ABSTRACT

21   Ultra-high-resolution imaging of the osteocyte lacuno-canalicular network (LCN) three-

22   dimensionally (3D) in a high-throughput fashion has greatly improved the morphological knowledge

23   about the constituent structures – positioning them as potential biomarkers. Technologies such as

24   serial focused ion beam/scanning electron microscopy (FIB/SEM) and confocal scanning laser

25   microscopy (CLSM) can image in extremely high resolution, yet only capture a small number of

26   lacunae. Synchrotron radiation computed tomography (SR-CT) can image with both high resolution

27   and high throughput but has a limited availability. Desktop micro-computed tomography (micro-CT)

28   provides an attractive balance: high-throughput imaging on the micron level without the restrictions

29   of SR-CT availability. Over the past decade, desktop micro-CT has been used to image osteocyte

30   lacunae in a variety of animals, yet few studies have employed it to image human lacunae using

31   clinical biopsies.

32   In this study, accuracy, precision, and sensitivity of large-scale quantification of human

33   osteocyte lacunar morphometries were assessed by ultra-high-resolution desktop micro-computed

34   tomography. For this purpose, thirty-one transiliac human bone biopsies containing trabecular and

35   cortical regions were imaged using ultra-high-resolution desktop micro-CT at a nominal isotropic

36   voxel resolution of 1.2μm. The resulting 3D images were segmented, component labeled, and the

37   following morphometric parameters of 7.71 million lacunae were measured: Lacunar number (Lc.N),

38   density (Lc.N/BV), porosity (Lc.TV/BV), volume (Lc.V), surface area (Lc.S), surface area to volume ratio

39   (Lc.S/Lc.V), stretch (Lc.St), oblateness (Lc.Ob), sphericity (Lc.Sr), equancy (Lc.Eq), and angle (Lc.θ).

40   Accuracy was quantified by comparing automated lacunar segmentation to manual

41   segmentation. Mean true positive rate (TPR), false positive rate (FPR), and false negative rate (FNR)

42   were 89.0%, 3.4%, and 11.0%, respectively. Regarding the reproducibility of lacunar morphometry

43   from repeated measurements, precision errors were low (0.2 – 3.0%) and intraclass correlation

44   coefficients were high (0.960 – 0.999). Significant differences between cortical and trabecular regions

45   (p<0.001) existed for Lc.N/BV, Lc.TV/BV, local lacunar surface area (<Lc.S>), and local lacunar volume

46   (<Lc.V>), all of which demonstrate the sensitivity of the method and are possible biomarker

47   candidates. This study provides the rigorous foundation required for future large-scale morphometric

48   studies using ultra-high-resolution desktop micro-CT and high-throughput analysis of millions of

49   osteocyte lacunae in human bone samples. Furthermore, the validation of this technology for

50   imaging of human lacunar properties establishes the quality and reliability required for the accurate,

51   precise, and sensitive assessment of osteocyte morphometry in clinical bone biopsies.

INTRODUCTION

Bone as an organ provides humans with the necessary structural support to sustain locomotion and dynamic movement in daily life. The organ is uniquely capable of adapting its structure to meet the mechanical demands that are placed upon it [1]. This adaptation of bone has been described by Roux as bone (re)modeling [2]. Central to this process are the osteocytes: the most abundant bone cell type, embedded deeply within the bone matrix, and each ensconced within individual compartments called lacunae [2, 3]. Woven together by a large number of dendrites that extend from each cell, the lacuno-canalicular network (LCN) is one of the most intricately connected networks in the human body, and the scale is comparable with the network of neurons in the human brain [4]. Compelling studies over the last thirty years have revealed and emphasized the functional importance of the cells and processes within the LCN to sense mechanical signals, to transduce them into chemical signals, and to orchestrate the bone (re)modeling process through guided bone formation and bone resorption [5-10].

After cell death, the fossilized lacuna remains intact, allowing the lacuna's three-dimensional (3D) geometry to be extracted via several imaging techniques at the sub-micrometer resolution. Today, serial focused ion beam/scanning electron microscopy (FIB/SEM) possesses the highest spatial resolution in the nanometer range. Yet, while this technology allows for features like individual dendritic processes to be resolved, the depth range is a major limitation, and only a few dozen lacunae in the tissue can be captured simultaneously [11-14]. Other researchers have implemented confocal laser scanning microscopy (CLSM) to investigate lacunar geometry in mice [15, 16] and in clinical bone biopsies [17], but again the shallow tissue depth that can be explored is a limitation and hence only small subsections of bone consisting of a few dozen to a few hundred lacunae can be measured with CLSM. Both FIB/SEM and CLSM suffer from a lack of scalability since the time required for a study with more than a few hundred lacunae makes the technologies impractical for any type of large-scale lacunar analysis. Alternatively, several groups have used high-resolution x-ray-based approaches such as synchrotron radiation computed tomography (SR-CT). Several studies, Mader et

78 al. [18] in particular, have been successful in separating the porous lacunae from the surrounding

79 matrix in a high-throughput fashion in complete intact mouse femurs [18-24]. However, SR-CT is an

80 imaging tool that requires access to a beamline facility, of which only a few in the world exist, and

81 hence the availability is limited for most researchers due to timing restrictions. A fourth imaging tool,

82 conventional x-ray based ultra-high-resolution desktop micro-computed tomography (micro-CT),

83 provides a reasonable balance between CLSM and SR-CT. Ultra-high-resolution desktop micro-CT

84 allows for the extraction of millions of lacunae from complete bone biopsies without the need to

85 request approval for limited time slots or experienced personnel at beamline facilities. Furthermore,

86 desktop micro-CT is an established and validated technology that has been implemented for

87 laboratory-based bone research for several decades [25-28]. Therefore, it is necessary that a

88 technique be developed for large-scale, high-throughput imaging of osteocyte lacunar networks in

89 clinical bone biopsies.

90 Equally as important as the 3D images acquired are the individual structures that are

91 extracted from these images as well as the accurate, reproducible, and sensitive quantification of

92 their morphometry. Specifically, with ultra-high-resolution osteocyte imaging, it is imperative that

93 the lacunar morphometric parameters are well defined and measured accordingly. Great strides have

94 been made towards the standardization of these metrics in recent years, and several studies have

95 explored different basic measures such as lacunar density, shape, and orientation [18, 20, 21, 29-34].

96 Mader et al. have most thoroughly described and validated both simple and abstract lacunar

97 morphometric parameters, and hence this study follows their naming convention and mathematical

98 definitions [18]. The combination of well-defined lacunar morphometric parameters and a rigorously

99 validated imaging and analysis methodology allow for the emergence of biomarkers. These

100 morphometric biomarkers have the potential to be used to differentiate between diseased and

101 healthy bone, old and young bone, or even the region of bone within the body.

102 This study aims to provide researchers with a fully validated method of large-scale lacunar

103 imaging, accurate automated segmentation, and measurements of each resulting 3D lacunar

Goff et al. 5

104   structure using a technology that is widely accessible – ultra-high-resolution desktop micro-CT.

105   Furthermore, we demonstrate the power of such a high-throughput analysis by measuring the

106   morphometric parameters of millions of osteocyte lacunae in human bone samples, using the

107   previously validated 3D lacunar metrics of Mader et al. [18]. The rigor of the method is confirmed by

108   accurate image segmentation, a standard precision study [35], and the sensitive detection of

109   differences between cortical and trabecular regions. Thorough validation highlights the value of the

110   imaging method, and we believe this study will provide a rigorous foundation for future large-scale

111   lacunar investigations.

112

## METHODS

Human bone biopsy preparation

115   Thirty-one transiliac bone biopsy samples from premenopausal women already described in

116   previous studies by Cohen et al. [36, 37] were used for this study. Biopsy samples had been obtained

117   in women, aged 18-48, recruited as a reference population for studies of bone structure and

118   metabolism in premenopausal women. Reference population subjects were required to have normal

119   areal spine, hip, and forearm BMD by dual-energy x-ray absorptiometry (DXA; Z score ≥ -1.0 at all

120   sites), no history of adult low trauma fracture, and no historical or biochemical evidence of diseases

121   or conditions known to affect skeletal integrity [36, 37]. All subjects provided written informed

122   consent; studies had been approved by the institutional review boards of all participating

123   institutions.

124   A hemi-cylinder fraction of each biopsy core, containing both cortical and trabecular regions,

125   was embedded in individual polymethylmethacrylate (PMMA) disks with a 25mm diameter.

126   Subsections of each sample were prepared to fit in the desktop micro-CT scanner, which limits the

127   diameter to a 4.0mm field of view (FOV) in the ultra-high-resolution mode. Hence, each PMMA

128   embedded core was cut three times parallel to the longitudinal axis of the biopsy using a circular

Goff et al. 6

129   diamond blade (SCAN-DIA Minicut 40, SCAN-DIA GmbH & Co. KG, Germany) and custom-made

130   mounts for sample fixation. This produced a rectangular block, which had the XY target dimensions

131   of 4.25 +/- 0.1mm with the Z dimension depending on the original placement in the PMMA disk and

132   ranging from 20-25mm. Each block was then turned on a conventional lathe (Schaublin 102, Bevilard,

133   Switzerland) to create a final cylinder of 3.8 +/- 0.05mm diameter and a length ranging between 10

134   and 15mm. The biopsy cylinder was then tightly fit into a custom sample holder as seen in Figure 1 to

135   minimize motion artifacts and to maximize the volume scannable within the 4.0mm diameter FOV.

136   Image Acquisition

137   Biopsy subsamples were imaged with a μCT50 (Scanco Medical AG, Brüttisellen, Switzerland),

138   operated with a 0.5mm aluminum filter, 72μA current, 4W power, 55kVp energy, 1.5s integration

139   time, level 6 data averaging, and with a total of 1500 projections. Images were reconstructed at a

140   nominal isotropic voxel resolution of 1.2μm with an anti-ring level 8 to minimize center ring artifacts

141   using the manufacturer's scanner software. Each image consisted of a cylindrical volume equal to the

142   full diameter of the sample (3.8 +/- 0.05mm) and the height of one scan stack (909 slices = 1.09mm).

143   The protocol for each sample consisted of three scans: 1. Prescan to warm the sample in the scanner

144   gantry in an effort to reduce motion artifacts caused by thermal effects (1 hour) 2. Cortical region

145   scan starting from the lowest point on the centerline of the sample and scanning up one stack (10

146   hours) 3. Trabecular region scan stack in the middle of the biopsy equidistant between both cortical

147   walls (10 hours). A visual example of this scanning protocol and resulting images can be seen in

148   Figure 1.
149

150 *Figure 1: A) Schematic of sample core extraction from hemi-cylinder biopsy, which consisted of three linear cuts*

151 *followed by a lathe turn. B) Photograph of final machined biopsy core inserted into a tolerance-fit sample*

152 *holder. C) Scout-view overview of entire sample (XZ plane) with the trabecular (Tb) and cortical (Ct) scanned*

153 *regions identified between the respectively labeled green lines. D) Ultra-high-resolution micro-CT scan of*

154 *trabecular region cross-section (XY plane) and E) enlarged trabecular subregion. F) Ultra-high-resolution micro-*

155 *CT scan of cortical region cross-section (XY plane) and G) enlarged cortical subregion.*

156   To determine the optimal beam energy, three samples of trabecular bone were scanned at

157 three beam energies: 55, 70, and 90kVp. These samples used for beam energy optimization

158 originated from a separate study [38]; however, they were also human bone biopsies from the iliac

159 crest and were considered to be comparable with our biopsy group. We aimed to maximize the

160 image signal-to-noise ratio (SNR) just as previous studies relating to other anatomical bone sites had

161 done [39]. The linear attenuation coefficient (raw signal) was measured for ten two-dimensional sub-

162 regions ($\sim$0.25mm^2) at every beam energy in three samples for 90 regions in total. SNR was then

163 calculated by adapting the Firbank equation to account for two distinct materials as described in

164 Equation 1 where μ is the average coefficient of linear attenuation of bone and the background

165 (PMMA) and σ is the standard deviation of the background [40].

166
$$SNR = 0.655\frac{\mu_{bone} - \mu_{PMMA}}{\sigma_{PMMA}} \tag{1}$$

167 Image Preprocessing

168   Preprocessing of each image consisted of a constrained 3D Gaussian low pass filter (σ=0.8,

169   support =1) to reduce noise and was applied using IPL (Scanco Medical AG, Brüttisellen, Switzerland).

170   Segmentation of lacunar structures was performed by inverting the image after applying a threshold

171   that was individualized for each image volume, which was necessary due to the large variation in

172   tissue mineral density (TMD) distributions between samples at this resolution. The lacunar threshold

173   was determined by fitting a Gaussian distribution to each sample's raw TMD distribution data and

174   calculating the first critical point (g') of the fitted distribution using a custom Python script (3.7.1,

175   Python Software Foundation, Delaware, USA). Bone volume (BV) was determined by fixing a

176   threshold of 520mg HA/ccm, applying to all samples, performing a closing operation, and calculating

177   the resulting BV using IPL software (Scanco Medical AG, Brüttisellen, Switzerland).
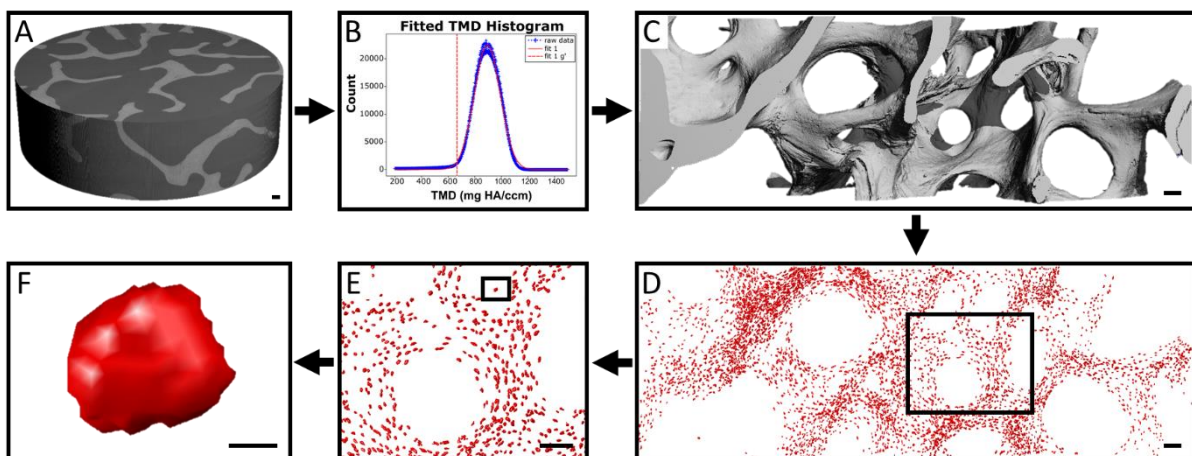

179   *Figure 2: Visual overview of large-scale lacunar segmentation. A) Gaussian filtered, unsegmented, complete micro-CT image*

180   *stack. B) Sample specific histogram of tissue mineral density (TMD) values fitted by a Gaussian function. A unique lacunar*

181   *threshold is chosen for each sample at the first critical point of the respective fit by calculating the maximum of the first*

182   *derivative (g'). C) Lacunar threshold calculated with (B) applied to (A). D) Image (C) inverted and component labeled to*

183   *identify lacunae. E) Enlarged subregion group of lacunae. F) Single visualized lacuna. Scale bar lengths: A-E) 100μm F) 10μm.*

184   All objects smaller than 50μm³ and larger than 2000μm³ were removed as to reflect the

185   range of human lacunar volumes reported in previous histological studies [41]. The lower bound

186   filters out noise structures while the upper bound excludes larger porosities like Haversian and

187   Volkmann canals. Similar volumetric ranges have also been implemented in previous studies [42, 43].

188   Several microcracks, blood vessels, and image ring artifacts escaped the volumetric filter, yet all

Goff et al. 9

189   exhibited similar thin structures with a high object-elongation value. Therefore, these were excluded

190   by removing all objects with an elongation above a threshold (Lc.St > 0.85). All objects sharing a

191   border with the image edge were also removed to exclude partially cutoff objects.

192   Image Morphometry

193   The lacunar morphometries were calculated with a custom Python script, which first

194   component labeled all lacunar objects, applied a surface mesh to each, and then measured basic

195   individual parameters. Lacunar density (Lc.N/BV) was calculated by normalizing the number of

196   lacunae (Lc.N) to the bone volume (BV) and lacunar porosity (Lc.TV/BV) by dividing the total volume

197   of all lacunae by the respective BV. Local parameters (denoted with <> and first defined by Stauber et

198   al. [44]) were each normalized to the sample Lc.N while population-based parameters (denoted with

199   []) were not normalized. Individual lacunar volume (Lc.V), lacunar surface area (Lc.S), and the Eigen

200   vectors were determined from the object specific mesh. This mesh was calculated by performing a

201   triangulation of the surface voxels of the object using Lewiner marching cubes (3.7.1, Python

202   Software Foundation, scikit-image library, Delaware, USA). The Eigen vectors were then used to

203   quantify more complex parameters including lacunar stretch (Lc.St) and lacunar oblateness (Lc.Ob),

204   which were first defined by Mader et al. [18]. Lacunar equancy (Lc.Eq) was the ratio between the

205   smallest and largest Eigen vectors (E3/E1) [21, 45] while lacunar sphericity (Lc.Sr) related the lacunar

206   object to a sphere via the ratio between Lc.S and Lc.V [43]. Lacunar angle (Lc.θ) was measured in

207   degrees and ranged between 0 and 180 degree in relation to an arbitrarily created unit vector that

208   was held consistent between images.

209   Validation

210   *Accuracy:*

211   To evaluate the accuracy of the threshold approach, sub-volumes from five samples

212   consisting of roughly 200 lacunae per region were hand-counted by a trained observer and then

213   compared with the automatically segmented data at the corresponding sample-specific g' threshold

Goff et al. 10

214   to calculate true positive, false positive, and false negative rates (TPR, FPR, FNR). All objects were

215   verified in 3D as depicted in Figure 3 and falsely classified objects were reclassified when appropriate.
216

217   *Figure 3: Manual vs. automatic lacunar segmentation. A) 3D cutplane of trabecular subregion with*

218   *automatically segmented objects highlighted in red. Examples of false negatives (FN) circled in blue, false*

219   *positives (FP) circled in white. B) Same cutplane as (A) used for visual comparison regarding classification of*

220   *automatically segmented objects, showing same FP and FN as in (A). C) 3D orthographic projection of (A&B)*

221   *with automatically segmented objects in red. D&E) 3D visualization comparing manual and automatic lacunar*

222   *segmentation. Red objects = true positives (TP); objects identified as lacunae both manually and automatically.*

223   *Gray objects = false positives (FP); objects identified as lacunae automatically but rejected manually. Blue*

224   *spheres = false negatives (FN); objects manually identified as lacunae but rejected by the automatic method. F-*

225   *I) TP examples. J-M) FP examples. Scalebar A-E) = 50μm; F-M) = 10μm.*

226   *Reproducibility:*

227   In accordance with literature that recommends a sufficient number of degrees of freedom

228   (DOF) to produce an upper confidence limit of the precision error that is 40% greater than the mean

229   precision error [35], six samples were measured five times and repositioned between each

230   measurement for a total of 20 DOF. Reproducibility was evaluated by calculating the precision error

Goff et al. 11

231   ($PE_{\%CV}$) and the intraclass correlation coefficient (ICC) for the measured lacunar indices using

232   Equations 2 – 4.

233

$$PE_{SD} = \sqrt{\sum_{j=1}^{m} \frac{SD_j^2}{m}} \tag{2}$$

234

235

$$PE_{\%CV} = \sqrt{\sum_{j=1}^{m} \frac{\%CV_j^2}{m}} \tag{3}$$

236

237

$$ICC = \frac{F_0 - 1}{F_0 + (n-1)} \tag{4}$$

238   *Sensitivity:*

239   To assess the sensitivity of the method, lacunar morphometric parameters from cortical and

240   trabecular regions were compared as there are known physiological differences between the

241   distribution and shape of lacunae in these regions in humans [43, 46]. Because each individual biopsy

242   contained both cortical and trabecular regions, it was possible to compare lacunae both within

243   samples and between samples.

244   <u>Statistical Analysis</u>

245   A paired t-test with the necessary Bonferroni correction was performed with respect to

246   energy-dependent imaging parameters in Table 1. With respect to the precision test, the 95%

247   confidence interval was calculated for each morphometric parameter using a chi-squared distribution

248   to gain an understanding of certainty with respect to the PE and ICC reported values in Table 3.

249   Creating two-parameter plots of the data presented in Table 3 is another way to evaluate the

250   reproducibility of the imaging method by means of clustering as is depicted in Figure 5. A paired

251 Student's t-test was performed to evaluate regional differences between lacunar parameters that

252 were normalized to tissue indices (p<0.001). Population-based parameters were not normally

253 distributed following a Kolmogorov-Smirnov test, and so a non-parametric Mann-Whitney U test was

254 performed to evaluate population differences (p<0.001). The inter-quartile ranges and medians were

255 computed for each morphometric parameter.

256

257 **RESULTS**

258 Image Acquisition

259 Images captured with a 55kVp beam energy exhibited a significantly higher SNR when

260 compared to images obtained with a beam energy of 90kVp (p<0.005). The SNR measured with the

261 70kVp beam energy fell in between the high and low beam energy values and did not differ

262 significantly from the other energies.

263 *Table 1: Energy dependency of imaging parameters. Energy level 55kVp used as baseline and paired t-test with*

264 *the necessary Bonferroni correction used to test for significant differences between energy levels in the three*

265 *following categories: contrast, standard deviation of the image background (σ_{PMMA}), and signal-to-noise ratio*

266 *(SNR). Significantly different (p<0.005) from baseline denoted with (*) and from 70kVp with (#).*

Energy (kVp)	Contrast (n=30)	σ_{PMMA} (n=30)	SNR (n=30)
55	1.84±0.46	0.14±0.02	8.34±2.20
70	1.33±0.33*	0.11±0.01*	7.65±1.88
90	0.92±0.23*#	0.09±0.01*#	6.67±1.60*

267

268 As shown in Table 1, both contrast and standard deviation of the background (PMMA in this

269 case) were inversely proportional to the beam energy. Specifically, the inverse proportionality was

270 approximately linear with contrast while σ_{PMMA} was quadratic (Figure 4), both important for the

271   computation of SNR as given in Equation 1. As a ratio of both noise and the standard deviation of the

272   image background (Equation 1), SNR was less dramatically affected by increasing beam energy. We

273   therefore set the beam energy to 55kVp for all scans in the study because this setting produced the

274   highest quality images with the highest contrast at acceptable noise levels.
275

276   *Figure 4: Beam physics relationships. A) Contrast exhibits an inverse relationship with beam energy. B) Standard*

277   *deviation of the background (σ_{PMMA}) has an approximate quadratic relationship with beam energy. C) Signal-to-*

278   *noise ratio is linearly related to beam energy as expected since it is defined as the contrast divided by the σ_{PMMA}.*

279

280   <u>Validation</u>

281   *Accuracy:*

282   Automated segmented objects were compared to the manual segmentation to evaluate TPR,

283   FPR, and FNR measures as seen in Table 2. Objects segmented automatically in each sample revealed

284   a strong agreement with the lacunae counted manually as is evident by the high TPR and low FPR and

285   low FNR. Roughly 200 lacunae were present in each sample subregion with sample 1 exhibiting the

286   highest TPR (93.9%) and lowest FNR (6.1%). Sample 4 had the lowest FPR (0.5%) while sample 3 the

287   lowest TPR (77.3%). The final accuracy measure was calculated as the mean of the five samples and

288   was computed to be 89.0% TPR, 3.4% FPR, and 11.0% FNR.

289   *Table 2: Quantification of accuracy measures and their corresponding rates obtained via comparison between*

290   *manual and automatic lacunar segmentation methods. TPR = True Positive Rate; FPR = False Positive Rate; FNR*

291   *= False Negative Rate.*

Sample	TP	FP	FN	TPR (%)	FPR (%)	FNR (%)
1	155	9	10	93.9	5.5	6.1
2	182	11	14	92.9	5.7	7.1
3	133	3	39	77.3	2.2	22.7
4	202	1	16	92.7	0.5	7.3
5	205	7	27	88.4	3.3	11.6
Mean	175	6	21	89.0	3.4	11.0

292

293   *Reproducibility:*

294   Measurement repeatability is crucial for validation and was quantified for measured lacunae.

295   Across all lacunar morphometric parameters, precision errors were very low (below 3%) and the ICC

296   were very high (above 0.980), which indicate that these lacunar measurements are extremely

297   reproducible. The 95% confidence interval range for precision errors was between 0.67% and 3.68%

298   while the range for ICC values were between 0.883 and 1.000, which indicates extremely low

299   measurement variability and high reproducibility.

300 *Table 3: Reported values from the reproducibility analysis (n=6, five repeated measurements). Morphometric*

301 *parameters include: lacunar total volume (Lc.TV), lacunar porosity (Lc.TV/BV), lacunar number (Lc.N), lacunar*

302 *density (Lc.N/BV), local lacunar volume (<Lc.V>), local lacunar surface area (<Lc.S>), local lacunar stretch*

303 *(<Lc.St>), local lacunar oblateness (<Lc.Ob>), local lacunar sphericity (<Lc.Sr>), local lacunar equancy (<Lc.Eq>),*

304 *and local lacunar angle (<Lc.θ>). In addition to mean values of each morphometric parameter across the*

305 *samples, we report the following for precision errors (PE): standard deviation (PE$_{SD}$) in absolute values,*

306 *coefficient of variation (PE$_{\%CV}$) of the repeated experiments, and the 95% confidence interval of the variation*

307 *(95% CI PE$_{\%CV}$). Also reported are the intraclass correlation coefficients (ICC) and the 95% confidence interval of*

309

310 Clustering of the individual repeated measurements indicates reproducibility and is especially

311 apparent in Figure 5A-B. These parameters also exhibited a very high correlation, which illustrated

312 that as bone volume increases so will the number of lacunae and the total lacunar volume. The

313 clustering in Figure 5C-D was not nearly as evident across all six samples due to the fact that <Lc.V>

314 and <Lc.St> were more difficult to reproduce. As BV/TV increases in Figure 5C-D, measured variability

315 decreases between the first and second cluster and then remains approximately constant. The strong

316 correlation of Lc.N (R^2 = 0.99) and Lc.TV (R^2 = 0.98) with BV/TV position them as potential lacunar

Goff et al. 16

317   biomarker candidates. <Lc.V> and <Lc.St> were more independent of BV/TV and no correlation was

318   found.
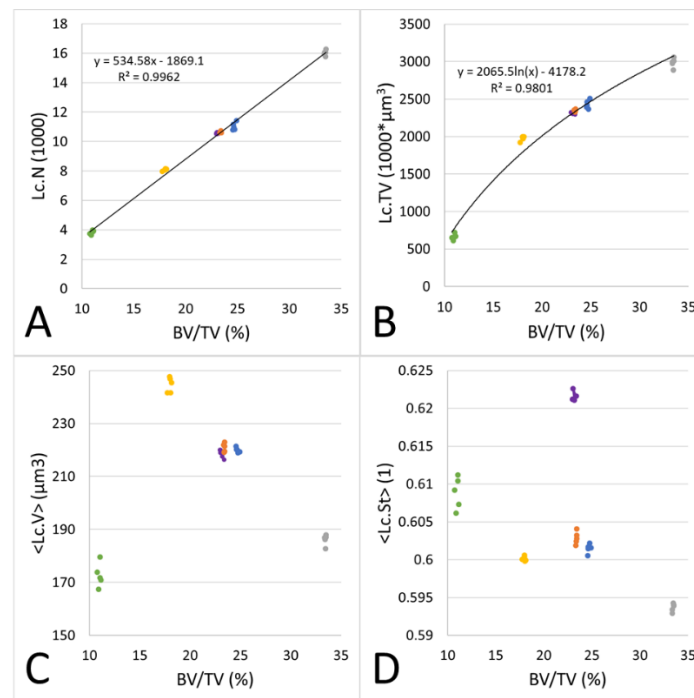

319

320   *Figure 5: Two-parameter plots that demonstrate the reproducibility of the imaging method. Each color*

321   *represents an individual sample and each data point represents a specific measurement (n=6, with 5 repeated*

322   *measurements). A) Lacunar number (Lc.N) vs. bone volume (BV/TV). B) Lacunar total volume (Lc.TV) vs. bone*

323   *volume (BV/TV). C) Local lacunar volume (<Lc.V>) vs. bone volume (BV/TV). D) Local lacunar stretch (<Lc.St>) vs.*

324   *bone volume (BV/TV).*

325   *Sensitivity:*

326   Cortical and trabecular bone regions were measured and compared. More bone was present,

327   and consequently, more lacunae were present in cortical bone when compared to trabecular bone.

328   Measured tissue values such as BV, and BV/TV in trabecular regions were consistently lower than

329   cortical regions as expected since trabecular bone is sparse and cortical bone is compact. Regarding

330   the global morphometries, which were normally distributed, Lc.N/BV median value in trabecular

331   bone was nearly half of what it was observed to be in cortical bone (16,611 vs. 26,429, p<0.001).

332   Similarly, the median value of Lc.TV/BV in trabecular bone was also nearly half of what it was in

333   cortical bone (0.30% vs. 0.58%, p<0.001), again indicating that cortical bone has a significantly higher

334   lacunar porosity than trabecular bone. Furthermore, we report in Table 4 that the normalized local

335   parameters <Lc.V> and <Lc.S> are significantly greater (p<0.001) in cortical bone (<Lc.V> = 223μm^3;

336   <Lc.S> = 233μm^2) than in trabecular bone (<Lc.V> = 178μm^3; <Lc.S> = 194μm^2). Most population-

337   based morphometric parameters were not normally distributed, and consequently we reported the

338   median values as well as the interquartile range for all indices to provide a sense of the distribution

339   of each parameter in Table 4.

350

351   Population-based lacunar parameters were not normally distributed. The interquartile ranges

352   between regions were similar, yet a non-parametric Mann-Whitney U test revealed significant

353   differences between cortical and trabecular regions ($p < 0.001$). The measure of sphericity ([Lc.Sr])

354   was approximately 0.75 for both regions of bone, indicating similarities between the measured

355   ellipsoids and an idealized sphere. The additional parameters [Lc.Eq], [Lc.St] and [Lc.Ob] allow for the

356   ellipsoidal lacunar shape to be described in more detail, and the median reported values suggest that

357   these are indeed ellipsoidal structures in both trabecular and cortical regions. The range of [Lc.Ob] in

358   trabecular bone was slightly higher than in cortical bone.

359   Figure 6 depicts selected global, local, and population-based morphometries from both

360   cortical and trabecular regions. When normalized to the analyzed tissue volume, both the lacunar

361   density and porosity were significantly different between cortical and trabecular regions (Figure 6A-

362   B) across all 31 samples, further supporting their potential as biomarkers. Local morphometries

363   (<Lc.V> & <Lc.S>) were also significantly different between the two regions (Figure 6C-D), yet not as

364   clearly separated as the global morphometries. Population-based morphometries (Figure 6E-F)

365   included all lacunar observations across all 31 samples: 1.14 million lacunae in trabecular bone and

366   6.57 million lacunae in cortical bone. The shape indices [Lc.St] and [Lc.Sr] were chosen to compare

367   between regions and were also significantly different. A visual comparison is presented in Figure 6G-

368   H between the samples containing the median Lc.N/BV values from Figure 6A, further illustrating the

369   differences between regions.

370
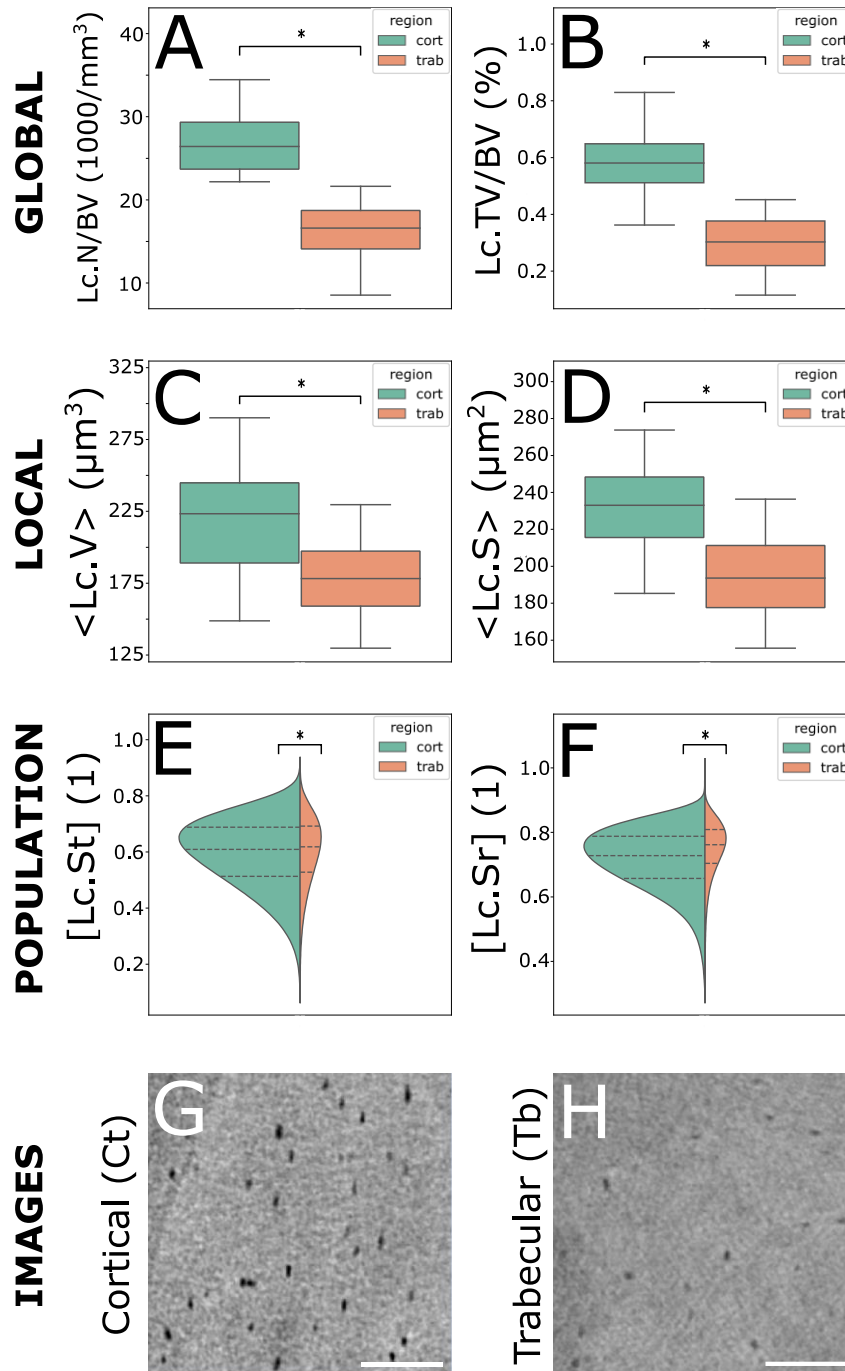

Figure 6: Comparison of cortical and trabecular regions regarding lacunar morphometric parameters. Included in the analysis were 31 samples which comprised of 6.57 million cortical lacunae and 1.14 million trabecular lacunae. A) Lacunar density (Lc.N/BV). B) Lacunar porosity (Lc.TV/BV). C) Local lacunar volume (<Lc.V>) normalized to sample. D) Local lacunar surface area (<Lc.S>) normalized to sample. E) Population-based local lacunar stretch ([Lc.St]) not normalized to sample. 379   *indicates p<0.001.*

DISCUSSION

381   Detailed examination of the LCN on a large scale demands a high-resolution 3D-imaging

382   methodology that is accurate, reproducible, and sensitive. Lacunae must be segmented and

383   morphometric indices measured accurately and repeatably. Therefore, it is paramount that

384   researchers select a fully validated imaging methodology for the large-scale assessment of osteocyte

385   lacunar morphometry. High-resolution desktop micro-CT is an ideal technology for large-scale

386   investigation of the lacunar network due to its wide accessibility. Micro-CT has been employed for

387   decades as a standard technology for bone tissue morphometry with nominal voxel resolutions in the

388   range of 10-40μm [25-28]. However, this technology has evolved in recent years, and with it, the

389   ability to image higher resolutions on the order of 1μm [47]. Hence, the development of validated

390   image acquisition, processing, and analysis tools to image lacunar morphometry is a logical

391   progression of the science as well as being crucial to understanding the biological impact of the LCN

392   on bone at other hierarchical levels.

393   Segmenting the lacunar structures from the surrounding mineralized bone matrix required

394   the careful selection of the threshold applied to the image. Typically, a single threshold is chosen by

395   the user via visual inspection and then applied to all samples in a study. At the tissue level this

396   method is acceptable when recommended guidelines are carefully followed [48] and was how BV

397   was calculated in this study. However, due to the wide variation of the TMD distributions between

398   samples at the 1.2μm resolution, this single-threshold method cannot be applied to all samples when

399   imaging lacunae (Figure S1). Therefore, our approach was to pragmatically locate a threshold that

400   was intrinsically linked to the sample specific TMD distribution, compare the resulting segmentation

401   with manual segmentation, and quantify the accuracy. Previous studies have tried similar individual

402   threshold approaches, which are offset from a reference point of the TMD histogram such as the

403   mean [49], but we found our specific images responded best to selecting the TMD histogram critical

404   point for segmentation (Figure S1). While no single segmentation threshold was able to capture all

405   lacunar structures, the visual comparison in Figure 3 is strikingly good. Alternative descriptors of the

406   TMD distribution were investigated such as the width of the distribution but did not prove to be as

407   effective as the first critical point (Figure S2).

408   The range of considered object volumes was also important for lacunar segmentation. This

409   range varies substantially between studies and could be as narrow as 50-610μm^3 or as wide as 175-

410   2000μm^3 [18, 21, 42, 43, 50, 51]. Previous examinations of histological slides have estimated the

411   human lacunae to be between 28μm^3 and 1713μm^3, yet lacunae observed below 50μm^3 were only

412   found in fracture callus [41]. After evaluating several different volume ranges and comparing both

413   qualitatively with 2D and 3D images and quantitatively with accuracy measures such as TPR, FPR, and

414   FNR, we determined a lower limit of 50μm^3 to be optimal for lacunar segmentation in human

415   trabecular and cortical bone [52]. The upper limit was chosen to be 2000μm^3 in line with a similar

416   study [21]. This range has a large impact on the number of lacunae segmented and is particularly

417   sensitive on the lower limit. This problem is especially pronounced with respect to desktop micro-CT

418   due to the limited photon count of its X-ray beam technology. Relative to studies conducted with

419   synchrotron CT systems [18, 42], the desktop micro-CT X-ray beam creates image projections with

420   fewer photons, which increases the resulting noise, reduces the image quality, and makes

421   visualization of small lacunae more difficult. A Gaussian filter with a low sigma value of 0.8 was

422   applied so noise would be reduced while the borders of the lacunae would not be blurred beyond

423   the recognition of a trained human observer. Several extremely elongated ring artifacts were

424   observed in segmentations and were successfully removed by implementing an anti-ring

425   reconstruction filter and applying a shape filter that removed objects with a Lc.St value greater than

426   0.85 [53].

427   We used ultra-high-resolution desktop micro-CT to image 7.71 million osteocyte lacunae

428   across cortical and trabecular regions in 31 human iliac crest biopsies. We have observed that

429   morphometric differences exist between lacunae in cortical and trabecular regions of bone, which

430   has also been shown in previous studies [43, 46]. Currently, only Akhter et al. [43] have reported

431   sample matched trabecular and cortical lacunar morphometric parameters in human iliac crest

432   biopsies. In contrast to their study, we report higher values of Lc.N/BV and Lc.TV/BV in cortical bone

433   when compared to trabecular bone. However, the narrow volume range they evaluate (50-610μm)

434   and their analysis of less than 1% of the number of lacunae that we examine severely limits the range

435   of variation that they could potentially consider. Additionally, we have proven our desktop micro-CT

436   imaging technique to be accurate, reproducible, and sensitive.

437   We evaluated not only global lacunar parameters related to tissue measures (Figure 6A-B),

438   but also local (Figure 6C-D) and population-based (Figure 6E-F) values. Population-based

439   morphometry was not normalized and presents the reader with an undistorted perspective of the

440   natural variation of certain morphometric indices across millions of lacunae (Figure 6E-F). This further

441   illustrates the method's sensitivity that we see in Figures 6A-D and also demonstrates the method's

442   ability to capture the natural variation of lacunae in a large-scale analysis.

443   Manual segmentation was used as our gold-standard for calculating accuracy, because

444   registration between micro-CT images and typical morphological gold-standards like histology is

445   extremely difficult. However, we were careful to create the best manual segmentation dataset

446   possible for comparison. Hernandez et al. have used similar accuracy comparisons in previous

447   studies and in fact, achieve similar rates of TP, FP and FN to ours [49]. Interestingly, sample 3 in our

448   accuracy calculation exhibited an inordinately low TPR and high FNR. This was due to a suboptimal

449   selection of the sample's subregion near the bone surface, which made manual identification of

450   lacunae slightly more difficult.

451 We observed very low precision errors and high intraclass correlation coefficients with

452 respect to our five consecutive measurements of six samples. These values were in the same range

453 as in the study of Hemmatian et al. who investigated the reproducibility of desktop micro-CT for

454 imaging murine lacunae [47]. The tight clustering of data points when creating two-parameter plots

455 as seen in Figure 5 further proves the reproducibility of the method. Figure 5A and 5B both exhibit

456 tight clustering within the measurements for each sample which is what we expect when comparing

457 lacunar parameters with tissue values like BV/TV. Bone tissue volume is a quantity that micro-CT is

458 excellent at measuring and hence we would expect it to be extremely reproducible. Physiologically

459 speaking, we would also expect Lc.N and Lc.TV to increase with increasing total bone volume, which

460 explains the strong correlation, further adds credibility to the imaging modality, and even positions

461 the two lacunar parameters as potential biomarker candidates. Yet in Figure 5C and 5D, we note that

462 the values of each sample are slightly less clustered in comparison and are not correlated. More

463 specifically, we note that BV/TV remains very consistent but the <Lc.V> and <Lc.St> varies. Small

464 objects are more difficult to mesh and both <Lc.V> and <Lc.St> are dependent on the object mesh

465 which would explain the difficulties with reproduction in comparison to Lc.N and Lc.TV. Hemmatian

466 et al. also found lacunar measures such as <Lc.V> to be less reproducible than tissue measures such

467 as BV/TV [47]. Consequently, <Lc.V> and <Lc.St> do not appear to be good biomarker candidates.

468 Previous studies have demonstrated that lacunar morphometric parameters differ between

469 trabecular and cortical regions of bone [43, 46]. We used this fact to evaluate the sensitivity of our

470 method by the ability to differentiate lacunae between regions. We report significant differences

471 between global, local, and population-based parameters including Lc.TV/BV, Lc.N/BV, <Lc.V>, <Lc.S>,

472 [Lc.St], and [Lc.Sr] as seen in Table 4 and Figures 6A-F. Furthermore, Figures 6G-H provide a visual

473 confirmation of the difference that we report in Figure 6A. Not only do we see that lacunar density is

474 lower in trabecular regions, but also the lacunae themselves look to be slightly smaller relative to the

475 cortical regions. This would indicate that lacunae in trabecular regions also consist of lower total

476 porosity (Lc.TV/BV), volume (<Lc.V>), and surface area (<Lc.S>). These visual differences further

Goff et al. 24

477   support our claim that the method is sensitive and reflects the statistically significant differences that

478   we report in Figures 6A-D.

479   The largest limitation of this study was the inability to compare extracted lacunar

480   morphometry from our ultra-high-resolution desktop micro-CT images with a higher resolution

481   technology such as FIB/SEM. This would have allowed for an accuracy measure not only with respect

482   to the lacunae segmented, but also the accuracy of morphometric parameters such as <Lc.V> and

483   <Lc.S>. Additionally, the segmented lacunar data was very sensitive to the selection of the lower

484   volumetric bound. This was difficult to select since volumetric data from previous studies regarding

485   the distinction between a lacuna and a micropore is limited. Finally, the precision study required

486   weeks of scanning time and consequently was only performed on trabecular bone.

487

488   **CONCLUSION**

489   We present a new, and rigorously validated high-throughput method to assess osteocyte

490   lacunar morphometry in human bone samples. We use ultra-high-resolution desktop micro-CT, an

491   individualized histogram-based segmentation procedure, and a custom evaluation algorithm to

492   calculate global and local morphometric parameters of 7.71 million lacunae in two distinct regions of

493   31 human iliac crest bone samples, revealing two potential biomarkers. The validation of our method

494   demonstrates high degrees of accuracy, precision, and sensitivity. Therefore, our new image

495   acquisition and evaluation methodologies greatly expand the number of investigable hypotheses

496   surrounding osteocyte lacunae, while simultaneously employing a widely accessible and mature

497   imaging technology – desktop micro-CT.

649 **SUPPLEMENTARY DOCUMENT**

650 Below are several figures which provide additional information regarding the specifics of the imaging

651 methodology.
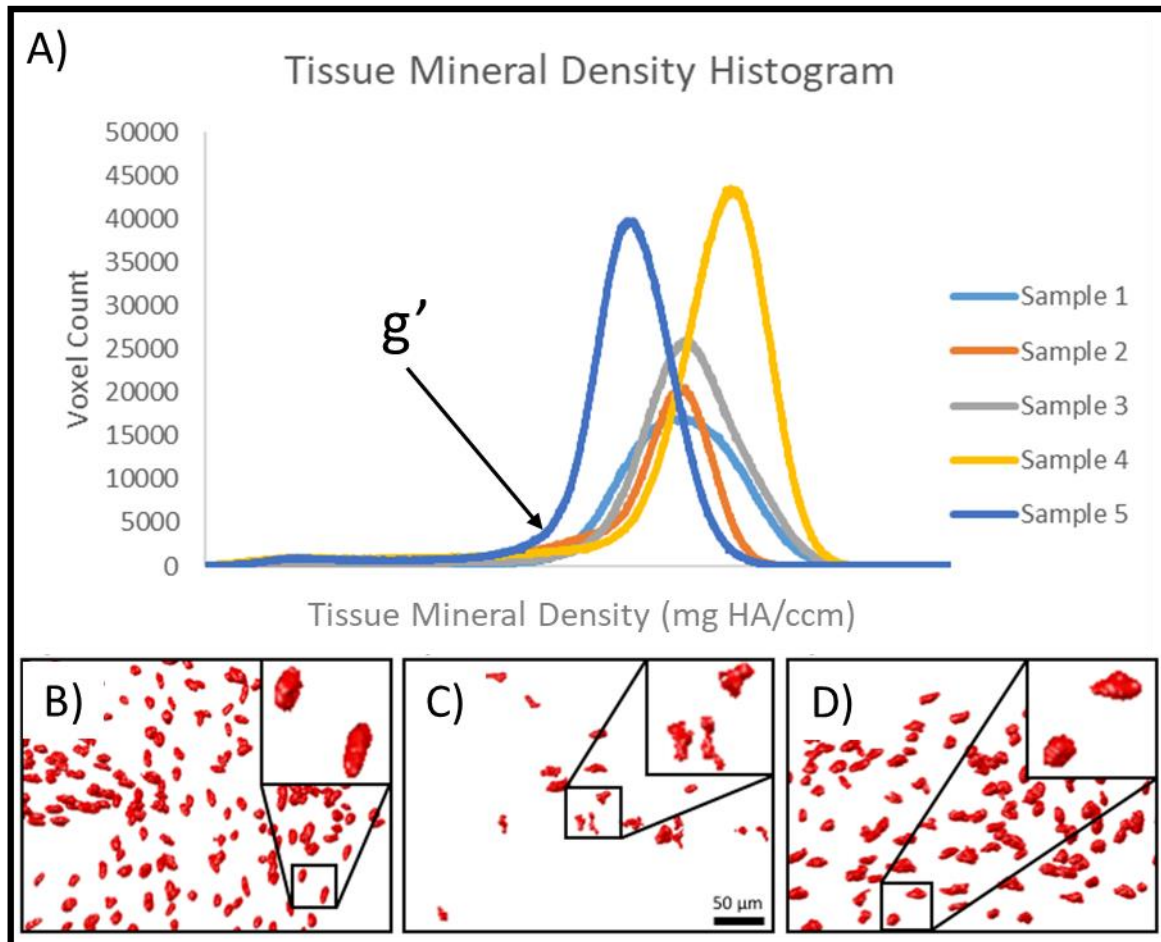

652

653 *Figure S1: A) TMD histograms for several samples where g' is the critical point. B) Segmented lacunae using a fixed threshold*

654 *applied to sample 1. C) Segmented lacunae using the same fixed threshold that was applied to sample 1 to sample 2. D)*

655 *Individualized threshold approach (g') calculated for sample 2 and the resulting segmented lacunae.*

656
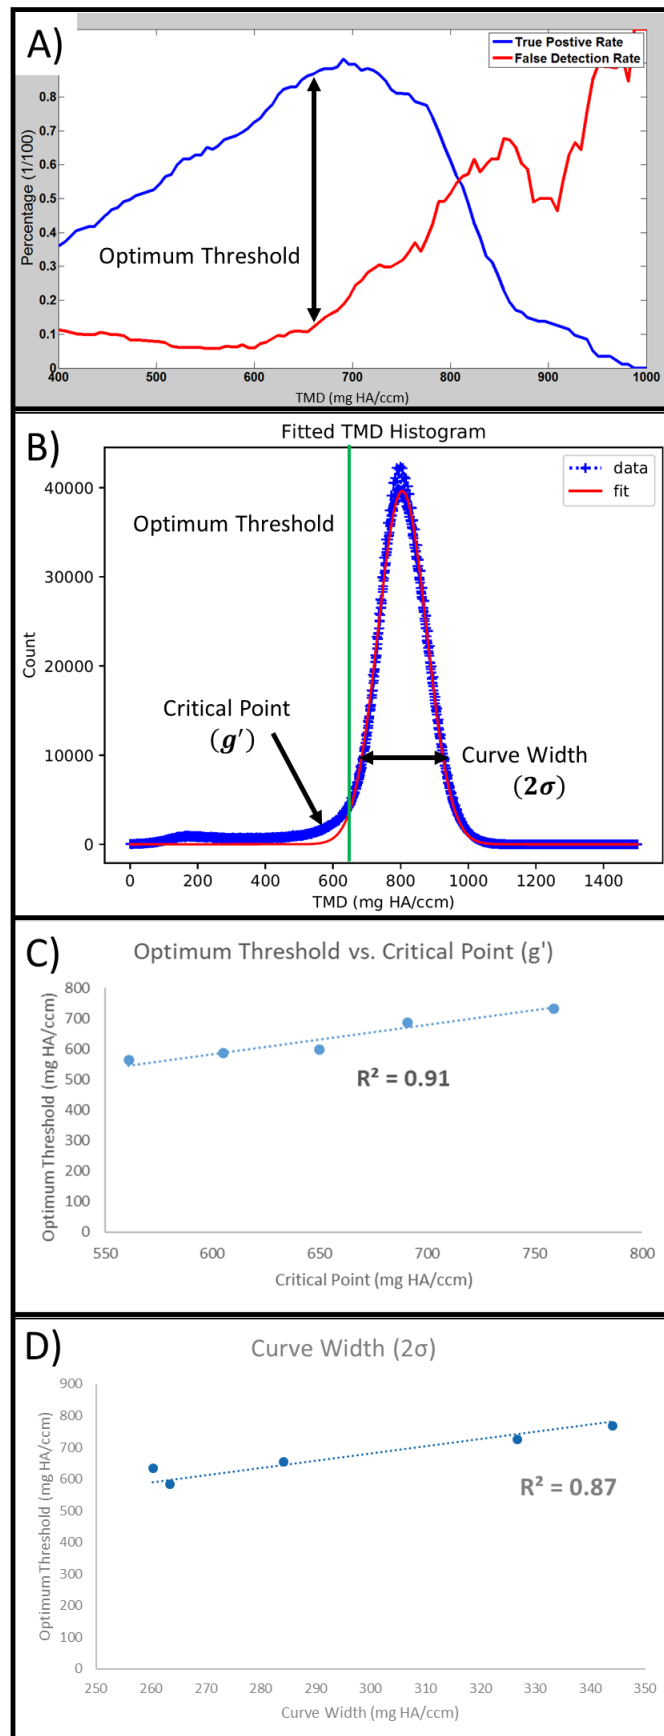

Figure S2: Individualized threshold selection. A) Iterative application of many single thresholds and each compared with the

manual segmentation 3D coordinates of a given image subregion. Optimum threshold was defined as the single threshold

659 *that maximized the true positive rate and minimized the false detection rate. B) Typical TMD histogram of the bone biopsy's*

660 *micro-CT image. Optimum threshold (green) determined from (A) and the distribution characteristics including the critical*

661 *point (g') and curve width (2sigma) were calculated from the Gaussian fit of the data. C) Correlation between the optimum*

662 *threshold for each of the five manually segmented subregions and the corresponding critical point (g') from each respective*

663 *TMD histogram. D) Correlation between the optimum threshold for each of the five manually segmented subregions and the*

664 *corresponding distribution width (2sigma) from each respective TMD histogram.*

665
666

667 *Figure S3: Animation of lacunar segmentation from the tissue level down to the individual cell level (see powerpoint file).*
