Abstract

Human neurodegenerative *proteinopathies* are disorders associated with abnormal protein depositions in brain neurons. They include polyglutamine (polyQ) conditions such as Huntington's disease (HD) and α -synucleinopathies such as Parkinson's disease (PD). Overexpression of NMNAT/Nma1, an enzyme in the NAD⁺ biosynthetic salvage pathway, acts as a powerful suppressor of proteotoxicities in yeast, fly, and mouse models. Screens in yeast models of HD and PD in our lab allowed us to identify three additional enzymes of the same pathway that achieve similar protection against proteotoxic stress: Npt1, Pnc1, and Qns1. Here, we report that their ability to maintain proteostasis is independent of their catalytic activity. Furthermore, we show that, under proteotoxic stress, the four proteins are recruited as molecular chaperones with holdase and foldase activities. In yeast cells, the NAD⁺ salvage proteins act by preventing misfolding and, together with the Hsp90 chaperone, promoting the refolding of extended polyQ domains or α -synuclein. For Nma1, we demonstrate that its foldase activity maps to the C-terminal domain of the protein. The proteostasis activity of Nma1, Npt1, Pnc1, and Qns1 does not require cellular protein quality control systems such as the proteasome or autophagy. We conclude that the entire salvage NAD⁺ biosynthetic pathway links NAD⁺ metabolism and proteostasis and emerges as a target for therapeutics to combat age-associated neurodegenerative proteotoxicities. Our observations also illustrate the existence of an evolutionarily conserved strategy of repurposing or moonlighting housekeeping enzymes under stress conditions.

Keywords

Salvage NAD⁺ biosynthetic pathways, mitochondrial OXPHOS, polyglutamine, α -synuclein, Nma1, Npt1, Pnc1, Qns1, HSP90

INTRODUCTION

Metabolic, mitochondrial, and protein folding abnormalities are a common feature of neurodegeneration and aging. Despite substantial recent progress in understanding the molecular and cellular perturbations associated with these processes, many fundamental questions remain open. As a consequence, no current therapies target the underlying cellular pathologies of age-related neurodegenerative diseases.

Searching for suppressors of proteotoxicity in model organisms has proven valuable for understanding the pathways involved and their contribution to cellular homeostasis and death. The different suppression mechanisms reported to date can be classified into two categories: (i) those suppressing the harmful effects of misfolded/oligomerized proteins upon specific cellular pathways, and (ii) those avoiding the accumulation of misfolded proteins. In the first category, suppression of proteotoxicity is achieved by protecting the cells against some downstream events, such as cytoskeletal instability (1), impaired gene transcription (2), and accumulation of kynurenine pathway toxic metabolites (3). We and others have shown that protection is also achieved by stimulating mitochondrial biogenesis, integrity, and function (2, 4). Specifically, we reported that boosting mitochondrial biogenesis suppresses proteotoxicity in yeast and fly models of Huntington's disease (HD) (4, 5). In the second category, proteotoxicity can be reduced by enhancing the clearance pathways for the removal of cytoplasmic aggregate-prone proteins through increasing autophagy (6), activating the ubiquitin-proteasome system (7) or the endoplasmic reticulum-associated degradation pathway (8). Toxicity is also ameliorated by modulating the chaperone systems involved in protein refolding, aggregation, and disaggregation (9-15).

In addition to dedicated heat-shock proteins, an unexpected inclusion into the class of molecular chaperones is NMNAT or nicotinamide mononucleotide (NMN) adenylyltransferase. This conserved enzyme is rate-limiting in the human salvage NAD⁺ biosynthetic pathway, in which it reversibly catalyzes the synthesis of NAD⁺ from ATP and NMN. Three NMNAT proteins have been identified in mammals with reported distinct tissue and cellular distribution: NMNAT-1 in the nucleus, NMNAT-2 in the cytoplasm, and NMNAT-3 in the mitochondria (16). NMNAT is essential for maintaining physiological neuronal integrity, and when overexpressed, protects against several

neurodegenerative conditions in fly and mouse models, including Wallerian degeneration (17, 18), exotoxicity (19), and neurodegeneration induced by spinocerebellar ataxia 1 (18, 20), Tau (21, 22), or huntingtin (5, 23). It has been hypothesized that increasing NAD⁺ concentration via NMNAT and the subsequent activation of the histone deacetylase SIRT1 plays a role in the protective mechanism (24, 25). However, although it remains controversial whether the neuroprotective effect of NMNAT is mediated by increased NAD⁺ levels or a non-catalytic role of NMNAT (18, 26), recent evidence indicates that it could be a contribution of both. It is known that NAD⁺ levels decline with age in mice and humans (27, 28), and treatment with NAD⁺ precursors can significantly improve health by supporting both metabolism and signaling pathways to NAD⁺ sensors such as sirtuin deacetylases and poly-ADP-ribose polymerases (PARPs) (29, 30). However, recent studies in mammalian cellular models of tauopathies (which includes Alzheimer's disease (AD)) have shown that NMNAT can act as a co-chaperone of the heat shock protein 90 (HSP90) to mediate proteostasis, independently of NAD⁺ levels (31). Moreover, structural approaches have revealed that NMNAT uses its enzymatic pocket to specifically bind the phosphorylated sites of pTau, in competition with the enzymatic substrates of NMNAT (32). Furthermore, the capacity of NMNAT to refold misfolded proteins requires a unique C-terminal ATP site, activated in the presence of HSP90 (31).

We and others have screened for suppressors of proteotoxicity using yeast models of polyglutamine (polyQ) disorders such as HD and α -synucleinopathies such as Parkinson's disease (PD). These models recapitulate the critical events preceding cell death that manifest in human conditions, such as protein misfolding and aggregation and mitochondrial dysfunction (4, 5, 8, 33-35). Using these models, we have demonstrated that the yeast homologs of NMNAT, Nma1 and Nma2, act as powerful suppressors of proteotoxicities (35). Furthermore, we revealed that three other enzymes in the salvage NAD⁺ biosynthetic pathway have a similar capacity (35). These are NPT1 (nicotinate-nicotinamide phosphoribosyltransferase), Pnc1 (nicotinamidase), and Qns1 (NAD⁺ synthase). We reported that the suppression mechanism is independent of NAD⁺ levels and sirtuins and does not necessarily require mitochondria-related functions (5, 35).

Here, we present data that strongly support the hypothesis that salvage NAD⁺ biosynthetic proteins Nma1/2, Npt1, Pnc1, and Qns1, whose capacity to protect against proteotoxicity is independent of their catalytic activity, have intrinsic chaperone activity. We demonstrate that these proteins have holdase and foldase activities, which rely on different domains of the proteins. Deleting the C-terminal domain of Nma1 markedly attenuates the Nma1 capacity to suppress 103Q- or α -synuclein-induced proteotoxicity. Furthermore, deleting the HSP90 chaperones Hsc82/Hsp82 abrogates Nma1-supported protection against 103Q, although it does not limit its ability to attenuate α -synuclein-induced toxicity. In vivo and in vitro chaperone assays indicate that NMA1 could act as a chaperone by itself and also as an Hsp90 co-chaperone, depending on the misfolding substrate. The mechanism by which Nma1/2, Npt1, Pnc1, or Qns1 clear misfolded/oligomerized proteins is independent of proteasomal degradation and autophagy. These observations further indicate that the NAD⁺ salvage proteins act as chaperones to prevent misfolding and assist in refolding misfolded polyQ domains and α -synuclein. Our studies identify new therapeutic targets to treat patients suffering from neurodegenerative proteotoxicities such as HD and PD.

RESULTS AND DISCUSSION

Catalytically inactive forms of NAD⁺ salvage pathway proteins retain protective activity against 103Q and α -synuclein toxicity in yeast

We and others have previously described that heterologous expression in the yeast *Saccharomyces cerevisiae* of either human mutant PolyQ domains (103Q) or α -synuclein fused to green fluorescent protein (GFP) under the control of a *GAL1* promoter induced by growth in media containing galactose (YPGAL) results in significant growth defects (5, 33-36). We have reported that in yeast models of HD and PD, overexpression of hemagglutinin (HA)-tagged versions of the *NMNAT* yeast homologs, *NMA1* and *NMA2*, or other genes in the NAD⁺ biosynthetic salvage pathway, including *QNS1*, *NPT1*, and *PNC1* (**Fig 1A and 1B**) suppresses 103Q- (**Fig 1C**) and α -Syn-induced cytotoxicity (**Supplemental Fig S1**), through a mechanism that involves extensive clearance of non-native proteins (**Fig 1D**).

Importantly, we have previously demonstrated that the suppression mechanism does not require the presence of a functional NAD⁺ biosynthesis salvage pathway because the deletion of one of the enzymes (*NPT1*), which lowered cellular NAD⁺ levels by ~2.2 fold, did not affect the suppression of 103Q-induced toxicity by *NMA1/2* or other components of the pathway (35). To further discern the properties of these salvage NAD⁺ biosynthetic proteins required to confer protection against proteotoxicity, we mutated the catalytic core of each protein by targeting previously identified relevant residues. The yeast *Nma1*-H181A (human H24A) (26, 37), *Npt1*-H232A (human H247A) (38), and *Pnc1*-C167A mutations affect the catalytic center of each enzyme and eliminate their function (39). *Qns1* has two functional domains; mutants in the glutaminase domain (C175A) or the synthetase allele D365A are non-functional *in vivo* (40). Catalytic mutants retain less than 5% of WT activity as reported (26, 37-40) and measured in purified recombinant proteins (see below). When the proteins were expressed in the HD and PD yeast models, the catalytically active and inactive variants of each protein accumulated at similar levels (**Fig 1B**). No difference was observed in the capacity of the catalytically active and inactive variants to suppress the growth defect induced by 103Q (**Fig 1C**) or α -Syn (**supplemental Fig S1**).

Catalytically active and inactive variants showed a similar ability to promote the clearance of non-native proteins (**Fig 1D** and **2**). Using fluorescence microscopy, we followed GFP-tagged mutant PolyQ expression and oligomerization in strains overexpressing wild-type or mutant variants of *NMA1*, *NMA2*, *PNC1*, *QNS1*, or carrying an empty vector (YE_p352). After 1 h of protein expression induction in galactose medium, the 103Q-GFP signal was primarily diffuse in the cytoplasm, forming a few small aggregates. The number and size of the aggregates progressed with time, and after only 3 h of induction, the protein formed large aggregates (**Fig 2D**). Overexpression of catalytically active or inactive variants of *NMA1*, *NPT1*, *PNC*, and *QNS1* was able to attenuate the fluorescence signal of both soluble and aggregated mutant PolyQ as well as the number of aggregates (**Fig 2D**). Approximately 75% of the 103Q cells contained at least one 103Q-GFP punctuate focus after 3 h of 103Q-GFP expression. This value was reduced to ~10–15% in cells overexpressing wild-type or mutant *NMA1* or *PNC1* (**Fig 2D**). Overexpression of *NMA1*, *NPT1*, *PNC1*, or *QNS1* did

not affect the level of expression of 103Q, as we have previously reported (35), suggesting that they prevent 103Q misfolding or increase its degradation. To assess the effect of catalytically inactive NAD⁺ proteins on the kinetics of 103Q oligomerization, we performed immunoblot analysis of protein extracts from cells expressing 103Q alone or in combination with the suppressor genes (**Fig 2A**). In agreement with our fluorescence microscope analyses, we observed a time-dependent protein aggregation pattern, as previously reported (33, 35). 103Q strain, after 2 h of expression, 103Q-GFP proteins were found both at their expected size and forming SDS-insoluble oligomers (**Fig 2B**). At later time points, 103Q-GFP was detected only as part of SDS-insoluble large oligomers trapped in the higher portions of the stacking gel (**Fig 2B**). As controls, 25Q accumulated in a soluble state (**Fig 2B**), and the deletion of *hsp104* largely prevented 103Q oligomerization (**Fig 2C**), as reported (41). Treatment of 103Q cells with the NAD⁺ precursor nicotinamide did not change the pattern of 103Q oligomerization. This result is consistent with the observation that boosting NAD⁺ biosynthesis with NAD⁺ precursors (nicotinamide, nicotinic acid or nicotinamide riboside) does not ameliorate 103Q- or α -Syn-induced proteotoxicity or the protection exerted by overexpression of salvage NAD⁺ biosynthetic proteins (**supplemental Fig S2**). The 103Q oligomerization pattern changed dramatically when catalytically active or inactive forms of NAD⁺ biosynthetic proteins were overexpressed in 103Q cells. In these cell lines, we detected lower amounts of SDS-insoluble large oligomers at several time points, accompanied by increased signal corresponding to either degradation products or intermediate states of protein oligomerization (**Fig 2E-H**). Note that the overexpressed proteins, which are ZZ-tagged, are also detected in these immunoblots.

The data presented in this section allowed us to conclude that the ability of NAD⁺ salvage proteins to protect against proteotoxicity in yeast is independent of their catalytic activity.

NAD⁺ salvage proteins function as chaperones with both holdase and foldase activities.

To assess if NAD⁺ salvage proteins can directly bind to substrates and reduce protein aggregation in the absence of other proteins, we performed a cell-free chaperone

activity assay based on the fact that, under thermal stress, citrate synthase (CS) aggregates leading to increased optical absorbance (31). In this assay, the use of purified candidate chaperone proteins allows assessing whether they can exert holdase activity to maintain CS in thermostable conformation in the absence of other chaperones, co-chaperones, or ATP. For this purpose, we expressed in *E. coli* and purified 6xHis-tagged recombinant catalytically active and inactive Nma1, Npt1, Pnc1, and Qns1 proteins (**Fig 3A**). The four wild-type yeast proteins were previously expressed in *E. coli*, purified, and found to be catalytically active (38, 40, 42-44). We have measured the activity of wild-type and mutant Nma1 and Pnc1 using spectrophotometric coupled enzyme assays (39, 45) to show that the mutant proteins are inactive (activity undetected/lower than 1% of wild-type). In the CS-aggregation assay, all the proteins, catalytically active or inactive, but not lysozyme, used as a negative control, prevented thermally induced CS aggregation in a dose-dependent manner (**Fig 3B**).

To further assess the chaperone activity of yeast NAD⁺ salvage proteins, we conducted a cell-based luciferase assay (31), which determines the ability of candidate proteins in preventing luciferase misfolding or facilitating luciferase refolding in intact cells with cellular protein repair machinery. In this assay, treatment with cycloheximide to block protein synthesis, followed by heat denaturation (at 42°C for 15 min), renders the endogenous chaperone machinery incapable of preventing luciferase aggregation and refolding (**Fig 3C**). This allows for direct measurement of the chaperone activity of the introduced test protein by its ability to prevent luciferase from undergoing heat shock-induced denaturation (holdase activity) and to promote its proper refolding (foldase activity) during recovery (at 37°C for 3 h). We found that wild-type and catalytically inactive mutants of all NAD⁺ salvage proteins have both holdase and foldase activity comparable to that of HSP70 (**Fig 3C**).

The proteasome, autophagy, or yeast chaperones proteins Hsp26, Hsp42, or Hsp70 (Ssa1) are not required for protection by NAD⁺ salvage pathway proteins

The salvage NAD⁺ biosynthetic proteins could protect against cytotoxicity either directly or indirectly (46). So far, it has been shown that the Nma1/2 homolog NMNAT directly

interacts with phosphorylated Tau and promotes the ubiquitination and clearance of toxic Tau species in the nervous system in a *Drosophila* model of tauopathy (21), and that NMNAT significantly mitigates mutant huntingtin (138Q)-induced neurodegeneration by reducing mutant huntingtin aggregation through promoting autophagic clearance (23). To reveal the potential protective pathways involved in the NAD⁺ biosynthetic protein-mediated clearance of mutant polyQ and α -Syn oligomers and aggregates in yeast cells, we tested whether the suppressor proteins could promote the unfolded protein response (UPR) or enhance autophagy, pathways that are affected by and mediate proteotoxic stress (8, 47-49). We observed that protection could not be abolished or diminished by inhibiting the proteasome with 10 μ M or 50 μ M MG132 (**supplemental Fig S3**), indicating that the proteasome is not required for protection by NAD⁺ salvage pathway proteins. We further established that blocking autophagy in yeast by introducing a $\Delta atg32$ mutation or blocking mitophagy by introducing a $\Delta atg12$ mutation did not modify the efficacy of proteotoxicity suppression by NAD⁺ salvage pathway proteins (**supplemental Fig S4 and S5**).

The salvage NAD⁺ biosynthetic proteins could also protect by enhancing the function of other chaperones (e.g. small Hsps or Hsp70 families) known to modify the folding, aggregation, and toxicity of mutant polyQ in yeast (10, 50-53). However, the absence of Hsp26 or Hsp42, known to sequester misfolding proteins in near-native conformation for cellular protection and efficient refolding (54) and to cooperate with Hsp140 and the Hsp70 chaperone Ssa1 in protein disaggregation (10), or deletion of *ssa1*, did not affect the ability of NAD⁺ salvage pathway proteins to protect against proteotoxicity (**supplemental Fig S6 and S7**). The lack of effect of Ssa1 could be explained by the fact that the major cytosolic Hsp70 family in yeast, the Hsp70-Ssa, consists of four members of Ssa (constitutively expressed Ssa1-2 and stress-induced Ssa3-4), which are functionally redundant to some degree as the expression of at least one family member is essential for growth (55).

These data indicate that the NAD⁺ proteins may confer protection through a pathway that does not require Hsp26, Hsp42, or Ssa1. Alternatively, when overexpressed, the protective proteins may substitute for the roles that Hsp26, Hsp42, or Ssa1 usually play.

HSP90-family chaperones are essential for the protective activity of salvage NAD⁺ proteins against proteotoxicity

In the yeast *S. cerevisiae*, there are two HSP90 exists as two isoforms, encoded by the genes *HSC82* and *HSP82* (56). The deletion of *Hsc82* in the 103Q background did not prevent protection by NAD⁺ proteins but slightly attenuated their efficacy (**supplemental Fig S8**). The double deletion $\Delta hsp82\Delta hsc82$ did not affect cell survival in YPD media. Still, it enhanced 103Q toxicity in inducing YPGal media and completely abolished the capacity of salvage NAD⁺ biosynthetic proteins to suppress proteotoxicity (**Fig 4**). These results agree with a recent study in mammalian cellular models of tauopathies showing that NMNAT2 can act as an HSP90 co-chaperone to mediate proteostasis, independently of NAD⁺ levels (31). Unexpectedly, however, the double deletion $\Delta hsp82\Delta hsc82$ did not interfere with the suppression of α -Syn-induced toxicity, suggesting that the HSP90 co-chaperone activity of salvage NAD⁺ proteins does not operate for all substrates.

The C-terminus of yeast protein Nma1 is essential for protective activity

To elucidate whether the catalytic and chaperone functions of NAD⁺ salvage pathway proteins occur in distinct domains of the protein is a very relevant question. We have shown that mutations in the catalytic core of each enzyme block their activity but not their capacity to act as molecular chaperones and protect against proteotoxicity (**Fig 1-3**). However, structural approaches have revealed that human NMNAT2 uses its enzymatic pocket to specifically bind the phosphorylated sites of pTau, in competition with the enzymatic substrates of NMNAT (32). Here, we have focused on Nma1 to perform structure-function relationship studies to identify potential domains required for its chaperone activity while not affecting its catalytic activity. The amino acids we chose to mutate were selected based on human NMNATs studies (57-59) and resulted in four Nma1 variants that we called H3, I-H, NI, and Δ ct (**Fig 5A and supplemental Fig S9**). Nma1/NMNAT has a structural similarity with *E. coli* chaperones UspA and Hsp100 (57). NMNAT α -Helix 3 (H3) has the best overlapping score and includes Nma1 amino acids 252-TAKVLDH-259 (57). In the Nma1 H3 mutant, the conserved amino acids VL

were changed to EE. Nma1 α -Helix 4 contains amino acids 220-RTGSDVRSFL-229 and occupies an internal position in the hexameric NMNAT1 structure (I-H). In the Nma1 I-H mutant, the sequence was changed to 220-ATGSAVRSFA-229. In the Nma1 NI mutant, two conserved residues, Nma1 341-NI-342, located in a hotspot region for human NMNAT1 mutations associated with Leber congenital amaurosis 9 (LCA9) who retain a substantial catalytic activity (58) were changed to -AA. Finally, because the capacity of NMNAT2 to refold misfolded proteins requires a unique C-terminal ATP site, activated in the presence of HSP90 (31), we created a Nma1 Δ ct variant missing aa 375-394 from the Nma1 401aa wild-type protein.

Yeast expressing each of these mutated Nma1 variants were then screened for their ability to protect against 103Q cytotoxicity. The H3, I-H, and NI Nma1 mutants were found protective, albeit that the efficacy of the H3 variant was slightly attenuated (**supplemental Fig S9**). On the contrary, protection against both 103Q and α -Syn-induced proteotoxicity by the Nma1 Δ ct variant was largely precluded (**Fig 5D**). The Nma1 Δ ct protein retains catalytic activity as it was able to restore the growth of a double mutant $\Delta nma1\Delta nma2$ strain in media lacking exogenous nicotinamide riboside (NR) (**Fig 5B**), and its overexpression in wild-type cells does not induce any gross dominant-negative effect in cell growth (**Fig 5C**). Purified recombinant Nma1 Δ ct (**supplemental Fig S10**) prevented heat-induced CS aggregation *in vitro*, suggesting retention of its holdase activity (**Fig 5E**). In 103Q yeast cells, we further confirmed that the Nma1 Δ ct protein was successfully and stably expressed (**Fig 5F**). Notably, upon 6h of 103Q induction in galactose medium, Nma1 showed a pattern of oligomerization and degradation similar to 103Q, suggesting an interaction. On the contrary, Nma1- Δ ct was stably expressed and did not follow that pattern (**Fig 5F**), which could result from a failure to bind 103Q.

The attenuation of the protection capacity by Nma1 Δ ct protein most probably results from a loss of its foldase activity. In *Drosophila* NMNAT (18) or human NMNAT2 (31), the deletion of the entire C-terminus of the proteins (aa 200-308) suppresses their foldase activity. A selective loss of foldase activity by the Nma1 Δ ct protein could be related to the nearby presence of a highly conserved ATP binding site 354-SSTKVR-

359 in Nma1 (31)(**Fig 5A**), whose folding could be altered. ATP binding is known to enhance the chaperone activity of the large heat shock proteins by suppressing their unfolding and oligomerization (60, 61). The loss of foldase activity has also been observed in NMNAT2 by deleting only the ATP binding motif (aa 269-SSTKVR-274), which also precludes the recruitment of HSP90 chaperones (31).

CONCLUSION

Accumulation of misfolded, oligomerized, and aggregated proteins is a hallmark of age-associated neurodegenerative disorders in humans. Several proteins of unrelated sequences, normally soluble, such as polyglutamine (polyQ) expanded huntingtin in HD, α -Syn in PD, and Tau and A β in AD, form neurotoxic amyloids that are morphologically similar and have a core structure of characteristic cross β -conformation (62-67). As the formation of protein oligomers and aggregates involve conformational changes in proteins, various chaperones have been extensively studied for their role in the process and as therapeutic targets, including the small heat shock proteins Hsp26 and Hsp42, as well as Hsp70, Hsp90, and Hsp100 family of proteins (9, 10, 50, 68-71). In addition to heat shock proteins, the salvage NAD⁺ enzyme NMNAT has been shown to act as a stress-response protein that works as a chaperone for neuronal maintenance and protection in fly and mouse models of neurodegenerative disorders (18, 31, 32, 57). Using yeast models of HD and PD, we have previously shown that in addition to the NMNAT homologs Nma1 and Nma2, three additional salvage NAD⁺ biosynthetic proteins, namely Npt1, Pnc1, and Qns1, suppress 103Q and α -Syn-induced proteotoxicity by promoting the clearance of misfolded/oligomerized proteins (35). In this manuscript, we show that (i) the anti-proteotoxicity role of Nma1, Npt1, Pnc1, and Qns1 is independent of their enzymatic activity in the salvage NAD⁺ biosynthetic pathway, (ii) they act as chaperones with holdase and foldase activities, and (iii) they can cooperate with HSP90-family proteins to sustain their foldase ability. A model of proteotoxicity suppression by salvage NAD⁺ biosynthetic proteins is presented in **Figure 6**.

In addition to their primary function of preventing protein aggregation, the role of chaperones in directing terminally misfolded proteins to either proteasome or autophagy is well established (72). Our data indicate that the yeast salvage NAD⁺ biosynthetic

proteins retain their protection capacity independently of the cellular protein degradation machinery. This contrasts with previous observations regarding the role of NMNAT made in fly models of tauopathy and HD in which the proteasome and autophagy are activated, respectively, when NMNAT is overexpressed (21, 23). Our data suggest that if Nma1, Npt1, Pnc1, and Qns1 were more efficient in preventing misfolding and supporting refolding of 103Q or α -Syn in the yeast than in the fly models (e.g., if the overexpression levels are higher), the cellular protein quality control systems could be differently recruited in the two model organisms.

The role of NMNAT proteins as neuroprotective chaperones independent of NAD⁺ synthesis has been controversial mainly because studies using models of Wallerian axonal degeneration proposed that NMNAT overexpression maintains axonal integrity by enhancing NAD⁺ synthesis and preventing the accumulation of the precursor NMN (73-75). However, it was later observed that NAD⁺ depletion upon axonal injury resulted from fast consumption by the prodegenerative SARM1 enzyme, which is blocked by NMNAT1 without enhancing NAD⁺ synthesis (76). However, the NAD⁺ biosynthetic function of NMNATs can be relevant in a context-dependent manner. For example, the deletion of NMNAT2 in cortical neurons renders them sensitive to both proteotoxic stress and excitotoxicity triggered by sustained neuronal depolarization (31). Still, whereas the chaperone activity of NMNAT2 is required to prevent proteotoxicity, its enzymatic function protects against excitotoxicity (31).

On the other hand, NAD⁺ levels steadily decline with age in mouse and humans (27, 28), resulting in altered metabolism and increased disease susceptibility (77). Restoration of NAD⁺ levels in old or diseased animals can promote health and extend lifespan (77). Treatment with NAD⁺ precursors can significantly improve health by supporting both metabolism and signaling pathways to NAD⁺ sensors such as sirtuin deacetylases and poly-ADP-ribose polymerases (PARPs) (29, 30). Supplementation with NAD⁺ precursors could, in principle, add to the neuroprotective role of salvage NAD⁺ biosynthetic proteins acting as chaperones against PolyQ or α -Syn-induced toxicity. However, in our yeast models, NA, Nam, or NR did not affect polyQ toxicity or suppression by Nma1, Npt1, Pnc1, or Qns1. Whereas the decline of NAD⁺ levels with age is significantly contributed by its degradation by the NADase CD38 (27, 28), it

remains to be determined whether it is also contributed by the repurposing of NAD⁺ salvage enzymes as chaperones to combat age-associated disruption of proteostasis.

It also remains to be understood how the four salvage NAD⁺ biosynthetic proteins switch between their two functional modes, catalytic in NAD⁺ synthesis vs. cytoprotective chaperones. However, recent data have shed light on the structural determinants of NMNAT moonlighting roles. Structural studies of NMNAT bound to pTau have shown that NMNAT is distinct from canonical molecular chaperones (32). NMNAT adopts its enzymatic pocket to specifically bind the phosphorylated sites of pTau, without inducing large conformational changes and can be competed out with the NMNAT enzymatic substrates (NMN and ATP) (32). Because NMNAT uses the same domain, even a shared pocket, for the binding of ATP and pTau, ATP hydrolysis is not required for the chaperone function of NMNAT. Additionally, NMNAT functions as an Hsp90 co-chaperone for the specific recognition of pTau over Tau (31, 32). Our data indicate that yeast Nma1 might also recruit the HSP90 chaperones Hsc82/Hsp82 via its C-terminal domain, since both are essential for the Nma1-driven attenuation of 103Q-induced toxicity.

In conclusion, the entire salvage NAD⁺ biosynthetic pathway links NAD⁺ metabolism and proteostasis and is emerging as a potential critical target for therapeutics to combat age-associated neurodegenerative proteotoxicities.

MATERIALS AND METHODS

Yeast strains and media

The *S. cerevisiae* strains used were the wild-type W303-1A (*MATa ade2-1 his3-1,15 leu2-3,112 trp1-1 ura3-1*) and the previously reported isogenic 25Q, 103Q, and α -Syn strains (35), and the previously reported W303-1A strains containing chromosomally integrated *N*-terminus of human huntingtin with 103Q or wild-type α -synuclein fused to GFP expressed under the control of the *Ga1* promoter (33, 35).

The plasmids overexpressing *NMA1*, *NMA2*, *NPT1*, *PNC1*, *QNS1*, and *TNA1* were obtained from Open Biosystems (Thermo Scientific, Lafayette, CO, USA), and transformed into the indicated strains. *ATG12*, *ATG32*, *SSA1*, *HSP26*, *HSP42*, *HSP82*, and *HSC82* were deleted by replacing the open reading frame with

a *KANMAX4* cassette. To generate a double deletion mutant $\Delta hsc82\Delta hsp82$, the HSP82 open reading frame was replaced with a HIS5 cassette in the $\Delta hsc82$ strains. Catalytic mutant variants of *NMA1*, *NPT1*, *PNC1*, and *QNS1*, and all mutant forms of *NMA1* were created using a Q5 site-directed mutagenesis kit (New England Biolabs, Ipswich, MA, USA).

The following complete YP (1% yeast extract, 2% peptone) and minimum WO (0.67% nitrogen base w/o amino acids) media were used routinely to grow yeast: YPD (+2% glucose) YPGal (+2% galactose), WOD (+2% glucose) and WOEG (+2% ethanol, 2% glycerol). The following chemicals were used to supplement solid YPGal plates: 10 mM nicotinamide, 10 mM nicotinic acid, and 10 μ M or 50 μ M MG132 (all from Sigma-Aldrich Corp., St Louis, MO, USA), and 10mM nicotinamide riboside (MedKoo Biosciences) at concentrations reported previously (78, 79).

Preparation of Cell Extracts for Protein Aggregation Analysis

Cell extracts were prepared according to the protocol outlined in (Ocampo et al., 2013). Briefly, fifty-milliliter cultures ($OD^{600} = 0.125$) of strains expressing either polyQ-GFP or α -synuclein-GFP together or not with overexpression of the salvage NAD⁺ biosynthetic proteins *Nma1*, *Npt1*, *Pnc1* or *Qns1*, were induced for 2, 4, 6, 8 and 24 h in complete media containing 2% galactose. Cells were harvested by centrifugation at 1100× *g* for 5 min and washed once with 1.2 M sorbitol. The cell wall was digested with 1 mg/ml zymolyase for 30 min, and the spheroplasts were re-suspended in lysis buffer (40 mM 4-(2-hydroxyethyl)-1-piperazineethanesulfonic acid buffer pH 7.4, 50 mM KCl, 1% Triton X-100, 0.3 mg/ml dithiothreitol, 5 mM EDTA and 0.5 mM phenylmethylsulfonyl fluoride). Samples were collected following gravity sedimentation of cell debris for 1 h on ice. The samples (T) were centrifuged 10 min at 800*g* at 4°C. The supernatant (S) was collected, and the pellet (P) was washed once in lysis buffer and then resuspended in the same volume of lysis buffer. Protein concentration was quantified by Folin method. Equal amount of protein was resuspended in Laemmli buffer [1% SDS, 0.1% (v/v) glycerol, 0.01% β -mercaptoethanol and 50 mM Tris-HCl pH 6.8) for immunoblot analysis.

Recombinant Protein Purification

Yeast *NMA1*, *NPT1*, *PNC1*, and *QNS1* genes were cloned into the pET-41b(+) expression vector and then transformed into BL21 or BL21-star chemically competent *E. coli* cells (New England Biolabs, Ipswich, MA, USA). *E. coli* containing the expression plasmids were grown in complete LB broth (Thermo-Fisher Scientific, Waltham, MA, USA) at 30°C with shaking until cell cultures reached an OD 600 of approximately 0.5, at which point the temperature was lowered to 16°C and cultures were allowed to grow until reaching an OD 600 of approximately 0.7. Yeast recombinant protein expression was then induced by the addition of isopropyl β -D-1-thiogalactopyranoside (IPTG) (MilliporeSigma, Burlington, MA, USA) to the final concentration of 0.1mM, after which cultures were grown for an additional 12 to 72 hours at 16°C. Cells were collected and resuspended in a solution containing 50 mM sodium phosphate, 300 mM NaCl, yeast protease inhibitor cocktail (MilliporeSigma, Burlington, MA, USA), 1mM PMSF, 30 μ g/ml benzamidine, and 10 μ g/ml DNase I and lysed at 12,000 psi using a French Press. The resulting lysate was clarified by centrifugation. Recombinant proteins were extracted from this crude lysate by affinity purification with TALON Affinity Resin (Takara Bio USA, Mountain View, CA, USA), washed with a solution containing 50 mM sodium phosphate, 300 mM NaCl, and 50 mM imidazole, and then eluted with a solution containing 50 mM sodium phosphate, 300 mM NaCl, and 200 mM imidazole. Buffer exchange was performed by running extracts through Sephadex resin columns (GE Healthcare, Chicago, IL, USA) and eluting with HEPES buffer (pH 7.4). Extracts were tested for purity by SDS page gel and Coomassie blue staining.

A batch of Nma1 and Nma1 Δ ct proteins were purified by GenScript.

Citrate synthase aggregation assay

Citrate synthase (CS) aggregation measurements were performed as described previously (18). Substrate CS (Sigma, St. Louis, MO) was desalted and mixed with either egg white lysozyme (Sigma), purified catalytically active or inactive Nma1, Npt1, Pnc1 or Qns1 (purified in house), Nma1 and Nma1 Δ ct (purified by GenScript (Piscataway, NJ) at varying concentrations (CS/protein: 1:0, 1:0.5, 1:1, 1:2, and 1:4) in HEPES (pH 7.4) buffer for 30 min. Aggregation of denatured CS was initiated at 43°C

and was monitored as Raleigh scattering absorbance at 360 nm as a function of time. A FluoStar Optima plate reader (BMG Labtech, Cary, NC) was used for absorbance measurements. The relative chaperone activity of NMNAT was calculated as the scattering of CS aggregates with time versus NMNAT concentration.

Luciferase Aggregation Assays

The luciferase aggregation assay was performed as described (31, 80), with a few modifications. HEK293T cells were transfected with pCMV-cytLuciferase and one of the following plasmids: pCMV6-*HSP70*, pCMV6-*NMA1*, pCMV6-*NPT1*, pCMV6-*PNC1*, pCMV6-*QNS1*, pCMV6-*NMA1* Δ *ct*, empty pCMV6, using Lipofectamine (Invitrogen, Grand Island, NY). 48 h post-transfection, the cells were treated with the protein synthesis inhibitor cycloheximide (50 μ g/mL for 3 h). Whereas one aliquot of cells was lysed immediately with luciferase lysis buffer (Promega, Madison, WI), two additional similar aliquots (second and third) were heat-shocked at 42°C for 15 min (which induced efficient unfolding of luciferase without killing the cells). The second aliquot of cells was lysed immediately after heat shock, and the third aliquot was allowed to recover at 37°C for 3 h. Luciferase activity was measured with the Luciferase Assay System (Promega).

Fluorescence microscopy

Wide-field fluorescence microscopy was performed to detect polyQ-GFP expression. We used an Olympus fluorescence BX61 microscope equipped with Nomarski differential interference contrast (DIC) optics, a Uplan Apo 100 \times objective (NA 1.35), a Roper CoolSnap HQ camera, and Sutter Lambda10-2 excitation and emission filter wheels, and a 175-watt Xenon remote source with liquid light guide. Images were acquired using SlideBook 4.01 (Intelligent Imaging Innovations, Denver, CO, USA). All experiments were performed at least in triplicate, with a minimum of 150 cells per sample.

Immunoprecipitation assays

For Nma1-Hsc82 interaction analysis, cells expressing Nma1-HA were converted to spheroplasts by incubation in zymolyase buffer (1.2 M sorbitol, 0.4 mg/ml zymolyase, 20

mM K₃PO₄ pH 7.4) for 30 min at 30°C, pelleted by centrifugation at 6,000g for 10 min, and then solubilized in extraction buffer (50 mM Tris-HCl, pH 7.5, 100 mM KCl, 20 mM MgCl₂, 1% digitonin, 10% glycerol, 1 mM PMSF, 1× EDTA-free protease inhibitor cocktail) and incubated for 30 min at 4°C. The lysates were cleared by centrifugation at 15,000 g for 15 min at 4°C. The lysate was incubated with 50 µl of washed recombinant protein A agarose beads (control) or anti-HA affinity gel beads at 4°C for 4 h with gentle rotation. The supernatant containing unbound material was subsequently collected, and the beads were washed four times with wash buffer (50 mM Tris-HCl, pH 7.5, 100 mM KCl, 20 mM MgCl₂, 10% glycerol, 1 mM PMSF, 1× EDTA-protease inhibitor cocktail). The bound proteins were eluted using 1× Laemmli buffer containing 300 mM DTT and incubated at 95°C for 5 min. The different fractions were analyzed by immunoblotting using antibodies against HA, and Hsc82.

Miscellaneous procedures

Standard procedures were used to prepare and ligate DNA fragments, transform and recover plasmid DNA from *E. coli*, and transform yeast. Western blots were treated with antibodies against the appropriate proteins followed by a second reaction with anti-mouse or anti-rabbit IgG conjugated to horseradish peroxidase (Sigma, St. Louis, MO, USA). The SuperSignal West Pico and Femto substrate kits (Pierce, Rockford, IL, USA) were used for the final detection.

Statistical analysis

All experiments were performed at least in triplicate. Data are presented as means ± SD or SEM, as appropriate, of absolute values or percent of control. Values were compared by t-Student test or One-Way ANOVA, as noted in the figure legends. $P < 0.05$ was considered significant. Statistical analysis of citrate synthase aggregation assay measurements was performed with Graphpad Prism 6 software.

Supplementary Material

Supplementary data includes 10 Figures.

FUNDING

This work was supported by a Research Grant from The Army Research Office (ARO) # W911NF-16-1-0311 (to AB), a Merit Award from the Veterans Administration (VA) Biomedical Laboratory Research and Development 1I01BX003303-01 (to AB), and an HD Human Biology Project Fellowship from the Huntington's Disease Society of America (HDSA) # GR009606 (to AR).

ACKNOWLEDGEMENTS

We thank Yi Zhu and Dr. Grace Zhai for sharing reagents and protocols for CS aggregation studies, and Julia Denissova for technical assistance. We thank Dr. Flavia Fontanesi for critical reading of the manuscript.

AUTHORS CONTRIBUTIONS

AB designed the project; MP finished the experimental work, purified some recombinant proteins, obtained some data with the polyQ models and all data with the α -Syn models; AR started the experimental work, purified most recombinant proteins and obtained data with the polyQ models; VB performed the protein aggregation assays and some microscopy studies; EN developed the luciferase assays; MP, AR and AB wrote the manuscript.

Conflict of Interest statement. None declared.

FIGURES AND FIGURE LEGENDS

Figure 1

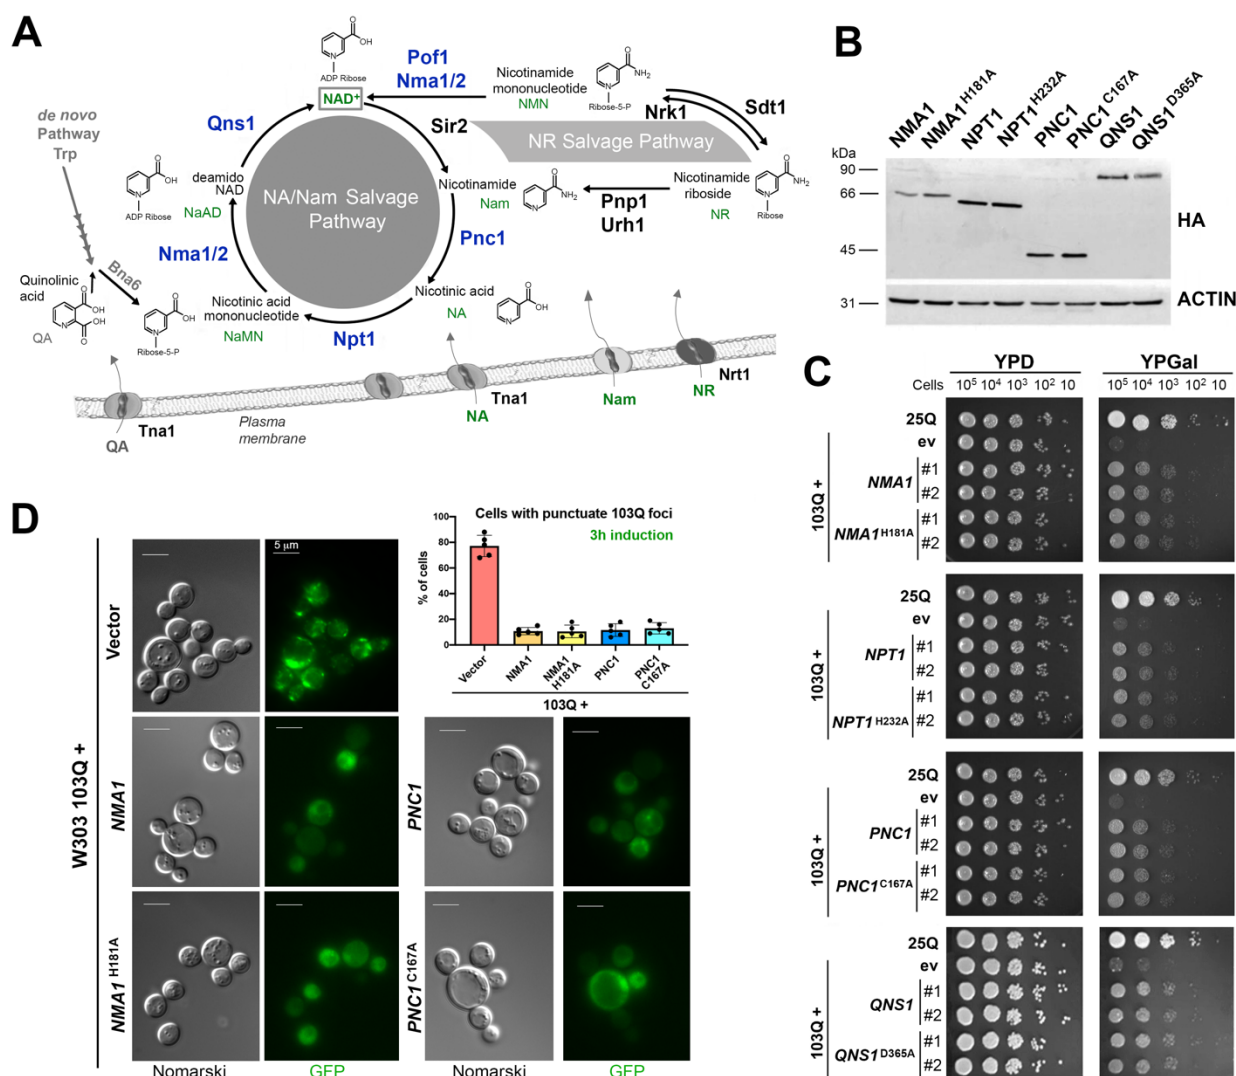

Fig 1. Catalytically inactive NAD⁺ salvage enzymes suppress 103Q-induced proteotoxicity in yeast. (A) Overview of the NAD⁺ salvage pathway in yeast. (B) Immunoblot analysis of expression of catalytically active and inactive HA-tagged NAD⁺ salvage proteins. ACTIN was using as a loading control. (C) Serial dilutions growth test of wild-type cells expressing non-toxic 25Q or toxic 103Q, and 103Q cells expressing WT or catalytically inactive variants of the indicated salvage NAD⁺ pathway genes, under the control of a galactose inducible promoter, in solid non-inducing media (YPD) and inducing galactose media (YPGal). #1 and #2 are two independent clones. Pictures were taken after 2 days of growth. (D) Visualization of PolyQ-GFP fusion protein expression and aggregation. The indicated strains were induced for 3 h in complete medium with 2% galactose, mounted on slides and visualized by fluorescence microscopy. Bar is 5 μ m. The graph quantifies the cells with at least one 103Q aggregation focus. Three hundred cells were counted in each case. Error bars are the mean \pm SD, of five independent assessments with *P*-values from comparisons to 103Q + vector strain denoted by **P* < 0.01.

Figure 2

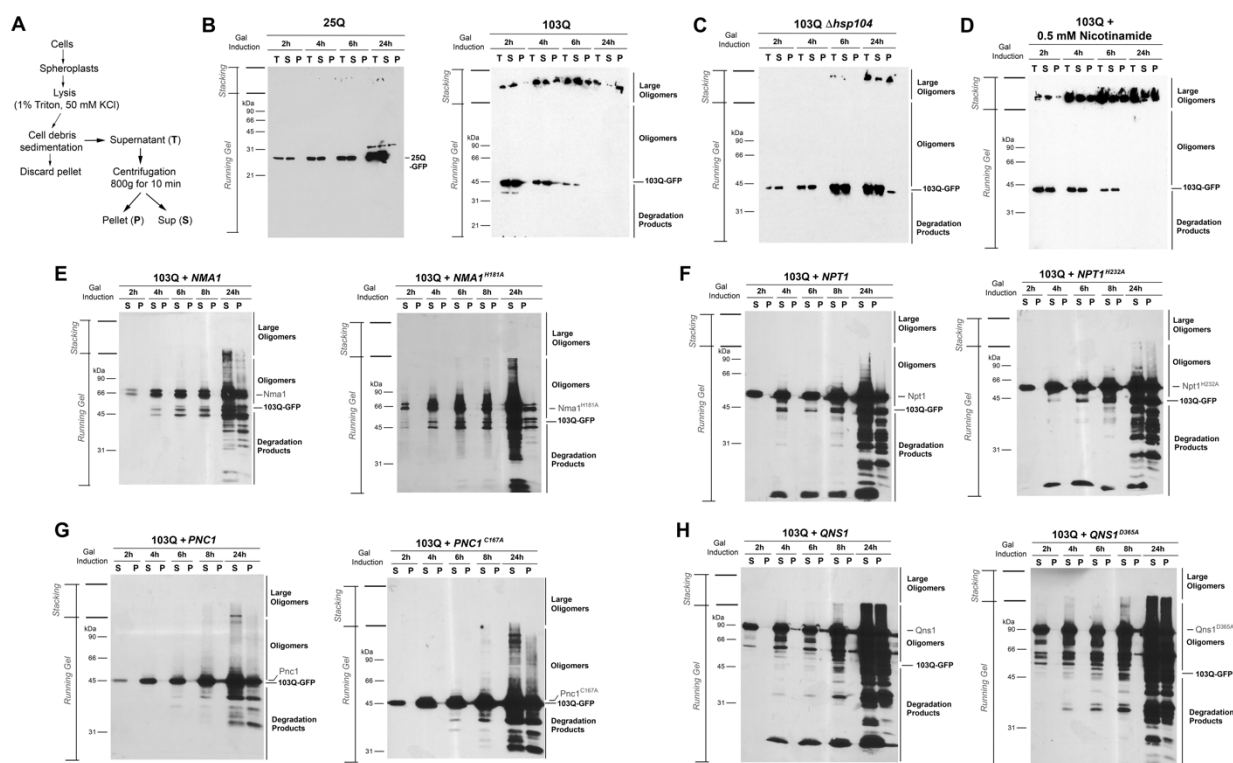

Fig 2. Suppression by catalytically active or inactive NAD⁺ biosynthetic proteins equally involves the clearance of cytotoxic protein species. (A) Scheme of the protocol followed to isolate aggregates from cultures expressing the short PolyQ and the long PolyQ constructs. Samples corresponding to the cell lysates after removal of the cell debris sedimented by gravity (T), the pellet (P) and supernatant (S) fractions resulting from centrifugation at 800 g for 10 minutes were taken and kept frozen until further use. (B-H) Detection of PolyQ-GFP fusion proteins. Wild-type W303-1A cells carrying integrative plasmids expressing 25Q-GFP or 103Q-GFP fusion proteins under the control of a *GAL1* promoter were grown on minimal synthetic media supplemented with prototrophic requirements and 2% galactose to induce protein expression. After several times of induction, the cultures were processed as described in (A). PolyQ-GFP fusion proteins were detected by western blot using equivalent amounts of the T, S and P fractions. After separation on a polyacrylamide gel, proteins were transferred to nitrocellulose paper. The fusion proteins were detected using an anti-GFP monoclonal antibody (Clontech, Palo Alto, CA) and visualized with anti-mouse IgG peroxidase-conjugated secondary antibody (Sigma) using the Super Signal chemiluminescent substrate kit (Pierce).

Figure 3

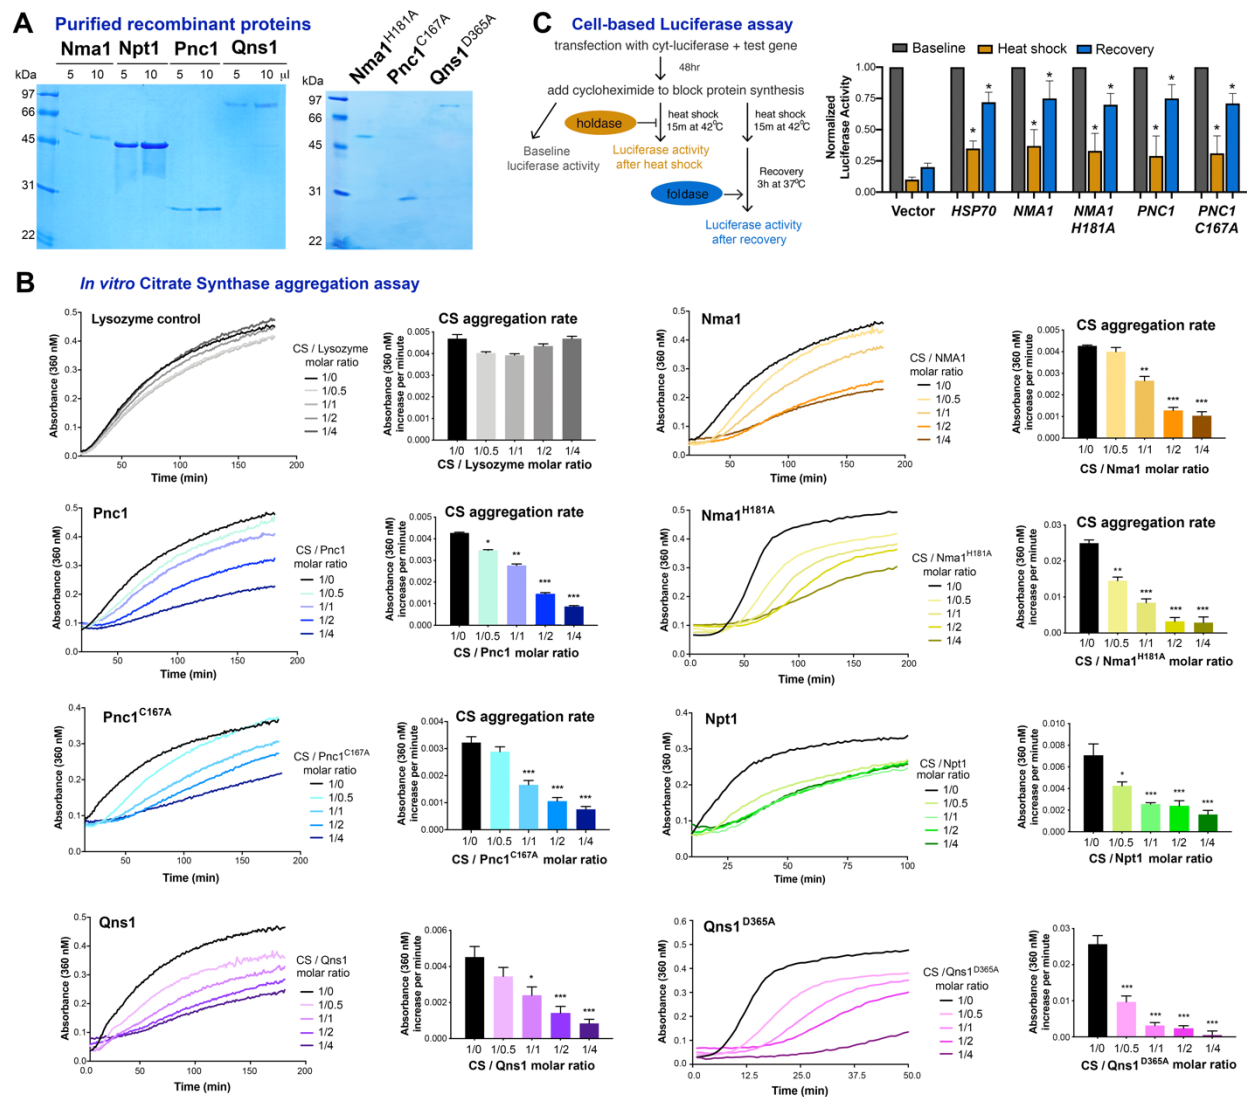

Fig 3. NAD⁺ salvage proteins function as chaperones with both holdase and foldase activities. (A) Coomassie blue stained gel showing the recombinant proteins purified as 6xHis fusion proteins from *E. coli*. (B) Citrate synthase (CS) aggregation assay for NMA1, NPT1, PNC1, and QNS1 WT and catalytically inactive mutants. At least five independent repetitions were performed for each protein. The bar graphs represent the average aggregation rates of citrate synthase alone (1μM citrate synthase) or 1μM citrate synthase plus the indicated amount of protein of interest during the period in which the rate of citrate synthase aggregation is linear. Error bars are the mean ± SEM. *p ≤ 0.01, **p ≤ 0.001, ***p ≤ 0.0001. (C) The diagram illustrates simplified experimental procedure of cell-based luciferase denaturation and refolding assay. The graph summarizes the chaperone activity of HSP70, and various NMA1 and PNC1 WT and mutant variants. Grey bars show baseline luciferase activity. Orange bars show luciferase activity immediately after heat shock, while blue bars show activity after recovery. Error bars are the mean ± SD, of three independent assays with P-values from comparisons to Vector cell line denoted by *P < 0.01.

Figure 4

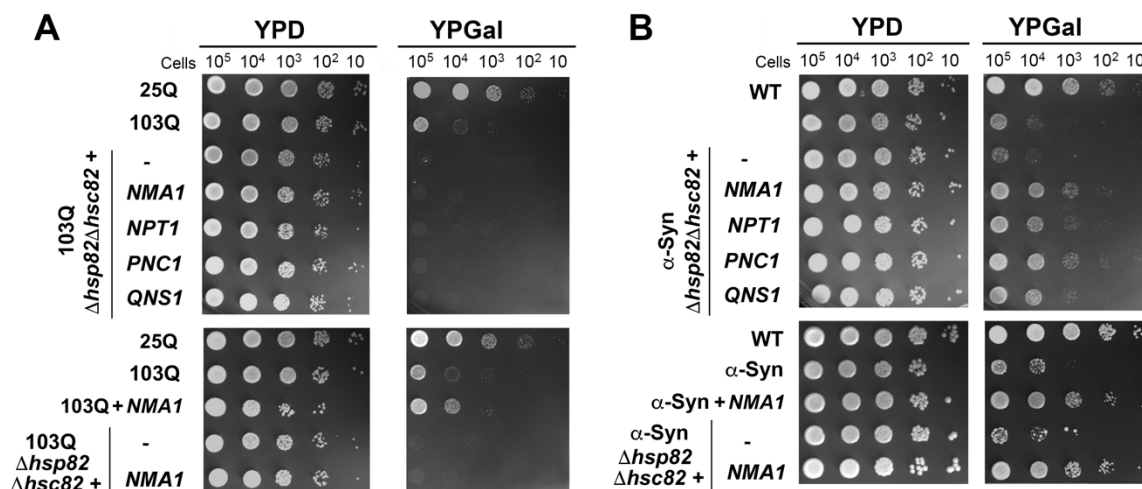

Fig 4. Double deletion of the two HSP90 chaperones, Hsp82 and Hsc82, prevents the suppression of 103Q-induced but not α -Syn-induced toxicity by NAD⁺ salvage proteins. (A) Serial dilutions growth test of wild-type cells expressing non-toxic 25Q or toxic 103Q, and 103Q cells deleted or not for *hsp82* and *hsc82*, expressing the indicated salvage NAD⁺ pathway genes, under the control of a galactose inducible promoter, in solid non-inducing media (YPD) and inducing galactose media (YPGal). Pictures were taken after 2 days of growth. **(B)** Same as in (A) but for α -Syn-expressing strains.

Figure 5

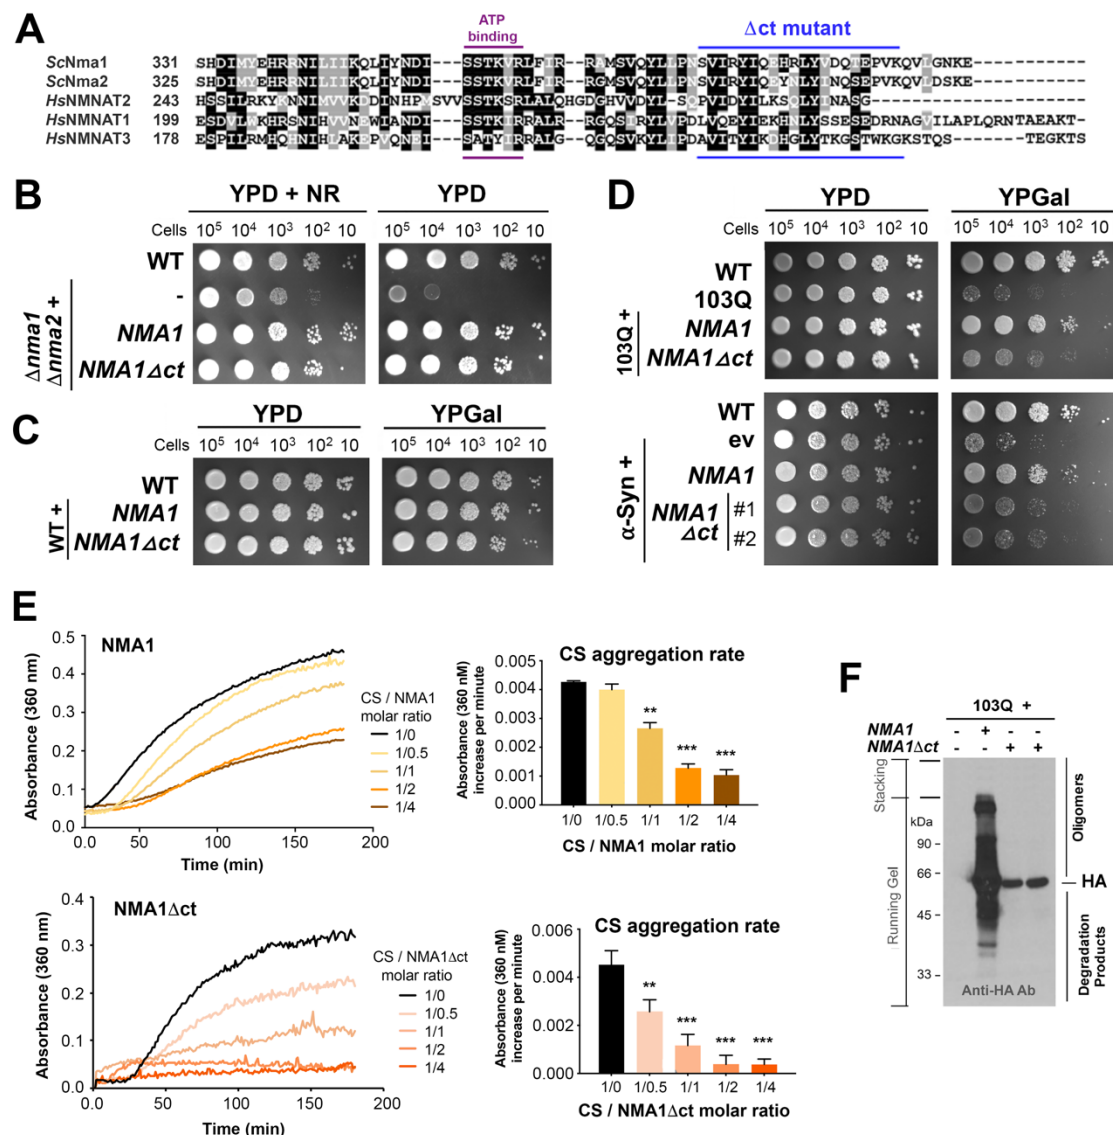

Fig 5. The C-terminus of Nma1 is required for full protection against proteotoxicity. (A) Multiple protein alignment of *Saccharomyces cerevisiae* Nma1 and Nma2 and *Homo sapiens* NMNAT1, NMNAT2, and NMNAT3 using the Clustal Omega program from EMBL-EBI. The C-terminal fragment deleted in the NMA1 Δ ct yeast strain is marked in blue. **(B-D)** Serial dilutions growth tests as in Figure 4 to assess: **(B)** the ability of Nma1 Δ ct to restore growth of a double mutant $\Delta nma1\Delta nma2$ in YPD medium without nicotinamide riboside (NR); **(C)** the effect of NMA1 or NMA1 Δ ct overexpression in wild-type (WT) W303 cells; **(D)** the ability of Nma1 Δ ct to protect against 103Q-induced proteotoxicity. **(E)** Citrate synthase (CS) aggregation assay for recombinant Nma1 and Nma1 Δ ct performed as in Fig 3. **(F)** Cellular extracts from the indicated strains after 6h of induction in YPGal medium were prepared as reported (1), and analyzed by immunoblotting using an anti-HA Ab to detect WT and Nma1 Δ ct.

Figure 6

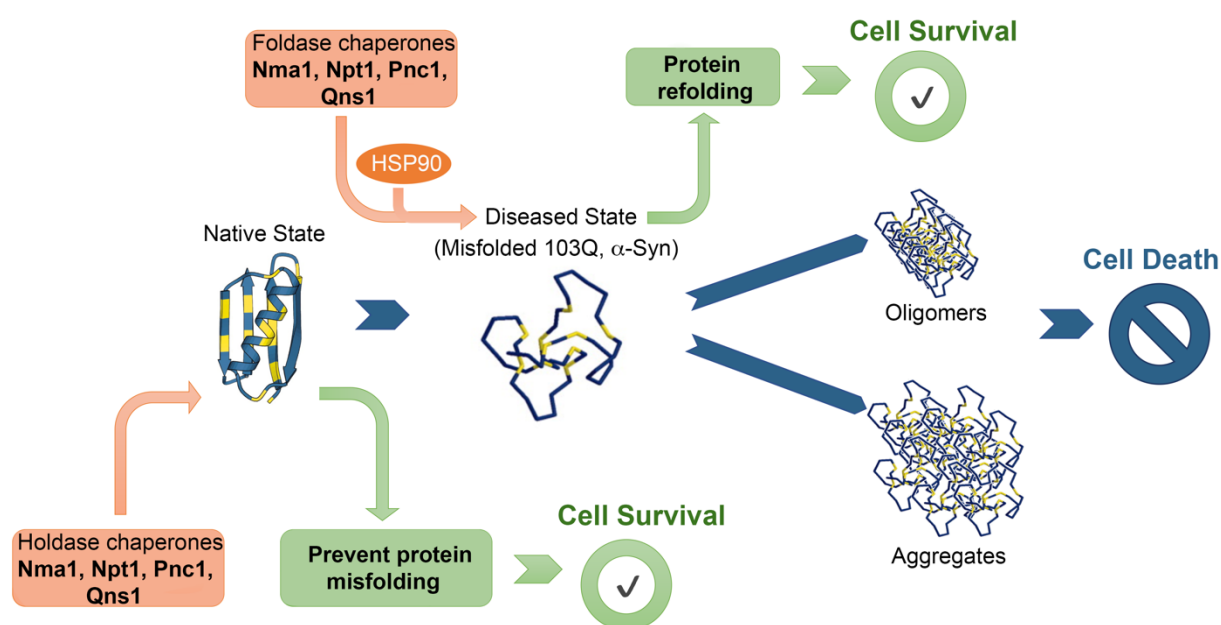

Fig 6. Model of proteotoxicity suppression by salvage NAD⁺ biosynthetic proteins. Under proteotoxic stress, salvage NAD⁺ biosynthetic proteins Nma1, Nma2, Npt1, Pnc1 and Qns1 are recruited to act as molecular chaperones. They display foldase activity to prevent protein misfolding and cooperate with HSP90-type chaperones to display foldase activity and promote protein refolding. In this way, NAD⁺ biosynthetic proteins contribute to minimize formation of toxic oligomers and aggregates to promote cell survival. See further explanation in the text.
