Abstract

29

30 *Spiroplasma*, known pathogens of arthropods and plants, are helical-shaped
31 bacteria lacking the peptidoglycan layer. They swim by alternating between left-
32 and right-handed cell helicity, which is driven by an internal structure called the
33 ribbon. This system is unrelated to flagellar motility that is widespread in bacteria.
34 The ribbon comprises the bacterial actin homolog MreB and fibril, the protein
35 specific to *Spiroplasma*. Here, we isolated the ribbon and its core, the fibril
36 filament, and using electron microscopy, found that the helicity of the ribbon and
37 the cell is linked to the helicity of the fibril. Single particle analysis using the
38 negative-staining method revealed that the three-dimensional structures of the
39 fibril filament comprise a repeated ring structure twisting along the filament axis.
40 Based on these observations, we propose a scheme for the helicity-switching
41 mechanism in which the twists caused by the conformational changes in the fibril
42 filament are accumulated, transmitted to the ribbon, and then propel the cells by
43 rotating the cell body like a screw.

44

Significance Statement

45

46 *Spiroplasma* are widespread globally as pathogens of animals and plants. They
47 are also recognized as male-killing bacteria of insects. Their special swimming
48 mechanism is caused by helicity switching, which could be the simplest
49 swimming mechanism. This mechanism has attracted research attention for
50 many years because of the possible application in the field of nano actuators;
51 however, the details of this mechanism remain to be clarified. Here, we reveal
52 the outline of the swimming mechanism by analyzing the structure of the core of
53 the *Spiroplasma* ribbon.

54

Introduction

55

56 Mollicutes, which are parasitic or commensal bacteria, have evolved from the
57 phylum Firmicutes that includes *Bacillus* and *Clostridium* by reducing their
58 genome sizes (1). In the course of evolution, the cells have become softer and
59 smaller owing to the loss of the peptidoglycan layer, allowing them to transmit
60 their internal housekeeping activities to the outside, resulting in the acquisition of
61 three unique motility mechanisms (1). Two of the three, represented by
62 *Mycoplasma mobile* and *Mycoplasma pneumoniae*, exhibit gliding motilities on
63 solid surfaces in which leg structures repeatedly catch sialylated
64 oligosaccharides on host cells, based on two different mechanisms (2-4). The
65 other motility system is the helicity-switching swimming of *Spiroplasma*, the
66 subject of the present study (Movie_S1) (2, 5-7). *Spiroplasma* species are

2

67 parasitic to plants and arthropods, and are characterized as polarized helical-
68 shaped cells with a tapered end (8, 9). They also show obvious chemotaxis
69 despite the absence of genes for the two-component regulatory system in the
70 genome, which is generally responsible for bacterial chemotaxis (10). In general,
71 swimming bacteria such as *Escherichia coli*, *Salmonella*, and spirochetes can
72 migrate by the rotational motion of the flagellar motor fixed to the peptidoglycan
73 layer, whereas *Spiroplasma* have a unique swimming system in which kinks
74 propagate along the cell body with a switch between left-handed and right-
75 handed cell helicity (Fig. 1A). This swimming is driven by an intracellular
76 structure called the "ribbon" which localizes along the innermost line of the helical
77 cell structure, and structural changes in the ribbon may switch the cell helicity
78 (11, 12). Therefore, the detailed structure of the ribbon should be elucidated to
79 determine this swimming mechanism.

80 In previous studies using electron microscopy, two types of filaments in the
81 ribbon were visualized (11, 12). One comprises a protein "fibril," specific to
82 *Spiroplasma*. The other is possibly MreB, the bacterial actin homolog (10-12). As
83 *Spiroplasma* MreBs are distantly located from other MreBs in the phylogenetic
84 tree, here, we use the term SMreB (13, 14). Fibril protein has been studied as a
85 linear motor protein which is responsible for the helicity-switching (15, 16). The
86 fibril filament is considered to function as a chain of elliptical rings. However, the
87 structure and function of the fibril protein remains unclear.

88 In the present study, we clarified the structure of the fibril filament, which is
89 unrelated to that of any other known cytoskeletal filament, using electron
90 microscopy (EM) and single particle analysis. Then, we proposed a scheme for
91 the helicity-switching swimming of *Spiroplasma*.

92

93 **Results**

94 **Cell helicity is derived from the internal ribbon structure**
95 To clarify which structure forms the helical cell morphology of *Spiroplasma*, we
96 first measured the helical pitches of the swimming cells using optical microscopy.
97 The helical shape of the cells can be observed as a series of density segments in
98 the defocused image plane, relative to the cell axis under phase contrast
99 microscopy (Fig. 1B). The helical pitches between the left- and right-handed
100 segments along the cell axis were 696 ± 32 (n = 159) and 697 ± 37 nm (n = 146),
101 respectively. Next, we performed EM to analyze the internal ribbon structure to
102 compare the helical pitches of the cells and the ribbons. The cells were bound to
103 EM grids non-specifically, chemically fixed by glutaraldehyde, and then stained

3

104 with uranyl acetate. Negative-staining EM showed the images of helical-shaped
105 cells with a narrow tip at one side (Fig. 1C). Next, we exposed the internal ribbon
106 structure by treating the cells with 0.1% Triton X-100 on the grid (Fig. 1D). The
107 ribbon showed a "spiral" flat structure comprising protofilaments. However,
108 generally, in negative-staining EM, the specimens are placed in vacuum and
109 dried and can result in distortions, which is disadvantageous for helix
110 observation. Therefore, we applied quick-freeze, deep-etch (QFDE) EM to
111 visualize the structure as close to the original as possible. In QFDE, a sample is
112 frozen in milliseconds, exposed by fracturing and etching, and then a platinum
113 replica is made by shadowing. The observation of the replica by transmission EM
114 gives subnanometer resolution images with high contrast (17, 18). The cells were
115 non-specifically bound to mica flakes and fixed by quick freezing in a liquid
116 condition. Then, we prepared replicas by fracturing and platinum coating. QFDE-
117 EM showed cell morphology consistent with the results from negative-staining
118 EM (Fig. 1E). Using QFDE-EM, we also observed the ribbon exposed with 0.1%
119 Triton X-100 treatment (Fig. 1F). The ribbon showed the "helicoid" structure in
120 which the twisted positions were aligned in a line. When the cells were starved in
121 phosphate-buffered saline (PBS) without glucose for 30 min, they all showed a
122 left helix with the same pitch. Therefore, we assumed that this structure is the
123 default state of the cell. Table 1 summarizes parameters that present the helicity
124 of cells and ribbons obtained with the two EM methods (Fig. 1G, H). The helical
125 pitches of the cells and the ribbons were in good agreement, indicating that the
126 ribbon forms the cell helicity. As the helix diameter of the ribbon was one-third
127 that of the cell helix, the ribbon should be localized along the innermost line of
128 the cell helix.

129 **Characterization of the isolated ribbon**
130 We intended to use A22, an inhibitor of MreB polymerization to examine the role
131 of MreBs in the ribbon (Fig. 2A) (19), because the binding of A22 to SMreBs has
132 been suggested from amino acid sequences (13). First, we examined the effect
133 of 1 mM A22 on swimming *Spiroplasma* cells (Movie_S2). The cells shifted to a
134 right-handed helix form and stopped moving in 2 min (Fig. 2B a, b), suggesting
135 that the functions of SMreBs are also inhibited by A22. The resulting helical
136 pitches of the cells were distributed around a peak at 426 ± 47 nm, shorter than
137 the original (Fig. 2B c).

138 The cell suspension was treated with 1% Triton X-100 and subjected to stepwise
139 gradient centrifugation, consisting of 0%, 20%, 30%, 40%, 50%, and 60%
140 sucrose layers. After centrifugation, we found a dense layer of cell contents at
141 the bottom of the 40% sucrose layer. We recovered and observed the fraction

4

142 under EM and found that the ribbon comprised protofilaments with a width of 66
143 ± 12 nm and length longer than 2 μm (Fig. 2C a). The ribbons were twisted with a
144 pitch of 350 ± 17 nm (n = 47) (Fig. 2D a) consistent with the helical pitches of the
145 cells and the ribbons prepared on the grid (Fig. 1, Table 1) (P = 0.7 > 0.01). To
146 analyze the number and width of the protofilaments involved in the isolated
147 ribbon, we traced a sectional image profile of the ribbon (Fig. 2D b). Six to nine
148 protofilaments were detected with widths ranging between 4–16 nm (Fig. 2D c, d
149 and Fig. S1). SDS-PAGE analysis of this fraction showed five protein bands
150 including six proteins (Table 2). The band (v) contained SMreBs 2 and 4. The
151 whole ribbon fraction mainly comprised fibril protein and the SMreBs 2 and 4 with
152 an intensity ratio of 47% and 37%, respectively (Fig. 2E).

153 Next, we examined the effects of A22 on the ribbon. We kept cells in 1 mM A22
154 for 2.5 h at 30 °C and observed the ribbon. The ribbons were observed in a
155 dispersed form with width distribution characterized by three peaks, 9.5, 15.0,
156 and 22.2 nm (Fig. 2C c, D d). SDS-PAGE analysis clarified the content as 67%
157 and 11% for fibril and SMreB proteins, respectively (Fig. 2E), suggesting that the
158 protofilaments comprising fibril protein are bundled by SMreBs in the ribbon
159 structure.

160 **Helical pitch of the isolated fibril filament**
161 To analyze the detailed structure, we treated the ribbon fraction with cholic acid
162 and isolated the fibril protein using sucrose-gradient centrifugation. SDS-PAGE
163 analysis showed that the fraction contains only fibril protein (Fig. 3A). We
164 examined the ATPase activity of fibril protein by monitoring phosphate release
165 because we expect ATP as the direct energy source for *Spiroplasma* swimming.
166 Fibril protein at 17 μM was mixed with 2 mM ATP in the presence of Mg ions, but
167 phosphate was not released even after 250 min at 30 °C. Then, we concluded
168 that the fibril protein does not have the obvious ATPase activity. Negative-
169 staining EM showed that the fibril protein forms filaments which include single-
170 and double-stranded filaments and bundles, suggesting various types of
171 interactions between fibril protein molecules (Fig. 3B a). A single-stranded fibril
172 filament consisted of repeated ring units approximately 10 nm long (Fig. 3B b)
173 and 7 nm wide as observed in the side view (Fig. 3B c). A double-stranded fibril
174 filament appeared to be formed by aligning two single-stranded filaments to face
175 each other at the side of the ring, resulting in a thickness and width of 14 nm and
176 7 nm, respectively (Fig. 3B d), forming a 10 nm long repeating structure. We
177 analyzed the helical pitches for the double-stranded fibril filaments, because the
178 double-stranded fibril filament had enough persistent length to cover the helical
179 pitch with a clear twist of the ring pattern along the filament axis. The images of

180   the fibril filament cropped from the electron micrographs using the straightening
181   selection tool of ImageJ software were subjected to a fast Fourier transform
182   (FFT) to remove noise, and then, the generated image was subjected to an
183   inverse FFT (Fig. 3C). To ensure that the FFT images did not include artificial
184   mistakes, we also generated the two-dimensional (2D) averaged images from
185   312 randomly picked particles with a box size of 45 nm along the filament axis
186   using RELION 3.0 software (Fig. 3D)(20). The three classes of images
187   corresponded well to different positions of the filament images generated by FFT,
188   suggesting that the FFT images reflect the original structures. The helical pitch
189   estimated from the FFT images was 343 ± 22 nm (n = 158) (Fig. 3G a). However,
190   we could not conclude the handedness of the fibril filament, because the
191   alignment of the filament on the EM grid was not distinguishable with negative-
192   staining EM. Therefore, we analyzed the isolated fibril filament using QFDE-EM
193   (Fig. 3F) because the replica is made by platinum, which is not transparent to an
194   electron beam. We succeeded in the determination of their handedness (Fig. 3F)
195   and concluded that the double-stranded fibril filament forms a left-handed helix
196   with a pitch distribution of 351 ± 33 nm (n = 50) (Fig. 3G b). The helix features
197   were consistent with the pitch of the cell in the default state and that of the
198   isolated ribbon (Table 1), suggesting that the fibril pitch is the determinant for the
199   pitch of the ribbon and cell.

200   **Three-dimensional reconstruction of fibril filaments**
201   To detect the conformational changes in the fibril three dimensionally, we
202   performed single particle analysis based on negative-staining EM. The double-
203   stranded fibril filament was not suitable for image averaging owing to the
204   positional variety in the binding of the two filaments (Fig. 3 and Fig. S2).
205   Therefore, we sonicated the purified fibril fraction to increase the proportion of
206   single-stranded forms and succeeded in the acquisition of single-stranded
207   images (Fig. 4A). From the selected 11 867 particles with good quality, the 2D-
208   averaged images were summarized into three types (i), (ii), and (iii) (Fig. 4A b).
209   Then, the initial 3D model was reconstructed using the *ab-initio* 3D function of
210   cisTEM software (21) and used as the reference for the following 3D
211   classification (Fig. 4A c). Three dimensional structures of the fibril filament
212   reconstructed from the total of 11 867 particles by RELION 3.0 software showed
213   three conformations, i.e., class 1: left-handed mostly straight (49%), class 2: left-
214   handed with curvature (24%), and class 3: right-handed with curvature (27%)
215   (Fig. 4A d and Fig. S3). Two dimensional re-projections from these three
216   structures corresponded well to the 2D class averages, indicating the validity of
217   the obtained 3D structures (Fig. S4). The 3D structure of the fibril filament had
218   repeating elliptical rings with a pitch of 8.7 nm along the filament axis, with long

219   and short axes of 11 and 6 nm, respectively. A short cylinder connects the ring
220   units causing a positive curvature (Fig. 4A d). These characteristics were
221   common to all three classes. Cross-sectional images perpendicular to the
222   longitudinal axis of the filament showed a "boomerang-like shape", which had a
223   dent at one side and protrusion at the other (Fig. 4B). We evaluated the twist of
224   the fibril filament around the filament axis by measuring the directions of the
225   Feret diameter, the longest diagonal line of cross-sectional images. Fibril
226   filaments twisted along the filament axis. The twisting angles were estimated
227   from the angle averages of the first and fourth units, as 4.8 (left-handed), 7.6
228   (left-handed), and 5.9 (right-handed) degrees for classes 1, 2, and 3,
229   respectively. Although superimposition of classes 2 and 3 showed diagonal shifts
230   between these two conformations, the positions responsible for the structural
231   shift could not be identified owing to the low resolution of structures (Fig. 4C). We
232   constructed long filament models representing a helical pitch by stacking the ring
233   units (Fig. 4D). Class 1 formed a left-handed helix with a diameter of 280 nm and
234   a pitch of 530 nm. Class 2 formed the left-handed helix with a diameter of 110
235   nm and a pitch of 210 nm. Class 3 formed the right-handed helix with a diameter
236   of 110 nm and a pitch of 310 nm. We attempted to reconstruct the double
237   stranded filaments through image averaging and failed (Fig. S2). It is likely
238   caused by the variation in binding positions in the formation of the double strand.
239   We reconstructed the double strand from the structure of the single-stranded
240   filament (Fig 3E), which was consistent with the images obtained using the other
241   methods.

242   **Assignment of the predicted fibril protein structure to a density map**
243   To predict the fibril structure, we searched for template structures for homology
244   modeling using SWISS-MODEL and obtained the methylthioadenosine/S-
245   adenosylhomocysteine (MTA/SAH) nucleosidase of *Bacillus anthracis* (PDB ID:
246   4QEZ) (22), which has a 25.6% amino acid sequence identity to the N-terminal
247   region amino acid residues 1–228 of the fibril protein. In contrast, the sequence
248   of the C-terminal region of amino acids 229–512 did not show significant
249   homology with other proteins in the BLAST search using non-redundant protein
250   sequences (searched on December 24, 2020). These results are consistent with
251   a previous observation in 2011 (15). Then, we assumed that the fibril protein can
252   be divided into the N-terminal domain, comprising amino acid residues 1–228
253   and the remaining portion. Secondary-structure prediction based on the amino
254   acid sequences showed similarity between the N-terminal domain of the fibril
255   protein and *B. anthracis* MTA/SAH nucleosidase (Fig. 5A), suggesting the
256   similarity also in 3D structures. Therefore, we used *B. anthracis* MTA/SAH
257   nucleosidase as a template for the homology modeling of the N-terminal region

258 of the fibril protein using SWISS-MODEL. The predicted model showed a
259 homodimer in which the monomers interact with each other to occlude a
260 hydrophobic surface, as observed in the crystal structure of *B. anthracis*
261 MTA/SAH nucleosidase (Fig. 5B). The predicted rod-shaped dimer had
262 dimensions of 75, 60, and 50 Å. We then manually searched for the position in
263 the density map from EM to assign the predicted molecular model (Fig. 5C). The
264 predicted rod structure could be assigned to only one position, because it was
265 too thick to assign to the other positions. The gap between the two subunits of
266 the predicted structure fit to a gap observed in the density map from EM. Based
267 on these results, we determined the alignment of the subunits in the
268 protofilament (Fig. 5D).

269

Discussion
270

271

Fibril and ribbon structures
272

273 Although the interconnected ring structure in the fibril filament has been observed
274 (10, 15), the 3D reconstruction of the fibril has not been achieved to date. In the
275 present study, we clarified the 3D structure of the fibril filament for the first time.
276 The sonication in the isolation process was effective in isolating the single
277 stranded filament, whose uniform structure was advantageous for image
278 averaging (Fig. 4). The structure determined here showed a width of 10.5 nm,
279 and was in good agreement with the corresponding filament structure obtained
280 through electron cryotomography (12), suggesting that the filaments isolated
281 here retained the original structure. The left-handed conformation accounted for
282 73% of the fibril filament, suggesting that this conformation is more stable than
283 others. This observation may explain the fact that both the cells in a default state
284 and the isolated ribbons were mostly left-handed (23, 24). The fibril structure is
285 likely more stable in the left-handed conformation than in the right-handed one.
286 The fibril filament did not show any polarity along the filament axis, although
287 *Spiroplasma* cells swim in a directed manner (Fig. 1) (5, 10). This directionality
288 could be caused by structures other than the fibril, for example, SMreB proteins
289 and the dumbbell formed at the cell front (10, 14, 25). We obtained three different
290 filament conformations with different curvatures, in other words, the helix
291 diameter. This variety in curvature may function in directing the ribbon formation,
292 in which the filament at the ribbon edges requires a longer helix diameter than
293 those at the central positions (Fig. 6).

Swimming mechanism
294

295 Based on these results, we can now suggest the core part of the helicity-

296 switching mechanism (Fig. 6). The ribbon comprises 6–9 fibril filaments
297 connected laterally and oriented along the innermost part of the helical cell (Fig.
298 6A). The fibril should support the cell membrane through their ring structures,
299 because the fibril filament has a positive curvature toward the backbone (Fig. 6B
300 a upper). Thus, the fibril twist forms the twist of the ribbon and the cell with the
301 same handedness, because the fibril filament binds to the adjacent filaments
302 through their fixed positions (Fig. 6B a lower). If the fibril filaments in the ribbon
303 have strong cooperativity along the ribbon axis and transmit the twist to the next
304 levels, the helicity shift travels along the ribbon axis, with accumulation of the
305 rotational angle (Fig. 6B b) (23). If we assume that such a ribbon is fixed at a tip
306 on the front end, then, the shift initiated at the tip travels backward, along with
307 rotation of the back portion to release the torsion, in a direction that pushes water
308 backward (Fig. 6C) (Movie_S1). The ribbon structure drives the cell structure and
309 propels the cell forward by pushing water backward like a screw.

310 **Possible molecular mechanism for helicity-switching**
311 The N-terminal region of the fibril protein has an amino acid sequence identity of
312 as much as 25.6% with MTA/SAH nucleosidase from a bacterial species, *B.*
313 *anthracis*. This protein is essential for bacterial growth because it recycles
314 adenine and methionine through S-adenosylmethionine (SAM)-mediated
315 methylation reactions and produces the universal quorum-sensing signal,
316 autoinducer-2 (AI-2) (26). The fibril protein probably evolved from this protein,
317 which is abundant in a cell, by acquiring a C-terminal region possessing
318 polymerization activity. Class Mollicutes lack the respiration pathway to generate
319 membrane potential and produce ATP through glycolysis and arginine
320 fermentation (27). Therefore, the energy for swimming should also be supplied
321 by ATP, rather than the membrane potential, because the energy required for
322 growth is supplied by ATP, which is produced by glycolysis in *Spiroplasma*. In
323 fact, the two motility mechanisms of Mollicutes genus, *Mycoplasma mobile*-type
324 and *Mycoplasma pneumoniae*-type gliding mechanisms depend on the hydrolytic
325 energy of ATP (28-31). The fibril protein derived from the MTA/SAH nucleosidase
326 is unlikely to have ATPase activity, and no ATPase activity was detected in the
327 fibril fraction. These facts suggest that other proteins may be involved in the
328 helicity switching (12, 14, 32). The ribbon contains SMreB proteins, and
329 interestingly, most genomes of the *Spiroplasma* code for five classes of SMreBs
330 (13, 14, 33). Moreover, in the present study, we showed that SMreBs have roles
331 to bundle fibril filaments (Fig. 2 C). Generally, MreBs exhibit polymerization
332 dynamics based on ATP hydrolysis, and function to assign peptidoglycan
333 synthesizing complexes (1, 17, 19, 34) and as a rail for the gliding motor of
334 *Myxococcus xanthus* (35). SMreB5, a member in the five classes, is known to be

9

335 essential for helix formation and swimming of *Spiroplasma citri* cells (14). These
336 facts suggest that SMreBs support and drive the helices formed by the fibril.
337 Perhaps, SMreB itself also forms filamentous structures along the cell axis (11,
338 12). In fact, MreB-like filaments have been observed along the cell axis by EM
339 analyses of *Spiroplasma melliferum* (12).

340
341
342 **Materials and Methods**
343
344 **Bacterial strains and culture conditions**
345 The type strain, TDA-040725-5^T, of *Spiroplasma eriocheiris* was cultured in R2
346 medium (2.5% [wt/vol] heart infusion broth, 8% sucrose, and 10% horse serum)
347 at 30 °C to an optical density of 0.06 to 0.1 at 600 nm (10, 36).

348 **Optical microscopy**
349 Cultured cells were centrifuged at 11 000 × *g*, 10 °C for 10 min and suspended in
350 PBS consisting of 75 mM sodium phosphate [pH 7.3], 100 mM NaCl, containing
351 20 mM glucose and 0.6% methylcellulose to be of a cell density 10-fold higher
352 than that of the original (10, 36). The cells were inserted into a tunnel chamber
353 assembled by taping coverslips as previously described and observed under an
354 IX71 microscope (Olympus, Tokyo, Japan) (37). The video was captured using a
355 DMK33UX174 complementary metal–oxide–semiconductor (CMOS) camera
356 (The Imaging Source, Taipei, Taiwan) and analyzed using ImageJ v1.53a
357 (https://imagej.nih.gov/ij/).

358 **Electron microscopy**
359 To observe the intact cells, the cell suspension was placed on a hydrophilized
360 grid, fixed using 2% glutaraldehyde, washed with water, and stained with 2%
361 uranyl acetate. To observe the internal structure, the cell suspension on a grid
362 was treated with PBS including 0.1 mg/mL DNase and 1 mM $MgCl_2$ for 20 s, and
363 washed and stained with 2% uranyl acetate. QFDE-EM was performed as
364 previously reported for specimens suspended with mica flakes (17). The images
365 were acquired using a JEM1010 EM (JEOL, Akishima, Japan) equipped with a
366 FastScan-F214(T) charged-coupled device (CCD) camera (TVIPS, Gauting,
367 Germany) and analyzed using ImageJ v1.53a.

368 **Isolation of ribbon and fibril**
369 To isolate the internal structure, 10 mL of cell suspension in PBS was treated
370 with 1% Triton X-100, 0.1 mg/mL DNase, 1 mM $MgCl_2$, and 0.1 mM PMSF with
371 shaking for 10 min at 4 °C. The insoluble fraction was recovered by centrifugation

10

372 at 20 000 × *g*, 4 °C for 30 min and suspended in PBS to be 0.2 mL. The sample
373 was laid at the top of sucrose solution layers of 0%, 20%, 30%, 40%, 50%, and
374 60%, and centrifugated at 20 000 × *g*, 4 °C for 20 min in a 1.5 mL tube with a
375 fixed angle. To isolate the fibril filament, the insoluble fraction was additionally
376 treated with a solution consisting of 2% choric acid, 20 mM Tris-Cl pH 8.0, 150
377 mM NaCl at 4 °C for 8 h and subjected to stepwise density gradient
378 centrifugation.

379 **ATPase assay**
380 ATPase activity was assayed by a continuous spectrophotometric method using
381 a 2-amino-6-mercapto-7-methylpurine ribonucleoside–purine nucleoside
382 phosphorylase reaction to detect the released inorganic phosphate at 30 °C
383 (EnzChek kit; Life Technologies, Carlsbad, CA, USA). The reaction mixture was
384 as follows: 17 μM purified fibril filament, 1 mM $MgCl_2$, 20 mM Tris-HCl (pH 7.5) in
385 a total volume of 0.2 mL (38).

386 **Reconstitution of 3D structure**
387 The contrast transfer function (CTF) parameters for negative-staining EM images
388 were estimated using Gctf25 software (39). The images of fibril filaments were
389 selected automatically by RELION 3.0 (20) as helical objects and segmented as
390 squares of 200 × 200 pixels with 90% overlap. These 14 543 images were 2D-
391 classified and 11 867 images were selected for further analyses. *ab-initio*
392 reconstitution was performed by cisTEM (21) based on segmented images from
393 12 classes. The selected 11 867 particle images were 3D-classified using the 3D
394 map in RELION 3.0 (20).

510   **Table 1.** Dimensions of cell and ribbon

Parameters	Negatively stained electron microscopy	Quick-freeze, deep-etch electron microscopy	Optical microscopy
Cell thickness (a)	196 ± 26 nm	179 ± 23 nm	
Ribbon width (b)	147 ± 24 nm	118 ± 17 nm	
Cell helical pitch (c)	696 ± 73 nm	706 ± 43 nm (LH)	696 ± 32 nm (LH) 697 ± 37 nm (RH)
Ribbon 1/2 helical pitch (d)	348 ± 44 nm	350 ± 30 nm (LH)	
Ribbon helical pitch (e)	684 ± 60 nm	700 ± 60 nm (LH)	
Ribbon helical diameter (f)	137 ± 30 nm	118 ± 17 nm	
Cell helical diameter (g)	383 ± 45 nm	310 ± 26 nm	
Isolated ribbon pitch	350 ± 17 nm		
Isolated fibril pitch	343 ± 22 nm	351 ± 34 nm (LH)	

511   *, ** $p > 0.05$ (the agreements between cell pitch and ribbon pitch were supported by Student's t-test)

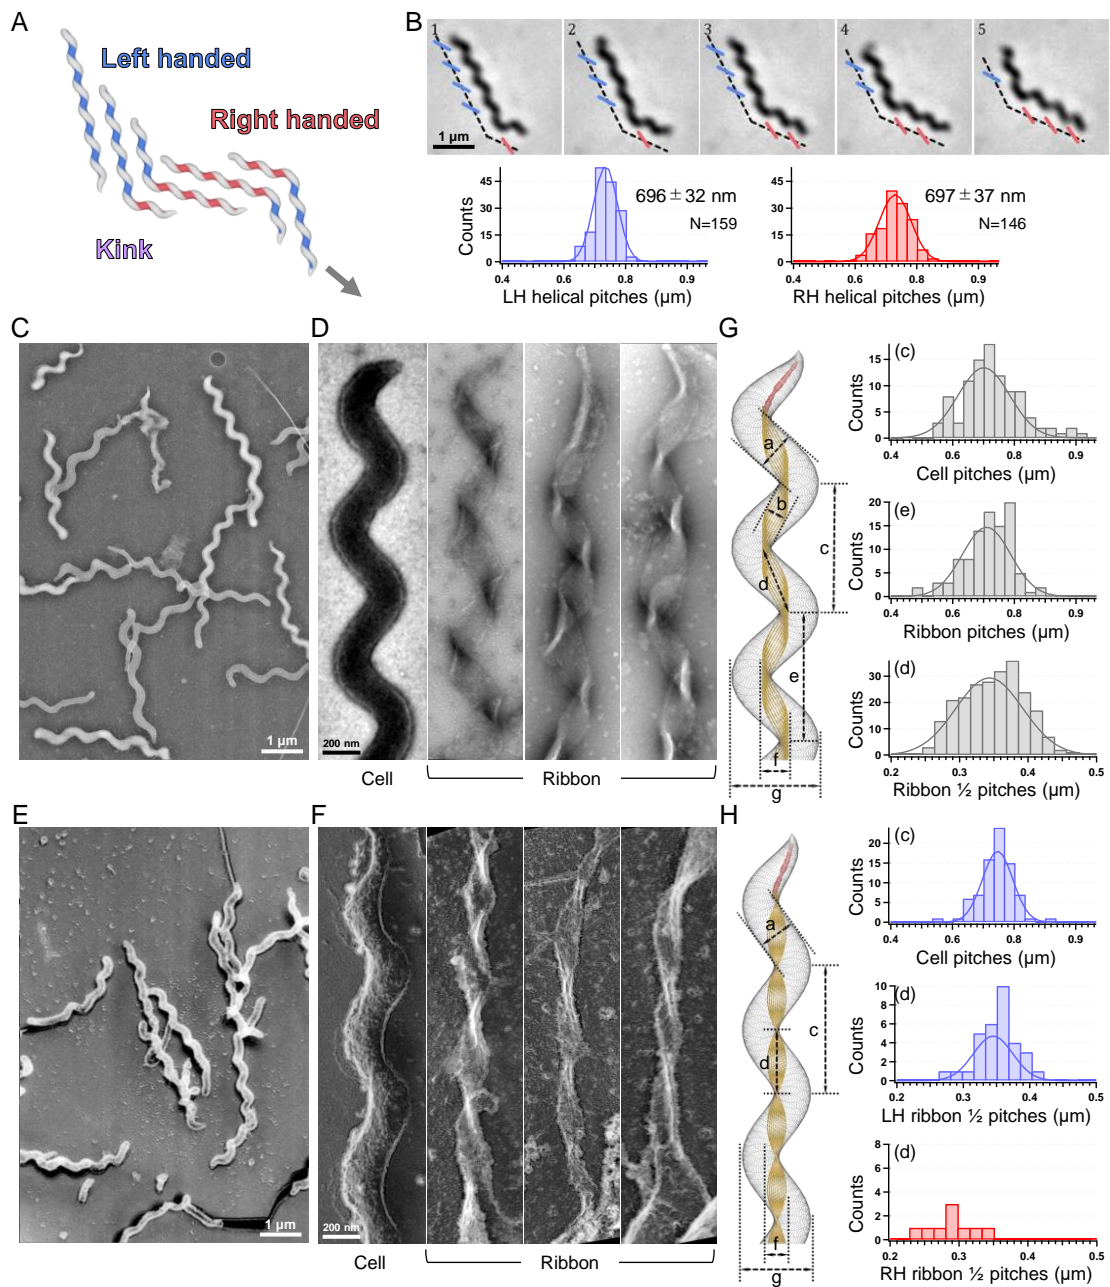

Figure 1. Cell helicity derived from the ribbon structure. (A) Schematic of helicity-switching swimming. The swimming direction is indicated by an arrow. (B) Phase-contrast microscopy of swimming cell. The blue and red segments indicate the left- and right-handed helicity, respectively (upper). Histograms of both left- and right-handed helical pitches of swimming cells, fitted by Gaussian curves with peak tops of 696 ± 32 and 697 ± 37 nm, respectively (lower). (C, E) Field image of cells acquired by negative-staining and quick-freeze, deep-etch (QFDE) electron microscopy (EM). (D, F) Intact cells (leftmost) and ribbons prepared on grids (others). (G, H) Dimensions marked in cell schematics (a)-(g) (left) are summarized in histograms (right) and Table 1.
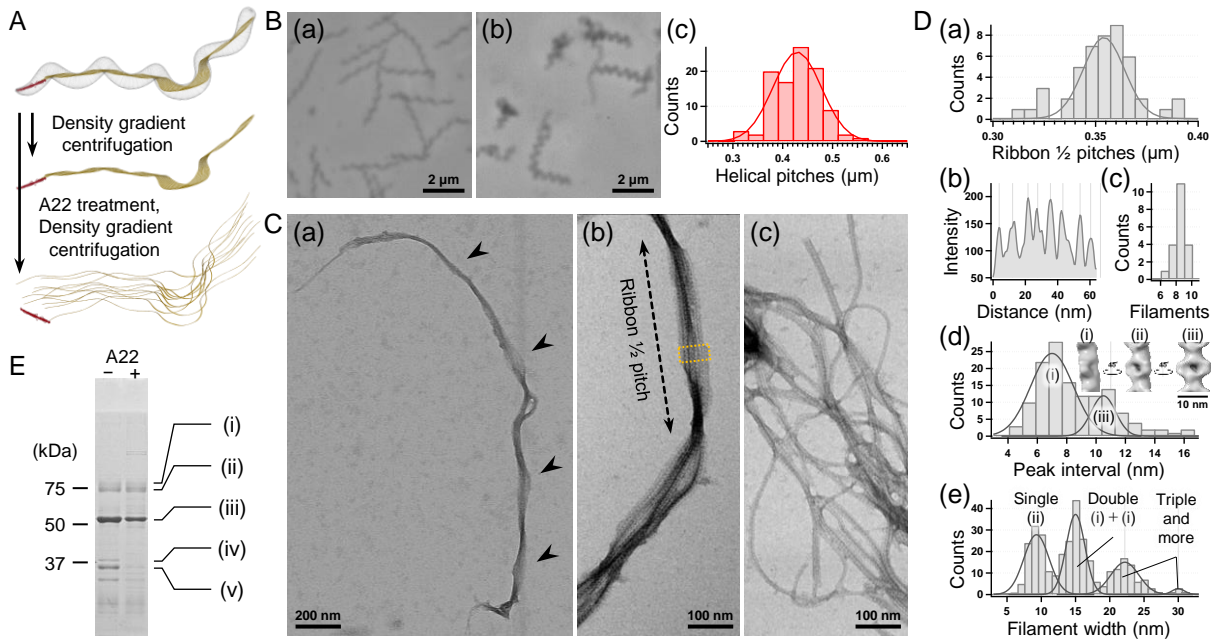

Figure 2. Isolation and characterization of ribbon. (A) Schematic for isolation and disassembly of ribbon. (B) Effects of A22 on swimming cells. (a) Untreated. (b) A22-treated for 2 min. (c) Histogram of the helical cell pitches after A22 treatment, fitted by a Gaussian curve with a peak at 426 ± 47 nm. (C) Electron microscopy (EM) observation of isolated ribbon fractions. (a) The whole structure of the isolated ribbon with helicity as shown by periodical wide positions (marked by arrows). (b) The magnified image of the isolated ribbon and the helical pitch is indicated by a bidirectional arrow. (c) Disassembled ribbon comprising protofilaments. (D) Numerical characterization. (a) Histogram for the helical pitches of the isolated ribbon, fitted by a Gaussian curve with a peak at 351 ± 16 nm. (b) Sectional image profile of the area boxed in panel (C-b). The peaks correspond to the center of the protofilament. (c) Histogram for the number of protofilaments involved in a ribbon. (d) Histogram for the protofilament width in ribbons. The distribution can be fitted by two Gaussian curves marked (i) and (ii), with peaks around 7.0 and 10.5 nm, respectively. (Inset) The images of the reconstituted structures viewed from different angles (refer to Fig. 4). (e) Histogram for the width of the protofilament in disassembled ribbons, fitted with three Gaussian curves with peak tops of 9.5, 15, 22.2, and 30.1 nm. (E) SDS-10% PAGE of the ribbon fraction isolated from original and A22-treated cells.
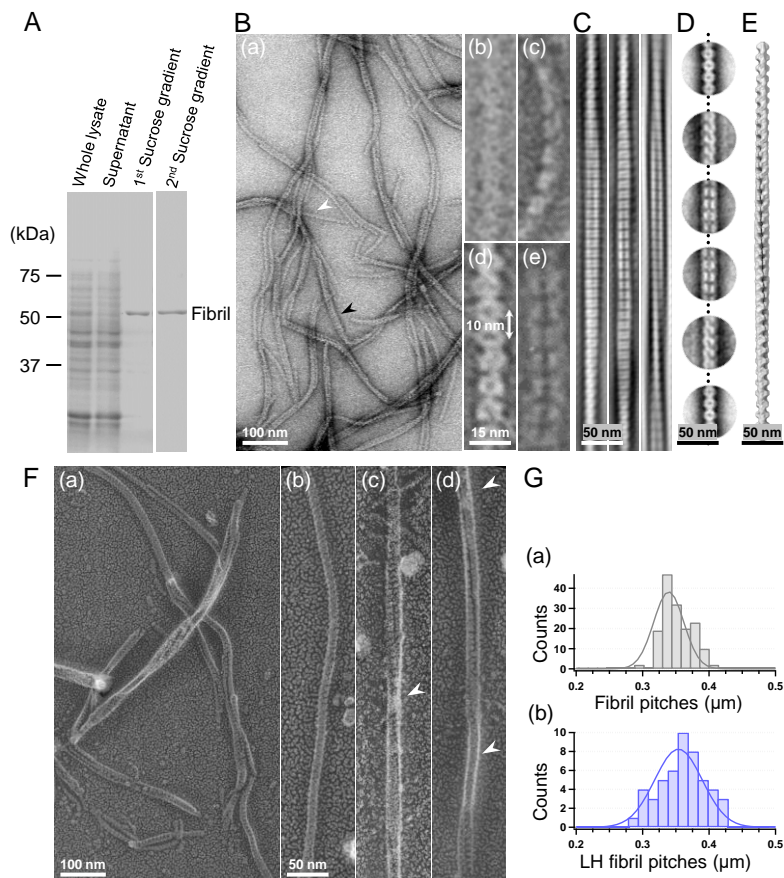

Figure 3. Helical pitches of the isolated fibril filament. (A) Protein profiles of fractions in purification process for fibril protein. (B) Purified fibril filaments observed by negative-staining electron microscopy (EM). (a) Field image. White and black arrows indicate single and double strands, respectively. (b, c) Front and side views of the single-stranded fibril filaments. (d, e) Front and side views of the double-stranded fibril filaments. (C) Double stranded filaments reconstituted through Fourier transformation. (D) Averaged images of double-stranded filaments reconstructed from 62, 11, and 23 images, respectively, for the topmost, second, and third panels. Repeated alignment of three images shown for comparison with panel (C). (E) Model for the double-stranded fibril filament (Refer to Fig. 4). (F) Fibril filaments observed by quick-freeze, deep-etch (QFDE)-EM. Field (a), single-stranded filament (b), and double-stranded filaments (c, d) are presented. (G) Histograms of the helical pitches for the fibril filaments measured for negative-staining (a) and QFDE (b) EM observations. Pitches were fitted by Gaussian curves with peaks at 343 ± 22 and 351 ± 34 nm.
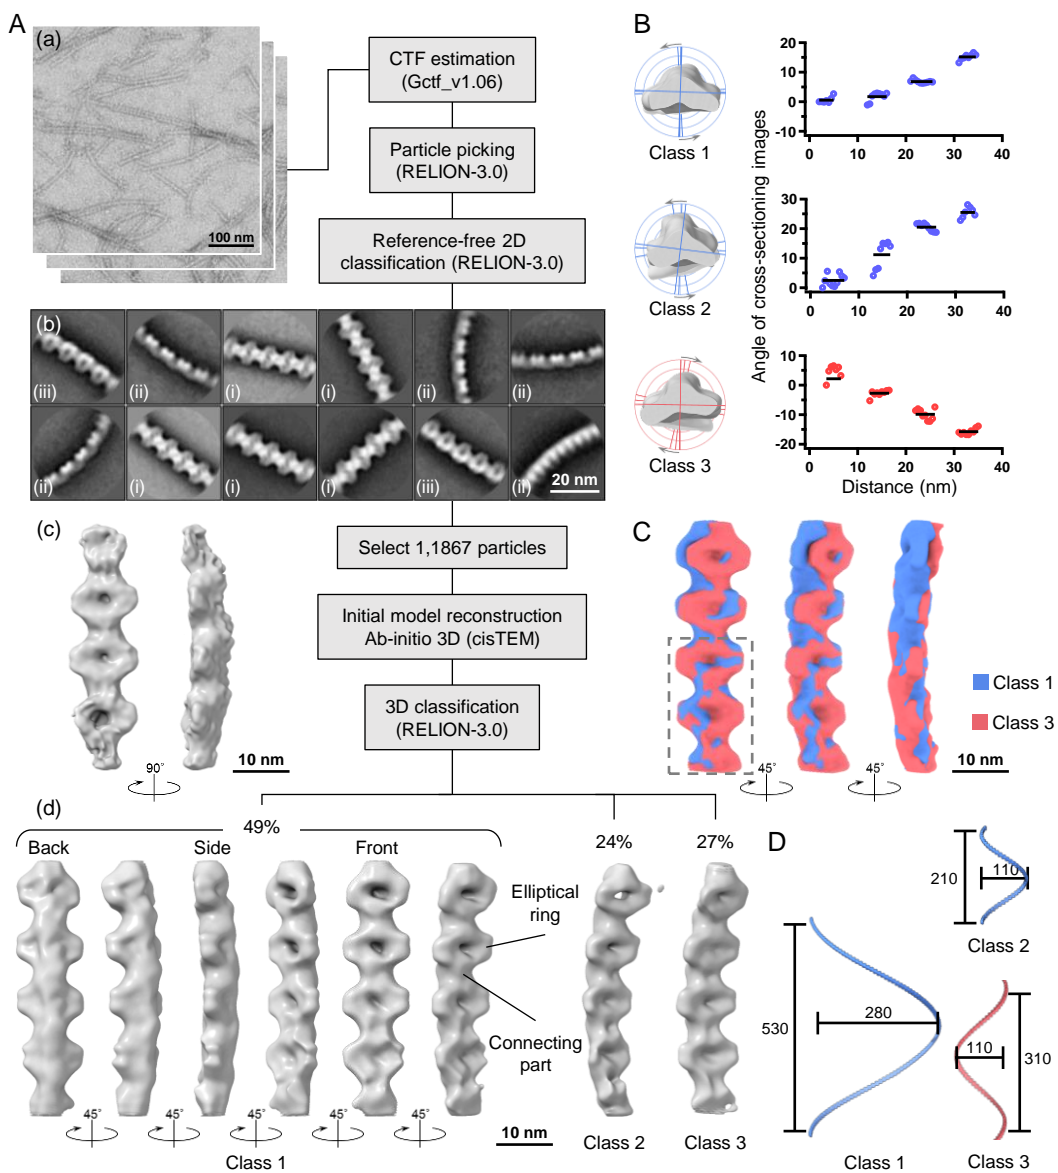

Figure 4. Three-dimensional reconstruction of fibril filaments. (A) Workflow of single particle analysis using negative-staining electron microscopy (EM). (a) Single-stranded fibril filaments prepared by sonication. (b) Averaged images by "2D classification." (c) Initial 3D model generated by *ab-initio* reconstruction of cisTEM software. (d) Three different conformations of the fibril filament reconstituted by "3D classification." (B) Rotation of repeated units along the filament axis. Feret diameter angles for the cross-sectional images were plotted along the filament in positions with a Feret diameter longer than 80% of the filament maximum (right). (C) Superimposition of class 1 (left-handed) and class 3 (right-handed) structures. The fitting reference is indicated by the dashed box. (D) Three types of fibril filament models showing 44 repeated units.
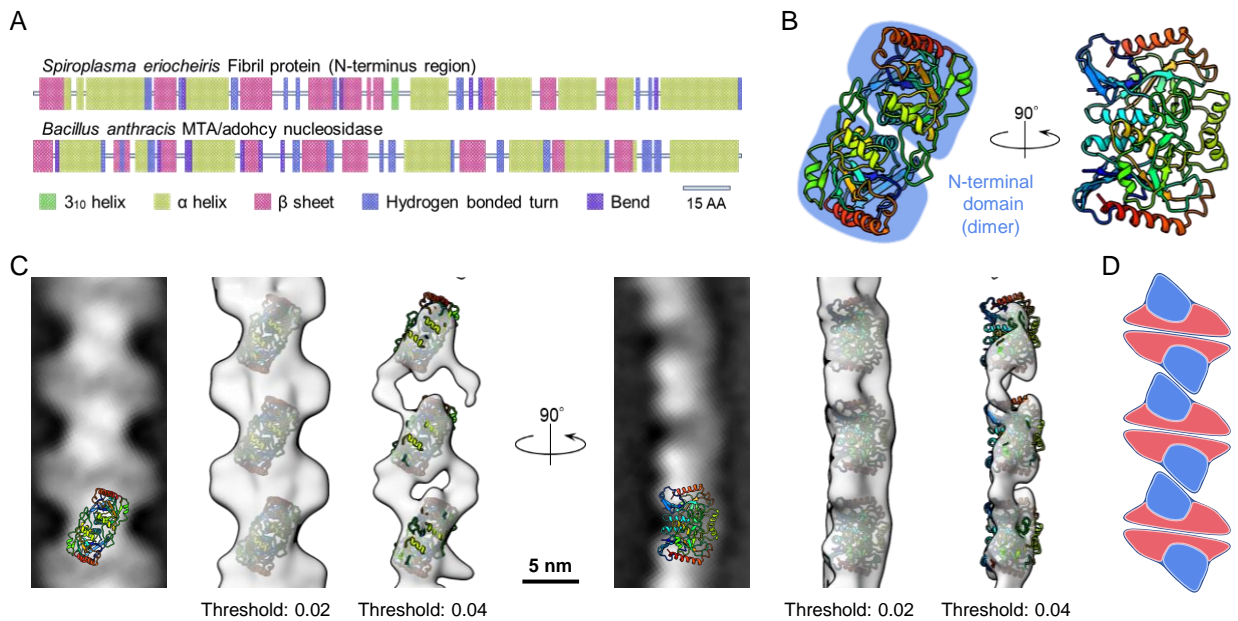

Figure 5. Assignment of predicted fibril protein structure to density map. (A) Comparison of the secondary structure predicted from amino acid sequences of the N-terminal region of fibril protein (upper) and methylthioadenosine/S-adenosylhomocysteine (MTA/SAH) nucleosidase of *Bacillus anthracis* (lower). (B) Predicted structure for N-terminal domain of fibril protein. The structure was predicted as a homodimer as marked by the blue background in the left image. (C) Alignment of predicted structure to density map. Two-dimensional averaged image (left in each) and fitting of N-terminal domain to density map of different thresholds (middle and right, in each) are viewed from two angles apart by 90 degrees. (D) Assignments of N-terminal (blue) and C-terminal (red) domains in the fibril filament.
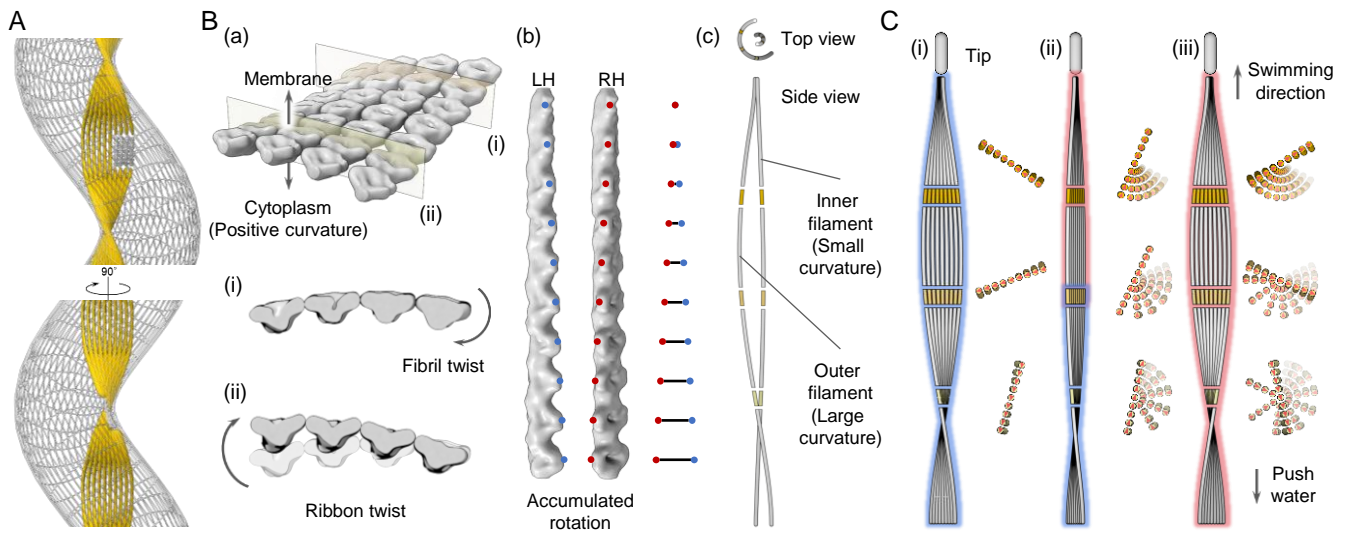

Figure 6. Model schematic for swimming. (A) Ribbon alignment along innermost line of helical cell body. (B) Relation between helicity of fibril filament and ribbon. (a) The ribbon comprises fibril filaments. Cross sections of the ribbon at positions (i) and (ii) are shown in lower panel. The filaments show positive curvature to the cytoplasmic side. The twists of individual fibril filaments result in the twist of the whole ribbon because the filaments bind to the neighboring filaments through their fixed positions. (b) The twist of the fibril filament accumulated through the stack of units. The horizontal positions of oval ends are shown for each unit. The positional difference of the end points is shown by lines between the red and blue dots. (c) Curvatures of the protofilament. For ribbon formation, each protofilament should take a different curvature. (C) Helix rotation caused by the accumulated twist (Movie_S3). The whole and small stack of ribbons are presented, respectively, in left and right, for each of three conformations (i), (ii), and (iii). The ribbon is stabilized by a "Tip" at the front end. The left-handed ribbon (i), the transition state of the ribbon from left-handed to right-handed by helicity-switching, with a switch point traveling from front to back (ii), and the resultant right-handed ribbon (iii) are presented. The left-handed and right-handed areas are marked by blue and red outlines, respectively. Rotation of small stacks from conformation (i) are presented by traces with transition from light to deep colors. The twist of the ribbon accumulates with the switch traveling. The rotations caused by the accumulated twist pushes water backward, resulting in the propelling force.
