complexes, we used a structure-guided approach, RosettaMHC, which aims to derive a physically
135 realistic fitness score for each peptide in the HLA-A*02:01 binding groove using an annotated
136 database of high-resolution structures and Rosetta's all-atom energy function (36). RosettaMHC
137 leverages a database of 241 HLA-A*02:01 X-ray structures encompassing a range of bound
138 peptides, to find the closest match to each target epitope predicted from the SARS-CoV-2
139 proteome. To identify the best template for structure modeling, we use matching criteria which
140 first consider the peptide anchors (positions P2 and P9/P10 for 9mer/10mer epitopes), followed by
141 a sequence similarity metric calculated from the alignment between the template and target peptide
142 sequences. The template assignment statistics for the four different classes of SARS-CoV-2
143 epitopes in our set is shown in Figure 2a. Using these criteria, we find that we can cover the entire
144 set of 718 predicted binders using a subset of 114 HLA-A*02:01 templates in our annotated, PDB-
145 derived database (Figure 2b). Each target peptide sequence is then threaded onto the backbone of
146 the best identified template, followed by all-atom refinement of the side chain and backbone
147 degrees of freedom using Rosetta's Ref2015 energy function (36).

148

149

150 *RosettaMHC models recapitulate features of high-resolution X-ray structures*

151 The sequence logos derived from all predicted 9mer and 10mer binders by NetMHCpan4.0 adhere
152 to the canonical HLA-A*02:01 motif, with a preference for hydrophobic, methyl-bearing side
153 chains at the peptide anchor residues P2 and P9 (Figure 3a). The anchor residue preferences are
154 recapitulated in representative 9mer and 10mer models of the two top binders in our set as ranked
155 by Rosetta's energy (Figure 3c and 3d), corresponding to epitopes TMADLVYAL and
156 FLFVAAIFYL derived from the RNA polymerase and nsp3 proteins, respectively, which are both
157 encoded by *orf1ab* in the viral genome (NCBI Reference YP_009724389.1). In accordance with
158 features seen in high-resolution structures of HLA-A*02:01-restricted epitopes, the peptides adopt
159 an extended, bulged backbone conformation. The free N-terminus of both peptides is stabilized by
160 a network of polar contacts with Tyr 7, Tyr 159, Tyr 171 and Glu 63 in the A- and B- pockets of

161 the HLA-A*02:01 groove. The Met (9mer) or Leu (10mer) side chain of P2 is buried in a B-pocket
162 hydrophobic cleft formed by Met 45 and Val 67. Equivalently, the C-terminus is coordinated
163 through polar contacts with Asp 77 and Lys 145 from opposite sides of the groove, with the Leu
164 P9/P10 anchor nestled in the F-pocket defined by the side chains of Leu 81, Tyr 116, Tyr 123 and
165 Trp 147. Residues P3-P8 form a series of backbone and side chain contacts with pockets C, D and
166 E, while most backbone amide and carbonyl groups form hydrogen bonds with the side chains of
167 residues lining the MHC-I groove. These high-resolution structural features are consistent across
168 low-energy models of all target peptides in our input set, suggesting that, when provided with a
169 large set of input templates, a combined threading and side chain optimization protocol can derive
170 physically realistic models.

171

172

173 *Comparison of binding energies for different peptide sets*

174 To evaluate the accuracy of our models and fitness of each peptide within the HLA-A*02:01
175 binding groove, we computed Rosetta binding energies across all complexes modeled for different
176 peptide sets. High binding energies can be used as an additional metric to filter low-affinity peptides
177 in the NetMHCpan4.0 predictions, with the caveat that high energies can be also due to incomplete
178 optimization of the Rosetta energy function as a result of significant deviations between the target
179 and template backbone conformations, not captured by our protocol. We performed 10
180 independent side chain optimization calculations for each peptide, and the 3 lower-energy models
181 were selected as the final ensemble and used to compute an average binding energy. The results
182 for all 9mer peptides are summarized in Figures 3e, f, while additional results for 10mers are
183 provided through our web-interface and Supplemental Table 1. As a positive reference, we used
184 the binding energies of the idealized and relaxed PDB templates, which are at a local minimum of
185 the Rosetta scoring function. As a negative control for poor binders, we modeled decoy structures
186 of poly alanine peptide sequences, threaded onto the same PDB templates. We observe a
187 significant (26 kcal/mol) energy gap between the average binding energies for PDB templates
188 (positives) and poly alanine negative controls. The binding energies for our modeled 9mers from
189 the SARS-CoV-2 genome fall between the distributions corresponding to positive and negative
190 control samples, and show a bimodal distribution with significant overlap with the refined PDB
191 template energies (Figure 1e). Inspection of the binding energies of 12 9mer peptides in our set
192 that are homologous to peptides in the SARS viral genome with confirmed binding to HLA-
193 A*02:01 in the IEDB (12, 37) shows a similar distribution, with the binding energies of 9/12
194 peptides falling within the distribution of the refined PDB templates (red dots in Figure 3e).
195 Comparison of the distributions between epitopes that are classified as strong versus weak binders
196 by NetMHCpan4.0 shows a moderate bias towards lower binding energies for the strong binders
197 and a larger spread in energies for weak binders, likely due to suboptimal residues at the P2 and
198 P9 anchor positions (Figure 3f).

199 Together, these results suggest that the high-resolution features seen in our models (Figure 3c, d)
200 yield optimal binding energies for a significant fraction of the epitopes predicted by

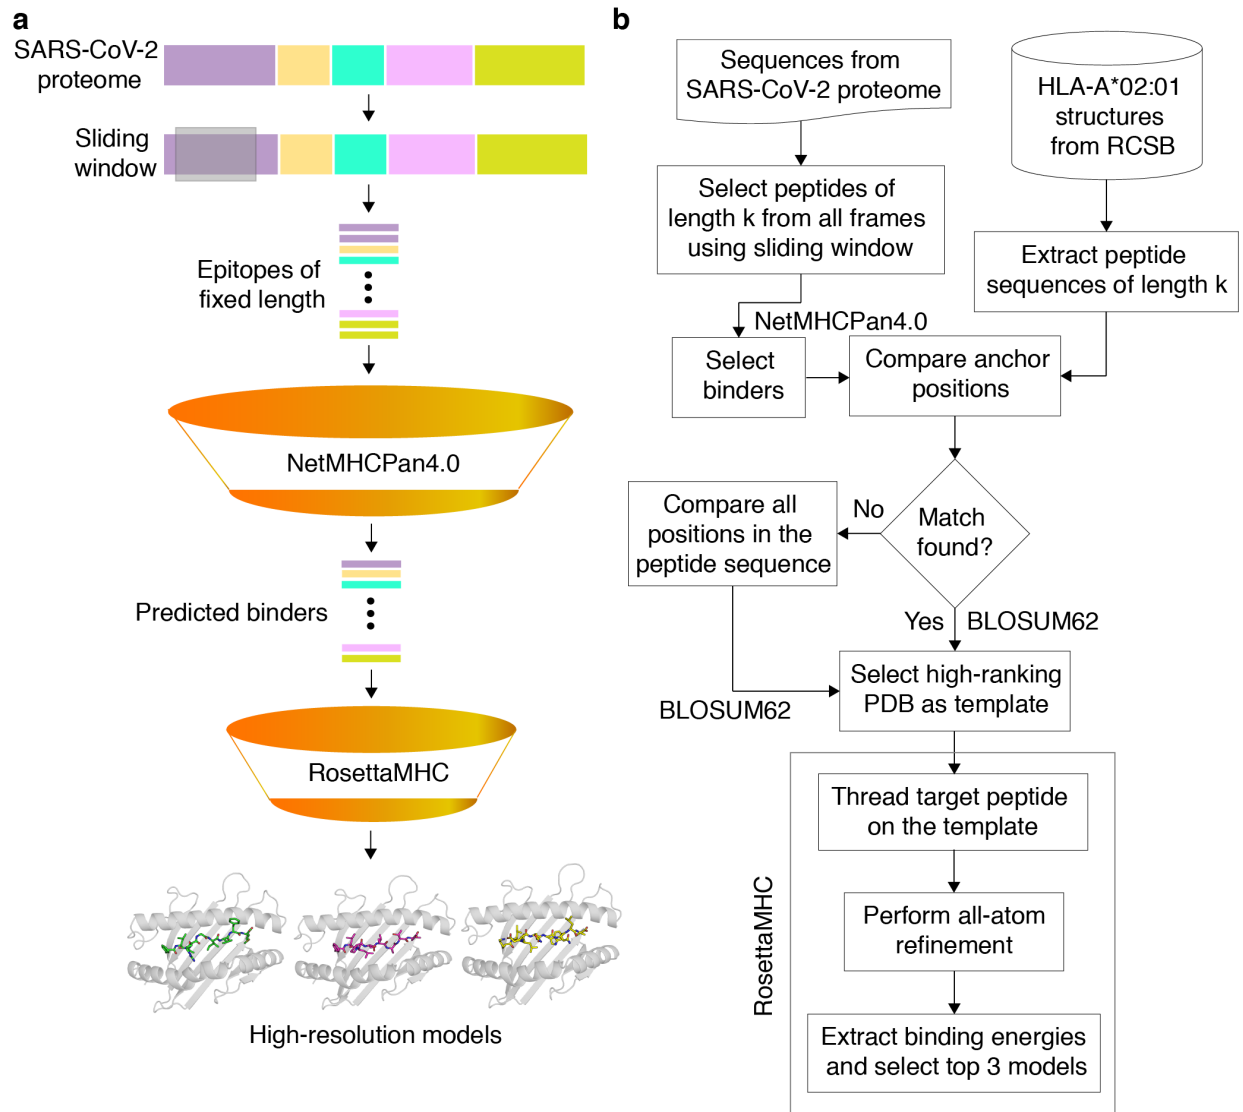

201 NetMHCpan4.0 (up to 45/33% of strong binders and 30/25% of weak binders for 9mers/10mers,
202 respectively), which are comparable to locally refined PDB structures. The average binding
203 energies for each peptide are provided in our web-interface, Supplemental Table 1 and can be used
204 to further select high-affinity peptides, by considering the structural complementarity of each
205 target epitope within the HLA-A*02:01 peptide-binding groove.

206
207

208 *Surface features of peptide/HLA-A*02:01 models for T cell recognition*

209 Visualization of our models through an interactive online interface provides direct information on
210 SARS-CoV-2 peptide residues that are bulging out of the MHC-I groove, and are therefore
211 accessible to interactions with complementarity-determining regions (CDRs) of T cell receptors
212 (TCRs). Given that $\alpha\beta$ TCRs generally employ a diagonal binding mode to engage pMHC-I
213 antigens where the CDR3 α and CDR3 β TCR loops form direct contacts with key peptide residues
214 (38, 39), knowledge of the surface features for different epitopes adds an extra layer of information
215 to interpret sequence variability between different viral strains. For other important antigens with
216 known structures in the PDB, such features can be derived from an annotated database connecting
217 pMHC-I/TCR co-crystal structures with biophysical binding data (40), and were recently
218 employed in an artificial neural network approach to predict the immunogenicity of different HLA-
219 A*02:01 bound peptides in the context of tumor neoantigen display (41). A separate study has
220 shown that the electrostatic compatibility between self vs foreign HLA surfaces can be used to
221 determine antibody alloimmune responses (42). Given that antibodies and TCRs use a common
222 fold and similar principles to engage pMHC-I molecules (39), it is likely that electrostatics play
223 an important role in recognition of peptide/HLA surfaces by their cognate TCRs in the context of
224 SARS-CoV-2 infection.

225 Surface electrostatics calculated using a numerical solution to the Poisson-Boltzmann Equation
226 (43) for our modeled peptide/HLA-A*02:01 complexes allow us to compare important features
227 for TCR recognition between different high-affinity epitopes (Figure 4). We observe a moderate
228 electropositive character of the HLA-A*02:01 α_1 helix, and a moderate negative potential on the
229 α_2 helix, which is consistent between complexes with different bound peptides. However, due to
230 substantial sequence variability in surface-exposed residues at the P2-P8 positions, we observe a
231 range of electrostatic features ranging from negative (sequence TMADLVYAL), to neutral
232 (sequence NLIDSYFVV) or positively charged (sequence KLWAQCVQL). Further classification
233 and ranking of the top binders in our set on the basis of their molecular surface features would
234 enable the selection of a diverse panel of peptides for high-throughput pMHC tetramer library
235 generation (23-25). Such libraries can be used to screen T cells of COVID-19 patients, recovered
236 individuals and healthy donors from high-risk groups towards identifying a minimal panel of
237 epitopes to monitor T cell responses in patients, and to select the top candidates for vaccine
238 development.

FIGURE 1. Structure-guided modeling of T cell epitopes in the SARS-CoV-2 proteome

(a) General workflow, outlined in detail in (b). (b) Protein sequences from the annotated SARS-CoV-2 proteome are used to generate peptide epitopes with a sliding window covering all frames of a fixed length (9,621 9mer and 9,611 10mer possible peptides). Candidate peptides are first filtered by NetMHCpan4.0 (35) to identify all predicted strong and weak binders (439 9mer and 279 10mer epitopes). For template matching, we use a local database of all 241 HLA-A*02:01 X-ray structures with resolution below 3.5 Å in the Protein Data Bank (22). Each candidate peptide is scanned against all peptide sequences of the same length in the database, and the top-scoring template is used to guide the RosettaMHC comparative modeling protocol.

250

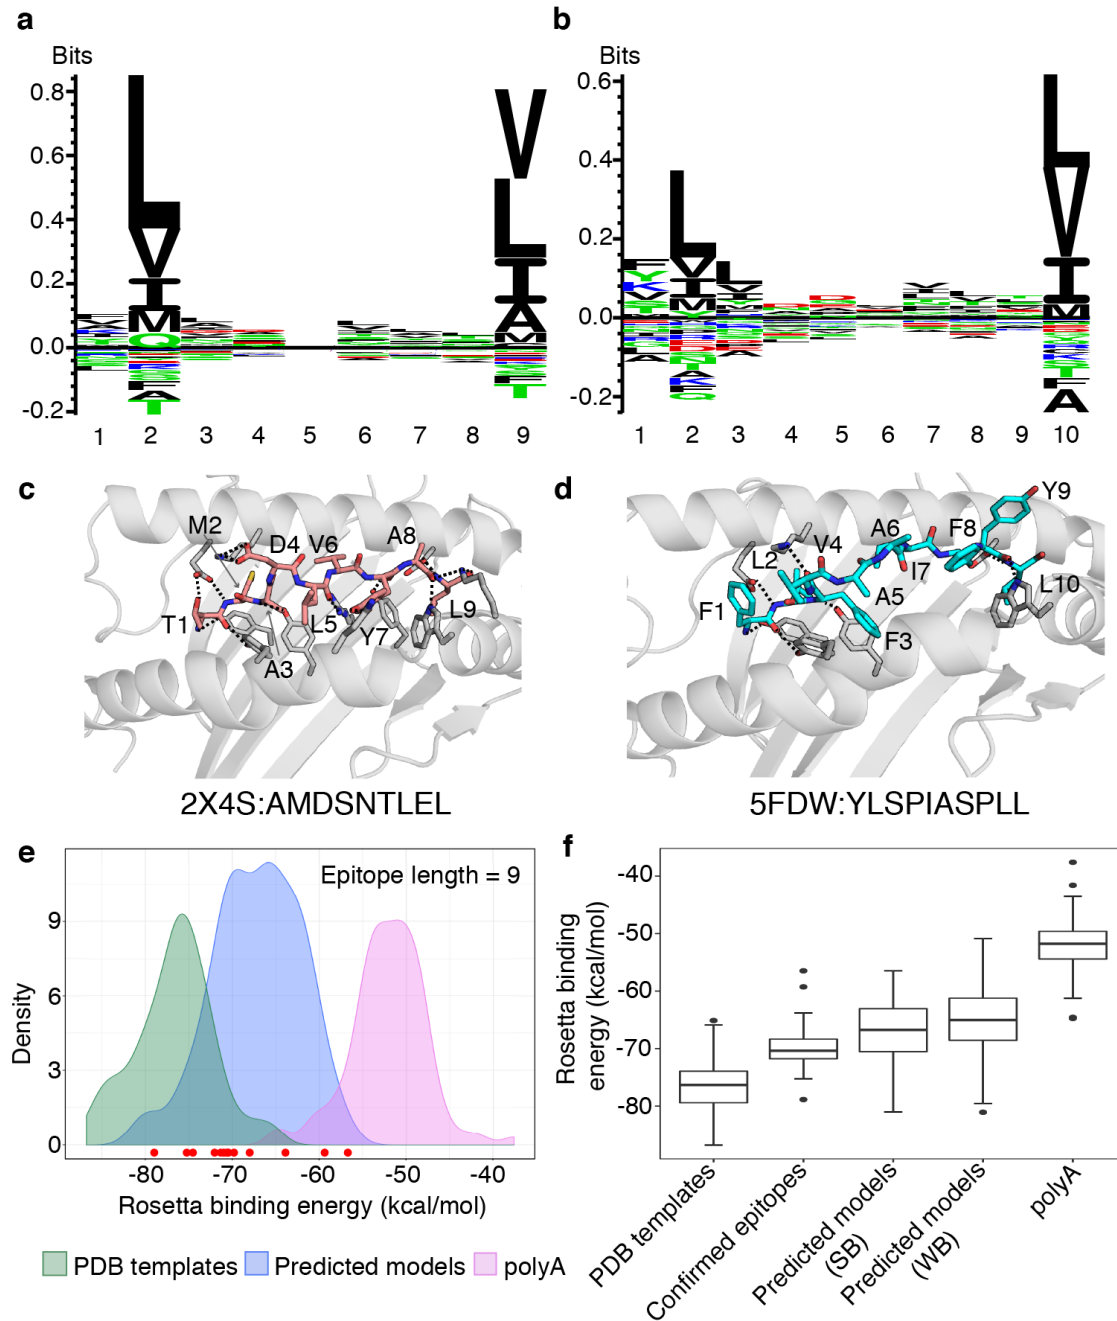

251 **FIGURE 2. Coverage of predicted HLA-A02 epitopes by structural templates in the PDB**

252 (a) Peptide anchor matching statistics of all predicted SARS-CoV-2 strong (SB) and weak binders

253 (WB) of lengths 9 and 10 to a database of 241 high-resolution HLA-A*02:01 X-ray structures (b)

254 Plot showing cumulative distribution (CDF) of strong and weak binder peptides of lengths 9 and

255 10, as a function of the total number of matching templates from the Protein Data Bank (22).

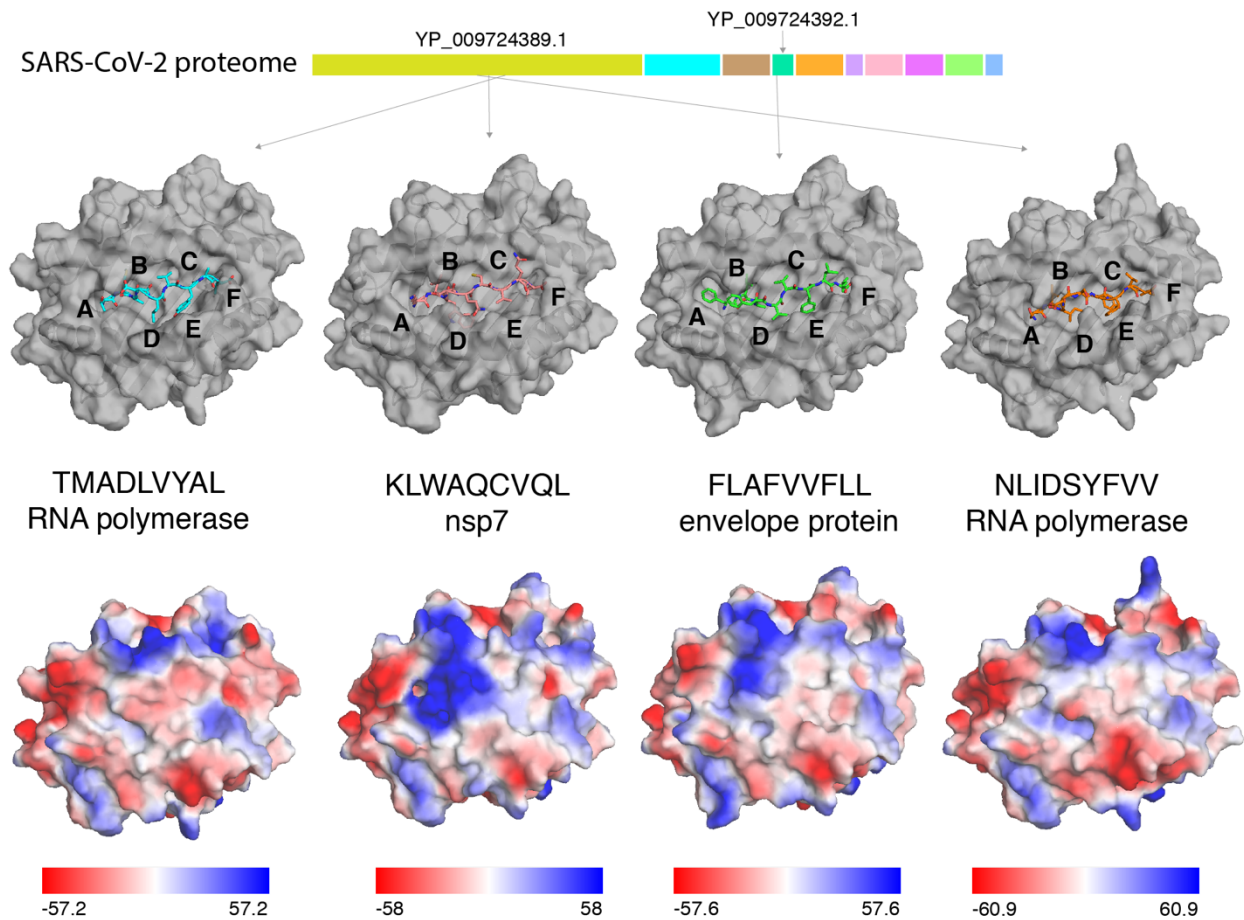

256

257 **FIGURE 3. Summary of RosettaMHC results for SARS-CoV-2 peptide epitopes**

258 Sequence logos for all HLA-A*02:01-restricted epitopes in the SARS-CoV-2 genome, predicted
 259 by NetMHCpan4.0 (35) are shown for epitopes of lengths (a) 9 and (b) 10. Top-scoring models
 260 with epitopes of lengths (c) 9 (TMADLVYAL, from RNA polymerase) and (d) 10
 261 (FLFVAAIFYL, from nsp3). Dotted lines indicate polar contacts between the peptide and heavy
 262 chain residues, with peptide residues labelled. The template PDB IDs and original peptides used
 263 for modeling the targets are indicated below each model. (e) Density plots showing distribution of
 264 average Rosetta binding energies (kcal/mol) for epitopes of length 9. Distributions reflect 93 PDB
 265 templates (green), 164 strong binding epitopes (blue), and 93 poly alanine peptides, used as

266 negative binders (polyA; pink). Confirmed SARS T cell epitopes from the IEDB (37) are indicated
267 by red circles at the bottom of the plot. **(f)** Box plots showing distribution of average binding
268 energies for PDB templates, poly alanine peptides, confirmed epitopes and RosettaMHC models
269 for strong (SB) and weak (WB) binder 9mer epitopes predicted from the SARS-CoV-2 proteome
270 using NetMHCpan4.0 (35).
271
272

273
274 **FIGURE 4. Variability in TCR recognition features of HLA-A02 with different high-affinity**
275 **peptides.** Molecular surfaces of SARS-CoV-2/HLA-A*02:01 RosettaMHC models are shown for
276 four top-scoring epitopes (ranked by Rosetta binding energy from left to right) captured in the A,
277 B, C, D, E and F pockets of the MHC-I groove (top panel). The origins of the peptide epitopes in
278 the ~30 kbp SARS-CoV-2 genome are noted. Electrostatic surfaces of the same top scoring models
279 (from top panel) are shown in the bottom panel. Solvent-accessible surface representation with
280 electrostatic potential in the indicated ranges (down to -60 kcal/(mol \cdot e) in red and up to $+61$
281 kcal/(mol \cdot e) in blue) were calculated using the APBS solver (44) in Pymol (45). All calculations
282 were performed at 150 mM ionic strength, 298.15 Kelvin, pH 7.2, protein dielectric 2.0, and
283 solvent dielectric 78.54. Electrostatic potentials are given in units of kT/e. A 1.4 Å solvent (probe)
284 radius and 10.0 points/Å² density was used to calculate molecular surfaces.

285 **Code and Data availability**

286 An online web-interface for visualization and download of all models is available at:
287 <https://rosettamhc.chemistry.ucsc.edu>. The RosettaMHC source code is available at
288 <https://github.com/snerligit/mhc-pep-threader>. Rosetta binding energies for all 718 HLA-
289 A*02:01-restricted peptides in our set are provided in Supplemental Table 1.

290

291 **Acknowledgements**

292 The authors are grateful to Alison Lindberg and ITS/ADC staff at UCSC for assistance in setting
293 up the web server for the database, and Hiram Clawson (UCSC Genome Browser) for providing
294 the SARS-CoV-2 protein sequence data. We thank Andrew McShan, Hailey Wallace (UCSC) for
295 assistance in the development of the RosettaMHC protocol, and David Haussler (UCSC), Michael
296 Betts (University of Pennsylvania) for helpful discussions. This work was supported through
297 Grants from NIAID (5R01AI143997) and NIGMS (5R35GM125034).
