Abstract

Influenza viruses (family *Orthomyxoviridae*) infect a variety of vertebrates, including birds, humans, and other mammals. Recent metatranscriptomic studies have uncovered divergent influenza viruses in amphibians, fish and jawless vertebrates, suggesting that these viruses may be widely distributed. We sought to identify additional vertebrate influenza-like viruses through the analysis of publicly available RNA sequencing data. Accordingly, by data mining, we identified the complete coding segments of five divergent vertebrate influenza-like viruses. Three fell as sister lineages to influenza B virus: salamander influenza-like virus in Mexican walking fish (*Ambystoma mexicanum)* and plateau tiger salamander (*Ambystoma velasci*), siamese algae-eater influenza-like virus in siamese algae-eater fish (*Gyrinocheilus aymonieri*) and chum salmon influenza-like virus in chum salmon (*Oncorhynchus keta*). Similarly, we identified two influenza-like viruses of amphibians that fell as sister lineages to influenza D virus: cane toad influenza-like virus and the ornate chorus frog influenza-like virus, in the cane toad (*Rhinella marina)* and ornate chorus frog (*Microhyla fissipes)*, respectively. Despite their divergent phylogenetic positions, these viruses retained segment conservation and splicing consistent with transcriptional regulation in influenza B and influenza D viruses, and were detected in respiratory tissues. These data suggest that influenza viruses have been associated with vertebrates for their entire evolutionary history.

Keywords: *Orthomyxoviridae*; influenza; metatranscriptomics; fish; amphibians; evolution; phylogeny

1. Introduction

43

44   Influenza viruses are multi-segmented, negative-sense RNA viruses of the family

45   *Orthomyxoviridae*, which also includes the genera *Quaranjavirus*, *Isavirus* and *Thogotovirus*, as well

46   as a wide diversity of orthomyxo-like viruses found in invertebrates [1-3]. Until recently, influenza

47   viruses had been limited to a small group of pathogens with public health importance for humans,

48   particularly those of pandemic and epidemic potential – influenza A virus (IAV, *Alphainfluenzavirus*)

49   and influenza B virus (IBV, *Betainfluenzavirus*). Influenza A virus is an important, multi-host virus

50   which is best described in humans, pigs, horses and birds [4-7]. These viruses are epidemic in humans

51   and are closely monitored for pandemic potential. Influenza B viruses similarly cause yearly epidemics

52   in humans [8], and their detection in both seals [9] and pigs [10] highlights the potential for non-human

53   IBV reservoirs.

54

55   While IAV and IBV are subject to extensive research, far less is known about two additional

56   influenza viruses: Influenza C virus (ICV, *Gammainfluenzavirus*) and Influenza D virus (IDV,

57   *Deltainfluenzavirus*). Influenza C virus has been found in humans worldwide and is associated with

58   mild clinical outcomes [11, 12]. Based on its detection in pigs, dogs and camels, it is likely that this

59   virus has a zoonotic origin [13-17]. Influenza D virus, first identified in 2015 [18], is currently thought

60   to have a limited host range and is primarily associated with cattle and small ruminants [18-20], pigs

61   [18] as well as dromedary camels [17]. Although there is no record of active infection in humans, there

62   are indications of past infection based on serological studies [12, 21, 22].

63

64   Despite intensive research on the characterisation of influenza viruses, our understanding of their

65   true diversity and their evolutionary history is undoubtedly limited. Of critical importance are recent

66   meta-transcriptomic (i.e. bulk RNA sequencing) studies that report the discovery of novel "influenza-

67   like" viruses from both amphibian and fish hosts – Wuhan spiny eel influenza virus, Wuhan asiatic toad

68   influenza virus and Wenling hagfish influenza virus [3]. Such a phylogenetic pattern, particularly the

69   position of the hagfish (jawless vertebrate) influenza virus as the sister-group to the other vertebrate

70   influenza viruses, is compatible with virus-host co-divergence over millions of years. This, combined

71   with relatively frequent cross-species transmission, suggests that a very large number of animal

72   influenza-like viruses remain to be discovered.

73   Given the previous success of data-mining to identify a range of novel viruses, including

74   rhabodviruses [23], flaviviruses [24] and parvoviruses [25], we hypothesised we could mine publicly

available transcriptome databases for evidence of undescribed vertebrate influenza viruses and that this would provide further insights into their evolutionary origins. Given the highly under-sampled nature of "lower" vertebrate hosts, such as fish and amphibians, we focused on data from these taxa. From this, we identified five novel influenza-like viruses that provide new insights into the evolution and host range of this important group of animal viruses.

2. Materials and Methods

2.1 Identification of divergent influenza-like viruses from vertebrate de novo transcriptome assemblies

To identify novel and potentially divergent vertebrate influenza viruses we screened *de novo* transcriptome assemblies available at the National Center for Biotechnology Information (NCBI) Transcriptome Shotgun Assembly (TSA) Database (https://www.ncbi.nlm.nih.gov/genbank/tsa/) and the China National GeneBank (CNGB) Fish-T1K (Transcriptomes of 1,000 Fishes) Project database (https://db.cngb.org) [26]. Amino acid sequences of the influenza virus reference strains - IAV A/Puerto Rico/8/34 (H1N1), IBV (B/Lee/1940), ICV (C/Ann Arbor/1/50) and IDV (D/bovine/France/2986/2012) - were queried against the assemblies using the translated Basic Local Alignment Search Tool (tBLASTn) algorithm under default scoring parameters and the BLOSUM45 matrix. For the TSA, we restricted the search to the Vertebrata (taxonomic identifier [taxid] 7742). Putative influenza-like virus contigs were subsequently queried using BLASTx against the non-redundant virus database. Two fish transcriptomes (BioProjects PRJNA329073 and PRJNA359138) were excluded because of the presence of reads that were near identical to IAV, strongly suggestive of contamination.

2.2 Recovery of additional influenza-like virus segments through de novo assembly and coverage statistics

Putative influenza-like viruses identified in the transcriptome data were queried against genus-wide RNA-Seq samples deposited in the Sequence Read Archive (SRA) using the BLASTn tool. Raw fastq files originating from transcriptome sequencing libraries were downloaded and imported to the Galaxy Australia web server (https://usegalaxy.org.au/, v. 19.05). Sequencing adapters were identified using FastQC, and reads were quality trimmed using Trimmomatic (Galaxy v. 0.36.4) under the following conditions: sliding window = 4 and average quality = 20 [27]. For the recovery of full-length transcripts corresponding to putative influenza-like viruses, clean reads were then *de novo* assembled using Trinity (Galaxy Version 2.9.1) [28]. For virus genome statistics, clean reads were re-mapped

4

105 against virus segments using the Burrow-Wheeler Aligner (BWA-MEM Galaxy Version 0.7.17.1)

106 under default conditions, and the resultant binary alignment file was analysed with the bedtools

107 (v2.27.1) genome coverage tool [29]. For the production of the salamander influenza-virus infection

108 heat map of *Ambystoma velasci* tissues, quantitation of abundance for each library was calculated using

109 the proportion of total mapped salamander influenza-like reads for each library and heatmaps were

110 produced using R v3.5.3 integrated in RStudio v1.1.463 and *ggplot2*.

111 *2.3 Influenza virus genome annotation*

112 Viral open reading frames were predicted using ORFFinder

113 (https://www.ncbi.nlm.nih.gov/orffinder/). To characterise functional domains, predicted protein

114 sequences were subjected to a domain-based search using the Conserved Domain Database version

115 3.16 (https://www.ncbi.nlm.nih.gov/Structure/cdd/cdd.shtml) and cross-referenced with the PFam

116 database (version 32.0) hosted at (http://pfam.xfam.org/). Transmembrane topology prediction using

117 the TMHMM Server version 2.0 (www.cbs.dtu.dk/services/TMHMM/). For the identification of

118 potential splice sites in influenza-like viruses we used alternative isoforms assembled using Trinity and

119 then manually validated for donor and acceptor sites using the Alternative Splice Site Predictor (ASSP)

120 (http://wangcomputing.com/assp/index.html) [30] for NS and M segments guided by experimentally

121 validated positions in IAV/IBV/ICV (Reviewed here [31]). Viral genome sequences have been

122 deposited in GenBank under the accession numbers: MT926372-MT926409

123 *2.4 Phylogenetic analysis*

124 Multiple sequence alignments of predicted influenza virus protein sequences were performed using

125 MAFFT-L-INS-i (version 7.471) [32]. Ambiguously aligned regions were removed using TrimAl (v.

126 1.3) under the automated 1 method [33]. Individual protein alignments were then analysed to determine

127 the best-fit model of amino acid substitution according to the Bayesian Information Criterion using

128 ModelFinder [34] incorporated in IQ-TREE (Version 2.1.1) [35] and excluding the invariant sites

129 parameter. For the PB1, PA, NP segments the Le-Gascuel (LG) model [36] with discrete gamma model

130 with 4 rate categories $(+\Box_4)$ and empirical amino acid frequencies (+F) was selected as the most

131 suitable. For the HA/HEF alignments, the Whelan and Goldman (WAG) model [37] with a discrete

132 gamma model with 4 rate categories $(+G_4)$ was selected. For the NA alignment, the FLU+G_4 model

133 was identified [38], and finally, PB2 and NS (LG+G_4). For the M1/M2 alignment, LG + FreeRate

134 model (+R3) [39] was selected. Maximum likelihood trees were then inferred using IQ-TREE (Version

5

135   2.1.1) with Ultrafast bootstrap approximation (n=40,000) [40]. Resultant consensus tree from combined

136   bootstrap trees were visualised using FigTree version 1.4 (http://tree.bio.ed.ac.uk/software/figtree/).

3. Results

3.1   Discovery and annotation of novel influenza-like viruses in vertebrates

139   We initially screened 776 vertebrate *de novo* assembled transcriptomes deposited in the

140   Transcriptome Shotgun Assembly Sequence Database (TSA) and a further 158 transcriptomes

141   available on the Fish-T1K Project. Within the TSA entries, the most abundant assemblies were from

142   the bony fish (*Actinopterygii)*, accounting for 346 transcriptomes. We also screened the amphibian

143   (n=57) and cartilaginous fish (n=9) transcriptomes. From these libraries, we detected influenza-like

144   viruses in 0.6% of the bony fish libraries (n=2) and in 7% (n=4) of the amphibian libraries.

145

146   Our transcriptome mining identified fragments of divergent IBV-like Polymerase Basic 1 and 2

147   (PB1, PB2) segments from an unpublished transcriptome of ear and neuromast samples from an

148   *Ambystoma mexicanum* (Mexican walking fish or Axolotl) laboratory colony housed by The University

149   of Iowa (BioProject Accession: PRJNA480225). BLASTx analysis of these IBV-like fragments

150   revealed 76.32% amino acid identity to the PB1 gene of IBV (Top hit Genbank accession

151   ANW79211.1; E-value: 0; query cover 100%) and 60.94% to the IBV PB2 (Top hit Genbank

152   accession: AGX15674.1; E-value: 2e-49; query cover: 83%) (Table 1). To recover additional segments

153   and full-length PB1 and PB2 genes, we used BLASTn to screen 2,037 *Ambystoma* RNA-Seq libraries

154   from several *Ambystoma* species available on the SRA. Accordingly, we were able to identify this

155   tentatively named salamander influenza-like virus in 139/2037 (6.8%) of screened libraries. BLASTn

156   positive libraries were subsequently *de novo* assembled, allowing the recovery of all eight segments of

157   this virus (Figure 1; Table 1). In addition to *A. mexicanum* samples infected with salamander influenza-

158   like virus we identified a smaller number of reads from Anderson's salamander (*Ambystoma*

159   *andersoni*) and spotted salamander (*Ambystoma maculatum*) libraries [42]. Finally, we identified a

160   variant of salamander influenza virus from RNA-Seq data generated from laboratory colonies of

161   another neotenic salamander, plateau tiger salamander (*Ambystoma velasci*) [41] with nucleotide

162   sequence identity between both variants of all segments between 89-94% at the nucleotide level (PB1

163   90%, PB2 91%, PA 90%, NP 91%, NA 90%, HA 89%, NS 94%, M 93%) (Table 1). The presence of

164   infection in up to four species of *Ambystoma* colonies indicates the potential for a wide host range for

165   this virus across this host genus. Additionally, as the majority of *A. mexicanum* colonies originate from

6

166 the *Ambystoma* Genetic Stock Center (AGSC, University of Kentucky, KY) [43-46] and in some cases
167 co-housed together with other species positive for this virus [42], this suggests that this virus may
168 circulate between numerous laboratory-reared salamander colonies.

170 We similarly identified an influenza virus in the Siamese algae-eater (*Gyrinocheilus aymonieri*)
171 (SRA accession: SRR5997773), tentatively termed siamese algae-eater influenza-like virus, sampled as
172 part of the Fish-T1K Project (Table 1) [26]. While there is limited meta-data available, the library was
173 prepared from gill tissues. There was no evidence of this virus in any other siamese algae-eater samples
174 available on the SRA (n=2) through BLASTn analysis.

176 Finally, we identified another IBV-like virus in chum salmon (*Oncorhynchus keta)*, provisionally
177 termed chum salmon influenza-like virus (Table 1). While the geographic origin of the samples is
178 unknown the meta-data from this library indicates the RNA-Seq originates from gill tissues of alevin
179 stage chum salmon, transferred to the Korea Fisheries Resources Agency (FIRA) laboratory and reared
180 in tanks with recirculating freshwater [47]. We identified chum salmon influenza-like virus sequences
181 in one of the three libraries from this project (SRA Accession: SRR6998471). However, all segments
182 were convincing *de novo* assembled and covered through re-mapping with reads corresponding to
183 0.045% of the library (45,151/100,244,990 mapped reads).

185 In addition to novel viruses related to IBV, we identified two influenza viruses of amphibians that
186 exhibited high pairwise amino acid identity to segments from IDV and ICV (Table 1). This result is
187 particularly noteworthy as the previously identified amphibian influenza virus, wuhan asiatic toad
188 influenza virus, was more closely related to IBV [3]. Cane toad influenza-like virus was identified in
189 four larval samples of cane toad (*Rhinella marina*), from two geographic locations in Australia,
190 Innisfail, Queensland, Australia (SRA accessions: SRR5446725, SRR5446726) and Oombulgurri,
191 Western Australia, Australia (SRA accessions: SRR5446727, SRR5446728) [48]. We did not identify
192 any virus reads in any adult tissue samples taken in Australia nor from libraries constructed from cane
193 toad samples from Macapa city, Brazil, from the same study [48]. Similarly, we did not recover any
194 cane toad influenza-like virus reads in any of the 16 liver tissue samples from Australia reported in
195 another metatranscriptomic study, which aimed to reveal the virome of the cane toad [49].

197 The final IDV-related virus identified was tentatively named ornate chorus frog influenza-like
198 virus detected in ornate chorus frog (*Microhyla fissipes*) (Table 1). This virus was identified in two

7

199 sequencing projects, both of which were from samples of ornate chorus frog collected from paddy

200 fields in Chengdu, China, albeit at different times; May 2014 (Bioproject accession: PRJNA295354)

201 [50] and June 2016 (Bioproject accession: PRJNA386601)[51]. Between both data sets, the largest

202 number of ornate chorus frog influenza-like virus reads originated from the lung tissue of the stage 28

203 tadpole (SRA accession: SRR5557878) in the second study (June 2016 [51]), representing 0.13% of all

204 reads (81,860/ 61,952,548). While there were fewer reads mapping to the ornate chorus frog influenza-

205 like virus in whole tissues of three developmental stages in the study carried out in 2014 [50]. In the

206 whole organism samples the highest viral abundance was in the metamorphic climax (1,462/59,993,514

207 reads) (SRA accession: SRR2418623), and pre-metamorphosis developmental phases

208 (1,113/63,073,925 reads) (SRA accession: SRR2418554) with only 7 reads were identified in the

209 complete metamorphosis library (7/56,000,000 reads) (SRA accession: SRR2418812). The nucleotide

210 identity of ornate chorus frog influenza-like virus variants between the 2014 [50] and June 2016 [51]

211 data sets was between 93.36%-97.10% for all segments (PB1 96.98% PB2 93.95% P3 93.36% NP

212 93.83% HEF 91.87% NS 97.10% M 96.29%).

213 *3.2   The genome organisation and transcription of novel influenza-like virus genes are highly*

214 *conserved*

215 Through a combination of *de novo* assembly and tBLASTn analysis we were able to identify and

216 assemble the complete coding segments of all novel influenza-like genomes described in this study

217 (Figure 1, Figure S1-S5, Table S1-S6). For the salamander influenza-like virus, siamese algae eater

218 influenza-like virus and chum salmon influenza-like viruses, all eight segments with genome

219 arrangements similar to that of IAV and IBV were identified (Figure 1). Prediction of the ORFs from

220 all segments and protein domain analyses suggested homology between these putative virus proteins

221 (Table S1-S4, Figure S1-S3). Additionally, we identified the glycoprotein NB, which is encoded

222 through a polycistronic mRNA of the NA segment of IBVs (Figure 1). The M2 domain of chum

223 salmon influenza-like was not identified through BLASTp, likely due to high levels of sequence

224 divergence. However, we did identify the N terminus using a domain search (Table S3). In contrast, we

225 identified seven segments for each of cane toad influenza-like virus and ornate chorus frog influenza-

226 like viruses, which are characteristic of ICV/IDV encoding 7 segments (Figure 1). We recovered all

227 ORFs expected of viruses similar to ICV and IDV (Table S5-S6, Figure S4-S5).

228

229 There were a number of important differences in the composition of segments among IAV/IBV

230 and ICV/IDV. For example, segment 3 is differentiated into "PA" or "P3" by isoelectric points. The

8

231 isoelectric point of ornate chorus frog influenza-like virus (~6.3) and cane toad influenza-like virus

232 (~6) are similar to those of the P3 segment of ICV/IDV, while those of salamander influenza-like virus

233 (~5.6), Siamese algae eater influenza-like virus (~5.3) and chum salmon influenza-like viruses (~5.4)

234 had isoelectric points more consistent with PA of IAV (~5.4) and IBV (~5.5). With the exception of

235 chum salmon influenza-like virus, we were able to assemble two discrete isoforms of the NS gene in all

236 our assembles and manually validate the splice junctions as *bona fide* through the identification of

237 splicing donor and acceptor sites (Table S2-6). The M segment in ICV/IDV related viruses is also post-

238 transcriptionally spliced to encode the M1 protein, and we were able to assemble two isoforms of the M

239 segment from cane toad influenza-like virus and ornate chorus frog influenza-like virus.

240 *3.3   Phylogenetic analysis of novel influenza-like viruses suggests a history of genomic reassortment*

241 One of the most striking observations of our study was that three novel influenza viruses from

242 amphibians and fish fell basal to IBV in the phylogenetic analysis, although none of the relevant

243 bootstrap values were exceptionally high (i.e. <75%) (Figure 2), and with pairwise amino acid

244 sequences similarities to the PB1 of IBV ranging from 67- 75%. The placement of these viruses, in

245 addition to Wuhan spiny eel influenza virus, at the base of the IBV lineage, strongly suggests that these

246 viruses have a long evolutionary history in vertebrates. Indeed, it is notable that salamander influenza-

247 like virus is the now the closest animal relative to IBV. Similarly, two other influenza-like viruses from

248 amphibians fell basal to IDV, this time with strong (>90% bootstrap support) and exhibited 77-80%

249 amino acid similarity in the PB1 segment.

250 These novel influenza viruses largely occupy consistent phylogenetic placements across

251 segments (Figure 3). However, chum salmon influenza-like virus is the sister-group to IBV in the

252 polymerase (PB2, PB1, PA) and NA segments, but is the sister-group to both IAV/IBV in the NP

253 segment. Also of note was that the two amphibian influenza-like genomes are the sister lineages to IDV

254 in all segments with the exception of the HEF, in which they are the sister lineages to the clade

255 containing ICV/IDV.

256 *3.4   Multi-tissue RNA-sequencing of developmental Plateau tiger salamander libraries suggests*

257 *conserved influenza virus tropism in vertebrates*.

258 To gain further insight into the tissue tropism of these divergent influenza viruses, we screened

259 libraries from a multi-tissue and developmental library of the plateau tiger salamander. This data set

260 comprised of 86 individual samples from gills, hearts and lungs at different stages of

261   premetamorphosis, prometamorphosis, metamorphosis and metamorphosis late [41]. We identified
262   RNA originating from salamander influenza-like virus abundantly in the libraries originating from gills
263   at the metamorphosis late stage with an average number of the reads in all 6 libraries corresponding to
264   approximately 0.22% of all reads (Figure 4). The second most abundant tissue and developmental stage
265   was the postmetamorphosis stage lung tissue which had, on average, 0.013% of all reads correspond to
266   salamander influenza-like virus. The only other tissue and developmental stage with all segments
267   represented were the gills from the premetamorphosis stage with an average ~0.003% of all reads
268   originating from Salamander influenza-like virus.

269

4. Discussion

271   We have identified five novel influenza viruses in fish and amphibians through mining publicly
272   available meta-transcriptomic data. Despite intensive research on influenza viruses for almost a
273   century, it is only recently that these viruses have been identified in hosts other than birds and
274   mammals. In particular, the recent identification of divergent influenza-like viruses in fish and
275   amphibians [3], as well as even more divergent orthomyxoviruses in invertebrates [2], suggests that
276   divergent members of this virus family may infect a wide range of animal hosts.

277

278   These data provide valuable insights into the evolution of influenza viruses across the vertebrates.
279   First, that the phylogeny of the IBV-like viruses in part follows the phylogeny of the hosts from which
280   they are sampled, with the Salamander influenza-like viruses falling as the sister-group to the
281   mammalian viruses and the fish viruses occupying basal positions in that group as a whole. This is
282   compatible with a process of virus-host co-divergence that likely extends hundreds of millions of years,
283   albeit with relatively frequent host-jumping. Under these circumstances, it must also be the case that
284   there are many more vertebrates carry IBV-like viruses that have yet to be investigated. Similarly, we
285   identified two amphibian viruses that fall as sister lineages to IDV, again suggestive of both long-term
286   co-divergence and highly limited sampling to date. Whether the same pattern will also be true of the
287   influenza A virus group is unclear and will only be resolved with additional sampling. Finally, it is
288   notable that Wenling hagfish virus, from a jawless vertebrate (a hagfish), occupies the basal position in
289   all of the vertebrate influenza virus, again suggesting that these viruses have been in existence for
290   hundreds of millions of years.

291

10

292   Despite detecting divergent influenza viruses, the stability and conservation of genome segments

293   and transcriptional regulation of viral genes through splicing is conserved. For example, salamander

294   influenza-like virus, siamese algae-eater influenza-like and chum salmon influenza-like virus, which all

295   fall basal to IBV, possess eight segments encoding all the predicted/required ORFs including NB,

296   which is a glycoprotein encoded on the NA gene of IBV only [52]. Similarly, cane toad influenza and

297   ornate chorus frog influenza had only seven segments and all ORFs consistent with ICV and IDV.

298   Overall, despite finding these viruses in non-mammalian hosts, the viral structure is highly consistent

299   with other influenza viruses strongly supporting the inclusion into these viral genera.

300   These new data also raise questions of whether influenza and influenza-like viruses have the same

301   tissue tropism among all vertebrate hosts. As with other influenza viruses, we detected all novel

302   influenza viruses in respiratory tissues (i.e. gills and lungs) of their hosts: the only exception was cane

303   toad influenza-like for which we don't have tissue-associated metadata. The most robust support for the

304   conservation of influenza-like virus infection in respiratory tissues was in the analysis of the multi-

305   tissue transcriptome of the plateau tiger salamander [41]. Before and during metamorphosis,

306   salamanders rely on gills for respiration. During metamorphosis, there is a significant reduction in gill

307   length, and in post-metamorphosis they rely on lungs for respiration [41, 53]. Based on the expectation

308   that we would find these viruses in respiratory tissues, we found salamander influenza-like virus in the

309   gills of metamorphosising salamanders and the lungs following metamorphosis. This suggests that all

310   influenza viruses primarily infect the respiratory tissues, consistent with other influenza viruses [54].

311   To date, the only exception are IAV infections which infect the surface epithelium of the

312   gastrointestinal tract in wild birds [55], and gut-associated lymphoid tissue and the squamous

313   epithelium of the palatine tonsils in bats [56].

314

315   Finally, it is interesting to speculate on whether these influenza-like viruses are host specialist or

316   generalist viruses. Influenza A-D viruses have extensive host ranges, including an array of mammalian

317   species, particularly those associated with food production (i.e. cattle and swine), and in the case of

318   IAV, wild and food production associated birds (i.e. poultry) [4-7, 18-20]. Salamander influenza-like

319   virus also appears to be a multi-host virus, being found in four salamander species raised in laboratory

320   colonies, with the greatest abundance in the Mexican walking fish and plateau tiger salamander. While

321   these species have very different life-history strategies, and their ranges do not overlap in nature [57,

322   58], both are abundant in the pet trade and used in laboratory research. Thus, breeding facilities may be

323   an important source of these viruses. Whether this multi-host trait is correlated with the use of breeding

324 facilities in salamanders, a parallel for animal production systems and influenza A-D viruses is unclear.
325 Further research is certainly warranted to determine if a broad host range is a feature of all influenza
326 viruses, including those found in "lower" vertebrates.

327

5. Conclusions

329 By mining transcriptome data we identified five novel influenza-like viruses in fish and
330 amphibians. These data strongly suggest that influenza-like viruses can infect diverse classes of
331 vertebrates and that influenza viruses have been associated with vertebrates for perhaps their entire
332 evolutionary history. While the public health and economic ramifications are undoubtedly more
333 significant for mammalian influenza viruses, only by looking at other vertebrate classes and other
334 animal lineages will we fully understand the origins and evolution of this hugely important group of
335 viruses.

515

516
Figure 1. Genome architecture of the novel influenza-like viruses identified here. Genome architecture of IAV/IBV and ICV/IDV is shown on the left. For each novel virus, we provide the segment name and size. PB1, RNA-dependent RNA polymerase basic subunit 1; PB2, RNA-dependent RNA polymerase basic subunit 2; PA, RNA-dependent RNA polymerase acidic subunit; NP, nucleoprotein; HA, hemagglutinin; HEF, Hemagglutinin esterase; NA, neuraminidase; M, matrix; NS, non-structural protein. Detailed annotations for each virus are presented in Table S1-S6, Figure S1-S5.

524

525

526
Figure 2. The evolutionary history of vertebrate influenza-like viruses. Maximum likelihood tree of the PB1 segment, which encodes the RNA-dependent RNA polymerase, of various influenza-like viruses. Lineages corresponding to IAV, IBV, ICV, IDV are coloured blue, green, red and orange, respectively. Viruses identified in this study are denoted by a black circle and pictogram of the host species of the library. Wenling hagfish influenza virus is set as the outgroup as per Shi et al. 2018 [3]. The scale bar indicates the number of amino acid substitutions per site.
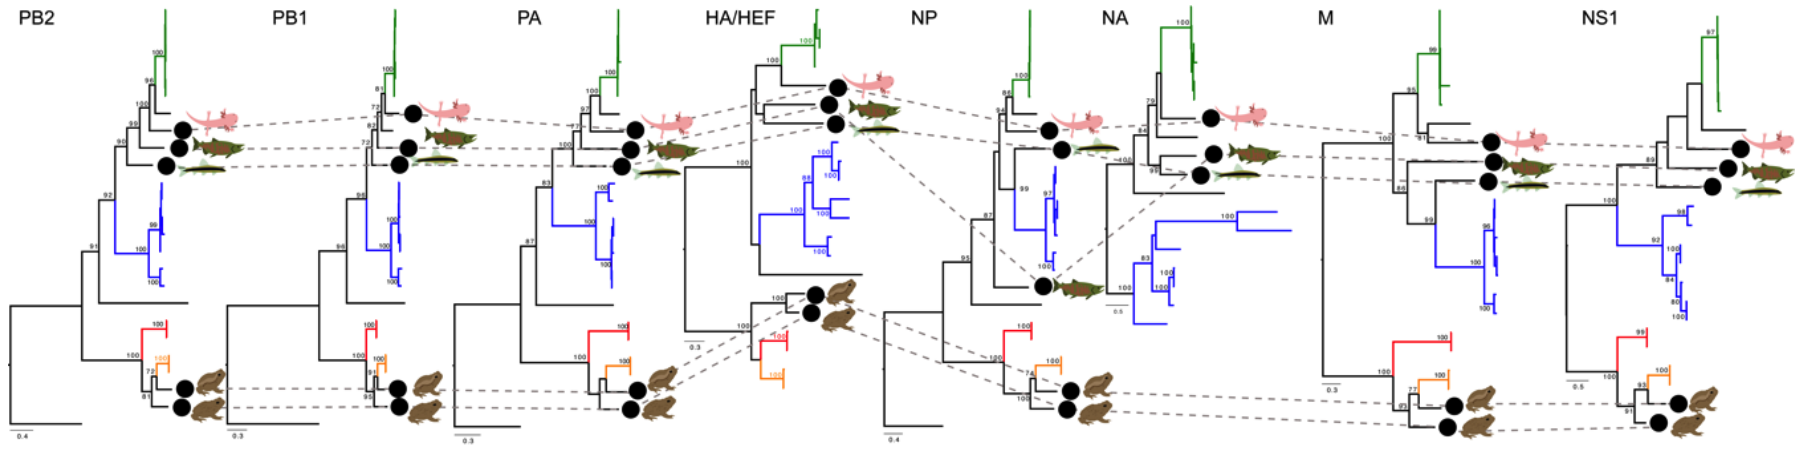

**Figure 3.** Phylogenetic trees for segments in cases where complete coding genomes could be recovered. Maximum likelihood trees for each segment ordered by (segment) size. Lineages are coloured by influenza virus, in which IAV, IBV, ICV, IDV are coloured blue, green, red and orange, respectively. Viruses identified in this study are denoted by a black circle and pictogram of the host species of the library. The phylogenetic position of each virus is traced across the trees with grey dashed lines. ICV, IDV, cane toad and chorus frog influenza-like viruses do not have an NA segment. The scale bar for each tree indicates the number of amino acid substitutions per site. Where possible the trees are rooted using the hagfish influenza virus (PB2, PB1, PA/P3, NP). The HA/HEF, M and NS trees were midpoint rooted.
Figure 4. Heat map of the abundance of Salamander influenza-like virus reads in the multi-tissue transcriptome library of developmental stages of Plateau tiger salamander [41]. Read abundance for this virus was highest in the gills of late metamorphosis salamanders, and lungs of postmetamorphasis salamander, strongly suggesting tropism for respiratory epithelium.

Table 1. Metadata for the novel influenza viruses identified in this study.

Virus name	Host	Tissue sampled	Reference	BLASTp output of predicted amino acid identity of polymerase genes			
				Segment	GenBank Accession	Coverage (%); Identity (%)	E-value
Salamander influenza-like virus	Mexican walking fish (*Ambystoma mexicanum*)	Various	[42-46]	PB1 Influenza B virus (B/California/24/2016)	QHI05420	100%; 75.70%	0.0
