COVID-19 Neuropathology: evidence for SARS-CoV-2 invasion of Human Brainstem Nuclei

3

4 **Abstract**

5 Neurological manifestations are common in COVID-19, the disease caused by SARS-CoV-

6 2. Despite reports of SARS-CoV-2 detection in the brain and cerebrospinal fluid of COVID-

7 19 patients, it's still unclear whether the virus can infect the central nervous system, and

8 which neuropathological alterations can be ascribed to viral tropism, rather than immune-

9 mediated mechanisms.

10 Here, we assess neuropathological alterations in 24 COVID-19 patients and 18 matched

11 controls who died due to pneumonia / respiratory failure. Aside from a wide spectrum of

12 neuropathological alterations, SARS-CoV-2-immunoreactive neurons were detected in

13 specific brainstem nuclei of 5 COVID-19 subjects. Viral RNA was also detected by real-time

14 RT-PCR. Quantification of reactive microglia revealed an anatomically segregated pattern

15 of inflammation within affected brainstem regions, and was higher when compared to

16 controls. While the results of this study support the neuroinvasive potential of SARS-CoV-2,

17 the role of SARS-CoV-2 neurotropism in COVID-19 and its long-term sequelae require

18 further investigation.

Introduction

Neurological manifestations are common in coronavirus disease 19 (COVID-19), the disease caused by severe acute respiratory syndrome coronavirus-2 (SARS-CoV-2)[1-5]. Symptoms range from anosmia, ageusia, dizziness and headache, which are commonly reported by patients with mild disease, to altered mental status, neuropsychiatric disorders, stroke, and, rarely, meningitis, encephalitis, and polyneuritis, which occur in hospitalized patients with severe disease[1,5]. Between 10 to 30% of people with SARS-CoV-2 infection experience long-term sequelae, referred as "long COVID", including neurological manifestations such as hyposmia, hypogeusia, headaches, fatigue, sleep disorders, pain, and cognitive impairment[3]. Despite some reports of detection of SARS-CoV-2 in the brain and cerebrospinal fluid of patients with COVID-19[2-3,6], it is still unclear whether the virus can infect the central nervous system (CNS). In particular, it still remains to be elucidated whether neurological manifestations and neural damage are a direct consequence of viral invasion of the CNS, are due to post-infectious immune-mediated disease, or are the result of systemic disease[1,6-11]. Studies on human neural cell cultures and brain organoids report conflicting data on SARS-CoV-2 neurotropism[12]. Overall, they suggest that SARS-CoV-2 does not infect and replicate efficiently in human neural cells, while it can replicate at high rates in choroid plexus epithelial cells[7,13-14]. At variance, intranasal inoculation of SARS-CoV-2 in transgenic mice overexpressing human ACE2 under the K18 promoter resulted in brain invasion and widespread infection of neurons, radial glia and neuronal progenitor cells[15-16]. Other coronaviruses, such as SARS-CoV and MERS-CoV, appear to be able to infect the CNS in both humans and animal models[17].

Data deriving from large autopsy studies in patients who died from COVID-19 suggest for the neuroinvasive potential of SARS-CoV-2 in the CNS[8-9,17], even though infection appears to be limited to sparse cells in the brainstem and not associated with encephalitis or other

49 specific changes referable to the virus[8]. Conversely, other studies failed to detect SARS-

50 CoV-2 antigens or genomic sequences in brain tissues of COVID-19 patients[11,17-18,37-38]. In

51 numerous instances, neuropathological changes in the brains of COVID-19 patients were

52 moderate and mainly represented by ischaemic lesions, astrogliosis, microglial nodules, and

53 cytotoxic T lymphocyte infiltrates, most pronounced in the brainstem, cerebellum, and

54 meninges[8-9,11,18,21]. While diffuse to focal hypoxic / ischaemic damage was a common finding

55 in COVID-19 patients across studies, no direct link between encountered neuropathological

56 alterations and direct viral invasion could be established, with systemic inflammation and

57 hypoxia playing a likely major role in mediating brain immune response[37]. Single-nucleus

58 gene-expression profiling of frontal cortex and choroid plexus tissues from severe COVID-

59 19 patients showed broad perturbations, with upregulation of genes involved in innate

60 antiviral response and inflammation, microglia activation and neurodegeneration[20], but no

61 direct evidence of viral tropism was found; similarly, Fullard et al.[38] were unable to detect

62 viral transcripts and S proteins in different brain regions of COVID-19 subjects. Deep spatial

63 profiling of the local immune response in COVID-19 brains through imaging mass

64 spectrometry revealed significant immune activation in the CNS with pronounced

65 neuropathological changes (astrocytosis, axonal damage, and blood-brain-barrier leakage)

66 and detected viral antigen in ACE2-positive cells enriched in the vascular compartment[18].

67 According to the study, the presence of viral antigen was linked to vascular proximity and

68 ACE2 expression, while also being correlated to the perivascular immune activation patterns

69 of CD8 and CD4 T cells and myeloid- and microglial-cell subsets[18], indicating a fundamental

70 role of the vascular and perivascular compartment, as well as Blood-brain-barrier

71 impairment, in mediating COVID-19 specific neuropathological changes. As evidenced by

72 the above case series, and considering the different case reports available[22-24], SARS-CoV-

73 2 infection of CNS seems to be limited to isolated cells within the perivascular compartment

74 of the brainstem and olfactory bulb, and have been reported in a subset of cases in the

75 various autopsy series, while widespread neuropathological sequelae (such as astrogliosis,

76 microgliosis, lymphocyte infiltration, microvascular injury, fibrinogen leakage) have been

77 documented in most examined specimens. The possibility of direct viral invasion, and

78 eventual associated long-term sequelae of infection, remain to be investigated.

79 In the present study, we assess the neuropathological changes of 24 patients who died

80 following a diagnosis of SARS-CoV-2 infection in Italy during the COVID-19 pandemic (from

81 March 2020 to May 2021) and 18 age-matched controls with comparable medical conditions

82 who died mainly due to pneumonia and / or respiratory failure.

Study design and Materials

84 Hospitalized patients who died following a diagnosis of SARS-CoV-2 infection in the Veneto

85 Region, Italy, during the peak incidence of COVID-19 (from March 2020 to May 2021) were

86 autopsied according to established COVID-19 infection security protocols. Inclusion criteria

87 for the study were: a) diagnosis of SARS-CoV-2 infection confirmed by molecular testing of

88 rhino-pharyngeal swabs and b) high-quality brain tissue samples available for

89 histopathological and immunohistochemical analysis. Tissue quality was determined by

90 Post-Mortem Interval (PMI) ≤5 days, absence of tissue maceration, fixation time ≤ 3 weeks

91 and adequate formalin penetration within the tissue. A total of 24 COVID-19 patients were

92 included in the study.

93 18 age- and sex-matched subjects with comparable general medical conditions, predating

94 the COVID-19 pandemic in Italy, were included as controls.

Methods

96 *Clinical information.* Available clinical data for COVID-19 subjects and controls were

97 examined, including ante-mortem medical history, neurological and neuroradiological

98 findings, hospitalization time, ICU and oxygen therapy status, and prescribed medication.

99   However, as most subjects died during the sanitary emergency of the first wave of the

100   COVID-19 pandemic in Italy, ante-mortem clinical data were at times limited, especially

101   when concerning post-hospitalization neurological status. This represents one of the main

102   limitations of our study, determining significant constrains to the association between ante-

103   mortem neurological findings and encountered neuropathological alterations, which is often

104   not unequivocal.

105   *Sampling and fixation procedures.* Sampled brains were immersion fixed in 4% phosphate-

106   buffered formalin solution following autopsy (mean PMI: 3 days; Range 0-5 days; average

107   fixation time: 2-3 weeks) and subsequently sectioned for histopathological and

108   immunohistochemical analysis. Samples of the cerebral cortex, basal ganglia,

109   hippocampus, cerebellar cortex, deep cerebellar nuclei, choroid plexuses and meninges

110   were obtained, while the brainstem was isolated at the level of the rostral extremity of the

111   midbrain and extensively sampled in its whole cranio-caudal extent. The 12 cranial nerves,

112   where available, including the olfactory bulb, tract and bifurcation, were also sampled. To

113   preserve antigen quality, a slow dehydration and clearing protocol was performed prior to

114   paraffin embedding (24h mean tissue processing time).

115   *Histochemical and immunoperoxidase staining.* Haematoxylin and Eosin staining was

116   employed for routine histopathological evaluation. Immunoperoxidase staining was

117   performed on a Dako EnVision Autostainer (Dako Denmark A/S, Glostrup, Denmark)

118   according to manufacturer recommendations. Antibodies for CD3 (Polyclonal Rabbit Anti-

119   Human, Citrate Buffer HIER, dilution 1:200, Dako Omnis, Code Number: GA503), CD20

120   (Monoclonal Mouse Anti-Human, Citrate Buffer HIER, dilution 1:200 Clone KP1, Dako

121   Omnis, Code Number: M0814) and CD68 (Monoclonal Mouse Anti-Human, EDTA Buffer

122   HIER, IHC dilution 1:5000, IF dilution 1:500, Clone L26, Dako Omnis, Code Number: M0756)

123   were employed to characterize lympho-monocytic infiltrations. Microglial Activation was

124 assessed using both CD68 (as above), HLA-DR Antibody (Monoclonal Rabbit Anti-Human,

125 Citrate Buffer HIER, dilution 1:50 Clone: LN-3, Invitrogen, Thermo Fisher Scientific,

126 Waltham, MA, USA), TMEM119 (Rabbit Anti-Human, Citrate Buffer HIER, dilution 1:250,

127 Abcam, Code Number: ab185333), while microglial proliferation was assessed using anti-

128 Ki-67 immunohistochemistry (Mouse Anti-Human, EDTA Buffer HIER, dilution 1:200, Spring

129 Bioscience, Code number: M3060). Anti-GFAP immunohistochemistry (Polyclonal Rabbit

130 Anti-Human, Proteinase K enzymatic antigen retrieval, dilution 1:1000, DAKO Omnis, Code

131 Number: GA524) was employed to assess reactive astrogliosis. Anti-CD61

132 immunohistochemistry (Monoclonal Mouse Anti-Human, Citrate Buffer HIER, dilution 1:75,

133 Clone Y2/51, Dako Omnis, Code Number: M0753) was also employed to evaluate the

134 presence of platelet-enriched microthrombi.

135 Anti-SARS-CoV-2 nucleocapsid (Rabbit Anti-Human, Citrate Buffer HIER, dilution 1:7000,

136 Sino Biologicals, 40143-R001) and -Spike Subunit 1 Antibody (Monoclonal Rabbit Anti-

137 Human, Citrate Buffer HIER, dilution 1:100, Clone 007, Sino Biological, Code Number:

138 40150-R007) immunostainings were employed to evaluate viral antigens within the tissue.

139 The expression of ACE2 Receptor protein (Rabbit Anti-Human Polyclonal, Citrate Buffer

140 HIER, dilution 1:2000, Abcam, Code Number: ab15348) and TMPRSS-2 protein (Rabbit

141 Anti-Human Monoclonal, Citrate Buffer HIER, dilution 1:2500, Abcam, Code Number:

142 ab242384) was assessed within the brainstem and cerebellum, and in all sections with

143 positive findings for viral proteins.

144 Anti-nucleocapsid and anti-spike antibodies were validated through SARS-CoV-2 infected

145 Vero E6 cells and autopsy-derived lung tissue from SARS-CoV-2 infected patients as

146 positive controls; non-infected cells and lung sections deriving from autopsy cases predating

147 COVID-19 pandemic (2017) were used as negative controls (Supplementary Figure 1).

148 Peroxidase reactions were repeated at least three times to ensure reaction consistency.

149 *Immunofluorescent staining and confocal microscopy*. Fluorescent immunohistochemistry

150 was performed manually. Antigen retrieval was performed on de-paraffinized tissue sections

151 using Dako EnVision PTLink station according to manufacturer recommendations. Following

152 antigen retrieval, autofluorescence was quenched with a 50 mM NH_4Cl solution for 10

153 minutes. Sections were treated with permeabilization and blocking solution (15% vol/vol

154 Goat Serum, 2% wt/vol BSA, 0.25% wt/vol gelatin, 0.2% wt/vol glycine in PBS) containing

155 0.5% Triton X-100 for 90 minutes before primary antibody incubation. The following

156 antibodies were employed: CD68 (#M0756; 1:500); TMEM119 (#ab185333; 1:200); Ki-67

157 (#M3060; 1:200); β-III Tubulin (#T8578; 1:300); Tyrosine Hydroxylase (#T2928; 1:6000);

158 SARS-CoV-2 Nucleocapsid Protein (#40143-R001; 1:3000); SARS-CoV-2 Spike Subunit 1

159 Protein (#40150-R007; 1:100); ACE2 Receptor Protein (#ab15348; 1:500) and TMPRSS-2

160 (#ab242384; 1:1000). Primary antibodies were diluted in blocking solution and incubated at

161 4°C overnight. Alexa-Fluor plus 488 Goat anti-Mouse secondary antibody (Code number:

162 A32723) and Alexa-Fluor plus 568 anti-Rabbit secondary antibody (Code number: A-11011)

163 were diluted 1:200 in blocking solution as above and incubated for 60 minutes at room

164 temperature. To further avoid background signal and tissue autofluorescence, slides were

165 incubated for 10 minutes in 0.5% Sudan Black B solution in 70% ethanol at room

166 temperature and abundantly washed with PBS, followed by Hoechst 33258 nuclear staining

167 (Invitrogen, dilution: 1:10000 in PBS) for 10 minutes. Slides were mounted and coverslipped

168 with Mowiol solution (prepared with Mowiol 4-88 reagent, MerckMillipore, Code number:

169 475904-100GM). Confocal immunofluorescence z-stack images were acquired on a Leica

170 SP5 Laser Scanning Confocal Microscope using a HC PL FLUOTAR 20x/0.50 Dry or HCX

171 PL APO lambda blue 40X/1.40 Oil objectives. Images were acquired at a 16-bit intensity

172 resolution over 2048 × 2048 pixels. Z-stacks images were converted into digital maximum

173 intensity z-projections, processed, and analyzed using ImageJ software.

174   *RT-PCR analyses*. Viral RNA analysis was performed on 20μm thick paraffin-embedded

175   sections collected in sterile 2ml Eppendorf vials; disposable microtome blades and tongs

176   were changed for each section to reduce contamination risk. Real-time RT-PCR analyses

177   were performed to detect SARS-CoV-2 genome sequences. Briefly, total RNA was purified

178   from selected material using a RecoverAll™ Total Nucleic Acid Isolation kit (Thermo Fisher

179   Scientific) following the manufacturer's instructions. One-step real-time RT-PCR assays

180   targeting SARS-CoV-2 nucleocapsid (N) coding region and subgenomic RNA were run on

181   ABI 7900HT Sequence Detection Systems (Thermo Fisher Scientific), as previously

182   reported[25].

183   *Histopathological and morphometrical evaluation*. Slides were examined by three

184   independent histopathologists and morphologists blind to patient clinical findings and

185   COVID-19 status. Disagreements were resolved by consensus. The degree of brainstem

186   hypoxic / ischaemic damage, astrogliosis and microgliosis were classified using a four-tiered

187   semi-quantitative approach for each evaluated section, while microglial density and

188   activation was assessed by the means of digitally-assisted immunoreactivity quantification

189   by three independent evaluators.

190   *Quantification of Activated Microglia.* The degree of microgliosis was assessed through a

191   digitally-assisted quantification approach at the level of the medulla, pons and

192   mesencephalon. For each subject, standard sections passing through the area postrema

193   (medulla), locus coeruleus (pons) and decussation of the superior cerebellar peduncles or

194   red nucleus (midbrain) underwent TMEM119 immunoperoxidase staining and TMEM119 /

195   CD68 double fluorescent immunohistochemistry. TMEM119+ structures with visible nucleus

196   and microglial-compatible morphology were classified as microglial cells, while TMEM119-

197   / CD68+ elements with compatible morphology were classified as monocyte/macrophages.

198   Ramifications and cell processes without a visible nucleus were excluded from our analysis

199 in order to avoid overestimation of cell densities by including neighboring structures

200 belonging to adjacent sections. Morphometrical evaluation occurred within six counting

201 fields (fields of view, FOV) spanning across the dorsal-to-ventral axis of the sections; FOV

202 boundaries and anatomical landmarks are summarized in Supplementary Table 1 for each

203 level of sectioning. The number of immunoreactivities per mm^2 was calculated for each

204 counting field and assigned to one anatomical compartment (i.e. tegmentum, tectum and

205 basis), based on their topography according to Mai and Paxinos[26]. Comparisons and

206 statistical evaluations were conducted per individual counting field, anatomical compartment

207 and level of section (medulla, pons, midbrain). To assess the degree of lysosomal-activity

208 as a marker for microglia phagocytic activity, CD68 immunoreactive area (expressed as

209 percentage of CD68+ immunoreactive area within a counting field, or A%) for 5 randomly

210 selected counting fields at each level of sectioning was computed through particle analysis

211 of the green fluorescent channel on ImageJ software.

212 *Statistical Analyses.* Statistical analyses and visualizations were performed using GraphPad

213 Prism 9. Differences in microglial densities (microglia / mm^2) within subgroups of the COVID-

214 19 cohort in figures 4A, 5A and 6A were analyzed by t tests with Welch's correction.

215 Microglial density between individual counting fields (FOVs) in COVID-19 subjects (Figures

216 4D, 5D, and 6D), as well as differences between anatomical compartments in COVID-19

217 subgroups (Figures 4B and 5B) and in COVID-19 versus controls (Figures 2E, 4C, 5B, 6E)

218 were determined by Welch one-way ANOVA tests corrected for Dunnett's multiple

219 comparisons. Correlation matrices in Figures 4E and 7G were computed as Spearman's rho

220 for continuous variables and as point-biserial correlations for nominal – continuous

221 variables. Spearman's rho and linear regression was performed in figure 2F. Further

222 statistical details for each plot can be found in the corresponding figure legend. Throughout

223 the manuscript * indicates $p < 0.05$, ** $p < 0.01$, *** $p < 0.001$ and **** $p < 0.0001$.

Results

The main cause of death in COVID-19 subjects was diffuse alveolar damage. Twenty-four COVID-19 patients were included in our study. In all patients, SARS-CoV-2 RNA was detected by molecular testing in rhino-pharyngeal swabs. Eleven were females, while 13 were males. The mean age of the included subjects was 73±13.7 years. Most included subjects were affected by preexisting chronic medical conditions. Eleven patients (7 female, 4 male) were affected by neurological or neurodegenerative disease prior to SARS-CoV-2 infection. Twenty-three patients were hospitalized prior to death. Patients were hospitalized for 14.5±11.3 days and died 1 to 34 days following admission. Eleven subjects were admitted to the ICU during hospitalization and received intensive oxygen therapy (IOT) (i.e. the administration of supplemental oxygen via nasal cannulae, face masks, or tracheal intubation). Fifteen subjects received antithrombotic therapy during hospitalization and were treated with corticosteroid medication. The available clinical data for our cohort is reported in Table 1.

The main cause of death of the control cohort was respiratory failure and pneumonia, aside from other relevant comorbidities. Eighteen age- and sex-matched subjects with comparable ante-mortem medical conditions were included as controls. All patients were negative for SARS-CoV-2 infection or died prior to the COVID-19 pandemic in Italy. Eight were female, while 10 were male. The mean age of included controls was 72±12 years. The mean hospitalization time was 20±15.6 days. Thirteen patients died due to pneumonia, while the remaining subjects died due to respiratory insufficiency, multiorgan failure or ischaemic heart disease. One patient died due to septic shock. Five patients had a clinical diagnosis of cognitive decline. The available clinical data for the control group are reported in Table 2.

Neuropathological examination

A wide spectrum of neuropathological alterations was detected in both COVID-19 and control subjects. The brains of 20 COVID-19 subjects displayed gross macroscopic abnormalities including mild-to-moderate generalized cerebral atrophy (N=9), diffuse cerebral edema (N=9) and chronic territorial ischaemic injury (N=6). Histopathological evaluation revealed diffuse hypoxic / ischaemic damage as a common finding in the COVID-19 cohort, with most subjects presenting mild-to-moderate diffuse hypoxic / ischaemic damage of the cerebral hemispheres and brainstem (Figure 1C), quantified according a four-tiered semi-quantitative scale (reported in Table 1). Furthermore, acute ischaemic injuries were evident in 5 patients. Small vessels were congested in most subjects with moderate perivascular extravasation at the level of the medulla, pons and deep cerebellar nuclei in 6 cases. Variable degrees of astrogliosis were evident in all subjects in all assessed regions, but were more pronounced at the level of the brainstem, as testified by GFAP staining (Supplementary Figure 3; semi-quantitative evaluation of astrogliosis across brain regions is available in Supplementary Table 2). Alzheimer Disease (AD) neuropathological changes, evaluated according to NIA-AA criteria, as well as Cerebral Amyloid Angiopathy (CAA) were detected in 5 subjects. In one case, Parkinson's Disease neuropathological alterations (i.e. deterioration of the ventrolateral substantia nigra and nigral lewy bodies) were found.

Control subjects presented similar macroscopic and histopathological alterations: mild-to-moderate generalized cerebral atrophy (N=7), mild-to-moderate diffuse cerebral edema (N=11) and chronic territorial ischemic injury (N=7); most subjects who died due to pneumonia or respiratory failure presented variable degrees of diffuse hypoxic / ischaemic damage, with mild to moderate damage of the brainstem being a common finding, similarly to COVID-19 subjects (Figure 1C); individual findings for hypoxic / ischaemic injury are reported in Table 2. Four subjects presented AD neuropathological changes and CAA, with

273   one subject presenting both AD and Lewy Body Dementia mixed pathology. The

274   macroscopic and histopathological findings of both COVID-19 subjects and controls are

275   reported in Table 1 and Table 2.

276

277   *CNS platelet-enriched microthrombi in small parenchymal vessels were detected in COVID-*

278   *19 subjects, but not in controls.* Small vessel thromboses were detected in 9 COVID-19

279   patients at the level of the pons, deep cerebellar nuclei and cerebral cortex, with one patient

280   presenting small vessel thromboses in multiple sites. No CNS or systemic thromboses were

281   detected in controls. In all COVID-19 cases, CD61 immunoperoxidase staining revealed

282   platelet-rich microthrombi in small parenchymal vessels, with no evidence of arachnoid of

283   meningeal vessels being involved, as seen in Figure 1D. Other organs were often affected,

284   such as the lungs, liver, intestine, and hypopharynx and even the carotid body[10,27-28], as

285   summarized in Table 1. In 3 out of 9 cases, microthromboses were identified only within the

286   CNS, while in the remaining 6 subjects, pulmonary thromboses were also detected.

287   Interestingly, 3 out of 9 subjects with CNS microthrombi were on antithrombotic medication,

288   4 were not actively treated prior to death, and in 2 cases clinical information regarding

289   antithrombotic medication was incomplete. In line with previous findings in literature, CNS

290   microthromboses appear to be peculiar to the COVID-19 cohort, with no control subject

291   presenting either fibrin- or platelet-enriched microthrombi in the CNS or other organs

292   regardless of the cause of death.

293

294   *Microglial cells with an activated phenotype and frequent microglial nodules were found in*

295   *COVID-19 subjects, but not in controls.* In 23 COVID-19 subjects parenchymal microglia

296   displayed an activated phenotype with characteristic thorny ramifications or amoeboid

morphology (Figure 2A-B). Interestingly, homeostatic microglial marker TMEM119 was consistently expressed in our cohort (Figure 2A-D), even though it is known to be downregulated upon microglial activation in various neuropathological conditions[36]. A similar pattern of immunoreactivity is also seen in Matschke et al.[8] and Schwabenland et al.[18]. Considering the relatively short hospitalization time prior to death of our COVID-19 cohort (14.5 days), and the similar immunoreactivity pattern compared to other available studies, it could be inferred that TMEM119 downregulation does not occur early in COVID-19.

While in both COVID-19 subjects and controls microglial marker TMEM119 and lysosomal-activity marker CD68 were found within the same cell (2A-D), COVID-19 subjects displayed a more widespread CD68+ immunoreactivity (2A-B), with statistically significant differences in CD68 immunoreactive area (A%) at the level of the medulla and midbrain, but not the pons, between the two groups (Figure 2E, Welch ANOVA W= 42.68; medulla p<0.0001; pons p=0.733; midbrain p<0.0001). Ki-67 immunoperoxidase staining, as well as Ki-67 / CD68 double label immunofluorescent staining did not reveal significant Ki-67 immunoreactivity ascribable to microglial cells, suggesting local microglial activation and migration without active proliferation in the considered cases. Microglial nodules associated with perineuronal HLA-DR+ / TMEM119+ / CD68+ cells were suggestive of neuronophagia in 18 COVID-19 subjects (Figure 3A-B, 4G, 6F) and were identified at the level of the substantia nigra (N=14), dorsal motor nucleus of the vagus (N=12), medullary reticular formation (N=9), area postrema (N=6) and basal ganglia (N=5); no microglial nodules were found in control cases, regardless of cause of death. Moreover, moderate to severe infiltration of CD68+/TMEM119- cells was found in 23 subjects (2A); given their prominent perivascular localization, these were likely monocyte-derived macrophages.

In COVID-19 subjects, a topographically defined pattern of microgliosis was found in the medulla oblongata and midbrain. At the level of the medulla oblongata, Welch one-way

323 ANOVA of individual counting fields (FOVs) (Figure 4C, F) revealed statistically significant

324 differences (p<0.001) in TMEM119+/CD68+ activated microglial cells between the

325 medullary tegmentum (T, FOV-13; 216,84±52,26 microglia / mm^2) and the ventral medulla

326 (pes, P, FOV4-6; 156,09±35,16 microglia / mm^2) (Figure 4E-F); no differences were found

327 between individual counting fields of the same anatomical compartment. Furthermore, no

328 significant differences were found when comparing microglial density between IOT and non-

329 IOT COVID-19 patients, as well as AD and non-AD patients with SARS-CoV-2 infection

330 (Figure 4A). When comparing microglial density between COVID-19 patients and the control

331 cohort, statistically significant differences were found when considering overall medullary

332 microgliosis, as well as single anatomical compartments (Figure 4C).

333 At the level of the pons, Welch one-way ANOVA of individual counting fields revealed

334 statistically significant differences only between the most dorsally located counting field

335 comprising the locus coeruleus (FOV1), and other counting fields (FOV2-6) (Figure 5D, C).

336 However, as for the medulla, no differences were found between IOT and non-IOT patients,

337 as well as for AD versus non-AD patients (Figure 5A). Differences in overall microgliosis, as

338 well as differences between anatomical compartments, were not significant between

339 COVID-19 subjects and controls (Figure 5B). Hence, while there appears to be a higher

340 degree of microgliosis in proximity to the locus coeruleus in COVID-19 when compared to

341 other regions of the pons, no differences were found within COVID-19 subgroups and when

342 compared to controls, indicating pontine microgliosis as a non-specific alteration in our

343 cohort (Figure 5E-F).

344 At the level of the midbrain, COVID-19 subjects presented marked topographical differences

345 between counting fields comprising the substantia nigra (midbrain tegmentum, FOV1-2 and

346 FOV3, Figure 6C) when compared to counting fields of the midbrain tectum and pes (FOV4-

347 6), as seen in Figure 6C-D. This anatomically segregated pattern of inflammation targeting

348 mainly the substantia nigra, but also part of the pre-acqueductal tegmentum, indicates an

349 increasing dorsal-to-ventral gradient of microgliosis which affects the gray matter of the

350 midbrain, sparing counting fields falling within the cerebral peduncle (FOV5-6). Similar to

351 other brainstem levels, no statistically significant differences in overall microgliosis were

352 found when comparing IOT and non-IOT subjects, as well as AD and non-AD subjects

353 (Figure 6A). When compared to controls, COVID-19 subjects presented significantly higher

354 microglial densities when considering both overall microgliosis, as well as microglial

355 densities within anatomical compartments (Figure 6E), suggesting for a COVID-19-specific

356 microglial response at the level of the midbrain (Figure 6F-G).

357 We also found a strong correlation between microglial densities across the different levels

358 of the brainstem, as well as CD68+ A% of the corresponding level, as summarized in Figure

359 2G. The strong positive correlation between microglial density and CD68 immunoreactive

360 area further underlines the activated phenotype displayed by microglial cells in COVID-19.

361 Interestingly, in the COVID-19 cohort, hospitalization time was positively correlated to

362 microglial density in the medulla (r= 0.44; p=0.044), but not with microglial density in the

363 pons and midbrain (Figure 2F). This appears to indicate an increase of microglial densities

364 in the medulla as infection progresses, while the levels of microgliosis within the rest of the

365 brainstem appear to remain relatively stable throughout time. Considering the numerous

366 instances of microglial nodules and neuronophagia encountered in the medulla of the

367 COVID-19 cohort, this is suggestive of prominent medullary impairment ongoing during

368 COVID-19, regardless of oxygenation status or prior neurodegenerative pathology.

369 Conversely, microglial density in the medulla also correlates with hypoxic / ischaemic

370 damage of the brainstem, evaluated along a four-tiered semi-quantitative scale (r= 0.59;

371 p=0.004), as also seen in Thakur et al.[37]. Hence, while microgliosis is strongly characteristic

372 of COVID-19 subjects and differs from controls, brainstem hypoxia / ischaemia plays a major

373 role in mediating medullary microgliosis, as seen in our cohort and in accordance to previous

374 literature.

375

SARS-CoV-2 Viral proteins were detected in neurons of the medulla and midbrain in a subset of COVID-19 subjects, but not in controls. Immunoperoxidase and immunofluorescent staining for SARS-CoV-2 spike protein and nucleocapsid protein was performed on all samples of included subjects, showing only positive results in cases with SARS-CoV-2 infection, but not in controls, indicating specificity. In particular, viral proteins were detected in seven subjects (#3, #7, #9, #10, #11, #17, #18) within CNS parenchyma and in five subjects (#3, #7, #9, #10, #17) with immunoreactive neurons within the anatomically defined boundaries of the solitary tract nucleus, dorsal motor nucleus of the vagus, nucleus ambiguus and substantia nigra (Figure 7A-D). As seen in double immunofluorescence labeling, SARS-CoV-2 Nucleocapsid protein antibody can be detected in β-III Tubulin (a pan-neuronal marker) immunoreactive structures, such as neuronal somata and neurites in the medulla and midbrain (Figure 7E-H), with no labeling in controls (Figure 7I). At the level of the midbrain, Nucleocapsid protein immunofluorescence was also found within tyrosine hydroxylase immunoreactive neurons and neurites of the substantia nigra, indicating the presence of viral antigens within dopaminergic neurons (Figure 8A-E). Some of these subjects (#7, #9, #11, #17, #18) also displayed endothelial cell immunoreactivity in small vessels of the cerebral cortex (subject #11), deep cerebellar nuclei (#17-18) hippocampus (#7) (Supplementary Figure 2) and midbrain (#9) (Figure 7H); small vessel thromboses, perivascular extravasation and hemorrhagic injury were found within affected regions of these cases.

In case #7, ischaemic injury of the right rostral hippocampal formation due to posterior cerebral artery (PCA) occlusion was associated with perivascular extravasation, edema, fibrinogen leakage and viral protein immunoreactivity within small vessel endothelium, further confirmed by RT-PCR. Acute hemorrhagic injury in the territory of the right middle cerebral artery (MCA) in #11 (Figure 1B) was associated with endothelitis within perilesional

401 tissue, displaying both viral protein immunoreactive endothelium and positive RT-PCR.

402 Similarly, the deep cerebellar white matter and dentate nuclei in cases #17-18 presented

403 small vessel thromboses and extensive hemorrhagic injury (case #17). Conversely, in some

404 cases with small vessel thromboses within the pons and frontal cortex (e.g. #19-20), viral

405 proteins and RNA was not detectable. There was no correlation between viral protein

406 immunoreactivity / RT-PCR Cycle threshold and hospitalization time (Figure 4E), suggesting

407 no apparent link between the detection of viral antigens and genomic sequences and post-

408 infection interval. However, the actual length of infection, particularly prior to hospitalization,

409 could not always be safely determined, as pre-symptomatic infection could not be excluded,

410 nor evaluated, from the available clinical data. ACE2 receptor protein and TMPRSS2 protein

411 immunoreactivity was compatible with the anatomical distribution of SARS-CoV-2 antigens

412 (Supplementary Figure 1, E-F), as detected with immunoperoxidase staining, but was not

413 consistently replicated in immunofluorescent staining (data not shown). Both proteins were

414 moderately expressed in vascular endothelial cells and brainstem neurons.

415

416 *RT-PCR analyses of FFPE tissue sections detected viral RNA in COVID-19 cases with viral*

417 *protein immunoreactivity.* Molecular testing by real-time RT-PCR detected SARS-CoV-2

418 RNA in 10 out of 24 COVID-19 subjects, 9 of whom had also SARS-CoV-2 S and/or N

419 protein-positive IHC / IF (Figure 7L-M, Supplementary Table 2). In positive tissue samples,

420 threshold cycles (Ct) of real-time RT-PCR for SARS-CoV-2 RNA ranged between 33 and

421 38, while in all samples the Ct values of the internal control RNAseP ranged between 27

422 and 34. The cycle threshold values for each analyzed section are reported in Supplementary

423 table 2 and in Figure 7L-M for the medulla and midbrain. SARS-CoV-2 subgenomic RNA

424 was investigated but not detected in our specimens, likely due to RNA degradation within

425 FFPE sections, as indicated by the low Ct values of RNAse P.

426 *Viral antigens are associated to higher microglial densities within affected anatomical loci,*

427 *but no differences are found in overall microgliosis, suggesting a specific topographical*

428 *response.* While overall levels of microgliosis within the medulla, pons and midbrain did not

429 differ significantly between COVID-19 subjects with and without detectable viral antigens,

430 Welch one-way ANOVA between anatomical compartments (i.e. tegmentum, tectum and

431 pes) revealed statistically significant differences within the COVID-19 cohort. Indeed,

432 subjects with detectable viral genomic sequences and antigens (RT-PCR+/IHC+) were

433 characterized by higher microglial densities in the medullary (p=0.017) and midbrain

434 tegmentum (p=0.0074) when compared to negative (RT-PCR-/IHC-) COVID-19 subjects, as

435 seen in Figure 4B and 6B. In association with frequent instances of microglial nodules and

436 perineuronal TMEM119+/CD68+ microglial cells suggestive of neuronophagia (Figure 3A-

437 B), this finding suggests a peculiar microglial response towards anatomical loci of the

438 brainstem in which SARS-CoV-2 antigens were detected, even though overall levels of

439 microgliosis within brainstem regions did not appear to differ significantly. Taken together

440 with little-to-no Ki-67 immunoreactivity and no detectable Ki-67+ / CD68+

441 immunofluorescent signal, migration of microglial cells towards the site of injury appears to

442 be the more likely mechanism occurring in COVID-19 inflammation, rather than microglial

443 proliferation within affected regions.

444

Discussion

446 In the present study, the neuropathological findings of 24 COVID-19 patients were examined

447 and compared with age- and sex-matched controls who died due to pneumonia and / or

448 respiratory insufficiency. Our findings indicate, in line with some of the previous autopsy

449 reports, specific neuropathological alterations in the brains of COVID-19 patients, with

450 particular regard to topographically-defined microgliosis within anatomical loci of the

451 brainstem and viral immunoreactivity in specific CNS compartments, either within the

452 boundaries of brainstem nuclei or in the context of ischaemic and hemorrhagic injuries.

453 Platelet and fibrin microthrombi, in particular, were characteristic findings of the COVID-19

454 cohort, and often affected multiple organs, such as the lungs, liver, intestine, hypopharynx

455 and even the carotid body[10,27-28], as summarized in Table 1. Microthromboses were more

456 frequent within the pons, deep cerebellar nuclei and cerebral cortex. In some cases,

457 hemorrhagic injury and microthromboses were found in regions with viral protein

458 immunoreactivity in vascular endothelial cells.

459 SARS-CoV-2 viral antigens, on the other hand, were confined to specific loci of the CNS. As

460 seen in Figure 7A-H, SARS-CoV-2 appears to be localized preferentially within neurons of

461 the vagal nuclei of the medulla and the substantia nigra, with the exception of one subject

462 who also presented immunoreactive cells throughout the whole brainstem (#3). While

463 Matschke et al.[8] reported SARS-CoV-2 invasion of cranial nerves IX-X, we were unable to

464 replicate these findings within our cohort; furthermore, unlike Meinhardt et al.'s findings[9],

465 viral proteins and RNA were not detectable in any of the sampled olfactory bulbs, tracts and

466 bifurcations, even though moderate edema, moderate-to-severe astrogliosis and moderate

467 microglial activation was encountered in most cases in our study. ACE2 Receptor and

468 TMPRSS-2 protein immunohistochemistry support this topographical localization, with

469 neurons within the dorsal motor nucleus of the vagus, solitary tract nucleus, nucleus

470 Ambiguus and Substantia Nigra being moderately immunoreactive (Supplementary Figure

471 1, E-F).

472 While previous studies identified viral protein immunoreactivity in sparse cells throughout

473 the brainstem[8-18] without specific topography, our findings appear to be in line with available

474 animal studies on other coronaviruses, i.e. SARS-CoV and MERS-CoV, which are known to

475 be able to infect the brainstem, and particularly the dorsal motor nucleus of the vagus,

476 solitary tract nucleus and nucleus ambiguus, so that an analog pattern of neuroinvasion for

477 SARS-CoV-2 has been suggested[17,29-31]. The peculiar and unexpected finding in our cohort

478 was the detection of viral antigens and genomic sequences within the substantia nigra, not

479 matching any known models of coronavirus neurotropism. Interestingly, SARS-CoV-2 S and

480 N protein were detected in both tyrosine hydroxylase positive and negative neurons (Figure

481 8). Immunoreactive neurons of the substantia nigra were frequently found in proximity to

482 blood vessels, which were at times immunoreactive to viral proteins as well (Figure 7H,

483 Supplementary Figure 2). Hence, aside from olfactory-transmucosal transmission identified

484 by Meinhardt et al.[9], and vagus/glossopharyngeal-mediated invasion identified by Matshke

485 et al.[8], SARS-CoV-2 may gain access to other districts of the CNS either through a yet-

486 unknown neuronal route or, as suggested by our findings in the midbrain and as seen in

487 Schwabeland et al.'s study[18], by crossing the blood-brain-barrier and infecting structures of

488 the peri- and juxtavascular compartment. We believe these findings encourage further

489 research on the possibility that these events may be the trigger of a neurodegenerative

490 process such as Parkinson disease in susceptible individuals. Future studies on COVID-19

491 survivors and Long COVID patients are therefore warranted[39].

492 However, despite the detection of viral proteins and genomic sequences in restricted regions

493 of the brainstem, we found no evident neuropathological alterations in SARS-CoV-2 infected

494 cells, such as necrotic changes and other cytological alterations, that could hint towards

495 possible direct consequences of viral invasion in human neurons. COVID-19 is

496 characterized by different evolutionary phases and heterogeneous individual responses,

497 and the short interval between infection and death in our cohort (mean hospitalization time

498 = 14 days), as well as the fact that included patients died during the acute phase of the

499 disease, may not be sufficient to determine detectable neuropathological alterations in

500 affected cells as a direct consequence of viral invasion, which may require more time to

501 develop[3,31]. Lastly, the detection of viral proteins in a subset of patients (5 out of 24), as

502   seen in this and previous studies may be related to the particularly severe disease, and

503   concurring comorbidities, of the patients subject to neuropathological examination.

504   Hence, while the consequences of SARS-CoV-2 neurotropism in the medulla have been

505   widely discussed in literature, and are supported by the detection of viral proteins and

506   genomic sequences in our study, the absence of direct neuronal damage and the

507   impossibility of performing functional assays on post-mortem samples should be taken into

508   consideration when discussing the clinical implications of COVID-19 neuropathology. Future

509   studies on "long COVID" patients[3] may be able to shed a light on the long-term

510   consequences of COVID-19, particularly concerning the detection of SARS-CoV-2 within

511   the CNS after the acute phase of the disease, and whether or not this leads to specific

512   neuropathological alterations as a consequence of viral invasion.

513

514   Concerning microglial activation and density, our findings appear to be in line with

515   Schwabenland et al.[18], who identified microglial nodules and parenchymal reactive microglia

516   as hallmark for COVID-19, in contrast to both controls and ExtraCorporeal Membrane

517   Oxygenation (ECMO) patients. In our cohort, patients with pneumonia and / or respiratory

518   failure served as control group and, although also characterized by microglial activation,

519   displayed lower microglial counts in the medulla and midbrain, but not in the pons, when

520   compared to COVID-19 subjects. We also found no significant effect of oxygen therapy on

521   microglial density within the COVID-19 group. Conversely, Deigendesh et al.[33] found

522   significant differences in HLA-DR+ activated microglia when comparing COVID-19 subjects

523   to non-septic controls, but no differences were found with patients who had died under septic

524   conditions; according to the authors[33] this may represent a histopathological correlate of

525   critical illness-related encephalopathy, rather than a COVID-19-specific finding. Aside from

526   the distinct populations serving as control subjects, significant methodological differences

527   between these studies must be taken into consideration. Our approach to microglial

528 quantification was more similar to Schwabenland et al.[18], as digitally-assisted manual

529 counting of TMEM119+ cells, a homeostatic microglia-specific marker, was performed to

530 estimate microgliosis; however, we also expanded on these findings by estimating

531 microgliosis in a topographically dependent manner by employing set counting fields within

532 anatomically defined regions; conversely Deigendesh et al.[33] quantified HLA-DR

533 immunoreactive area, a marker expressed on both microglia and on infiltrating lympho-

534 monocytic cells, as a fraction of the counting field (A%), and not as individual particles.

535 Hence, while our estimation selectively reflects the activity of microglial cells in COVID-19

536 and pneumonia controls within anatomically defined regions of the brainstem, Deigendesh's

537 study offers a broader representation of overall brainstem inflammation under different

538 conditions, including patients deceased under septic conditions, explaining differences

539 between our studies.

540 Interestingly, while no evidence of direct neuronal damage was found in SARS-CoV-2

541 infected cells, microglial densities within affected anatomical loci differed between subjects

542 with and without detectable viral antigens and genomic sequences (RT-PCR/IHC+ versus

543 RT-PCR/IHC- in Figure 4B and 6B), suggesting a link between the detection of SARS-CoV-

544 2 antigens and microglial response. Conversely, overall microglial density (i.e. without

545 topographical delineation) did not differ between the two groups, and a strong correlation

546 between microgliosis and hypoxic / ischaemic damage at the level of the brainstem was

547 found. Hence, while we found a suggestive link between microgliosis and the detection of

548 SARS-CoV-2 antigens in our cohort, other factors such as hypoxia / ischaemia and systemic

549 inflammation / cytokine storm ongoing during COVID-19, as previously reported by Thakur

550 et al[37], are likely to play a more prominent role in determining brainstem microgliosis, in

551 accordance to previous studies[33].

552

Conclusions

The present study contributes to define the spectrum of neuropathological alterations in COVID-19, as well as the neuroinvasive potential of SARS-CoV-2 within the CNS. Unlike previous findings, we have documented a subset of COVID-19 cases in which viral proteins and genomic sequences were detectable within anatomically defined regions of the CNS. Similarly, microglial activation in the brainstem appears to differ between COVID-19 and pneumonia / respiratory failure controls, with the former also presenting a pattern of increased microglial density in specific compartments of the medulla and midbrain. However, despite this evidence supporting the neuroinvasive potential of SARS-CoV-2, neuropathological alterations encountered in our cohort cannot be ascribed to viral antigens detected in the brainstem. In line with other studies in literature, hypoxic / ischaemic damage and systemic inflammation likely represent major contributors in determining neuropathological alterations in COVID-19, with little-to-no evidence indicating direct viral damage of the central nervous system in humans. Moreover, further investigation is required to determine whether or not SARS-CoV-2 neurotropism represents a major component of COVID-19 in the general population, as subjects included in neuropathological studies often present a much more severe course of the disease and major medical comorbidities. Nevertheless, the findings of our study suggest the possibility that, although not frequently, SARS-CoV-2 may gain access to specific regions of the central nervous system, especially the vagal nuclei of the medulla and the substantia nigra in the midbrain. As direct neuropathological alterations determined by SARS-CoV-2 neurotropism may not be detectable in subjects deceased during the acute phase of the disease, future studies are required to determine whether or not SARS-CoV-2 neurotropism is present in chronic COVID-19 patients, or in COVID-19 survivors suffering from the long-term effects of infection, and if eventual neuropathological alterations in these subjects can be ascribed to viral tropism, rather than immune-mediated mechanisms.

Limitations of the study

This study is based on post-mortem tissue samples obtained during the first wave of the COVID-19 pandemic in Italy. While the neuropathological alterations encountered in our work contribute to define the pathological mechanisms of COVID-19 and SARS-CoV-2 infection in the CNS, the lack of exhaustive post-infection neurological evaluation of included patients does not allow for unequivocal clinico-pathological correlations. It must also be considered that most patients included in the study died during the peak of the sanitary emergency in Italy, one of the first countries to face the COVID-19 pandemic in Europe, and neurological evaluation was not always possible. Hence, it remains to be determined whether the neuropathological alterations observed in this study are also linked to neurological symptoms, and whether they are also present in COVID-19 survivors.

Unlike previous studies in literature, we have included 18 controls who died due to pneumonia, respiratory insufficiency or multiorgan failure, rather than healthy controls. Retrospective selection of control subjects, however, could lead to unwanted selection bias. Furthermore, from the available clinical data of our controls, we have found no instances of intensive oxygen therapy or mechanical ventilation, but incompleteness of available clinical records cannot entirely be excluded. For this purpose, we have also performed comparisons within the COVID-19 group, identifying no statistically significant differences between subjects with and without neurodegenerative conditions, and no influence of oxygen therapy on brainstem microgliosis. The involvement of other brain regions, such the cerebral and cerebellar cortex and the basal ganglia, cannot be excluded but is beyond the scopes of this study. Moreover, as all patients died during the first wave of the COVID-19 pandemic, our findings may not reflect the possible neuropathological alterations encountered in patients affected by SARS-CoV-2 variants.

603   Limitations to viral antigen / RNA detection in our study must also be considered. Real-time

604   RT-PCR cannot exclude detection of viral RNA in blood vessels within samples. While

605   particular care was taken to avoid contamination by employing sterile instruments and

606   disposable microtome blades when sampling FFPE sections for RT-PCR analyses, the main

607   strength of our study was the complementary use of immunoperoxidase and

608   immunofluorescent staining with different antibodies to detect viral antigen as an indicator

609   of viral tropism. This is further strengthened by the strong concordance between these

610   assays in our cohort, quantified by a statistically significant positive correlation between RT-

611   PCR cycle threshold and IHC positivity (r=0.87, p<0.0001).

612   In conclusion, further investigation is required to determine the direct effects of viral invasion

613   within the CNS, with particular regard to cases of long-lasting infection and in COVID-19

614   survivors.

A) Welch corrected T-test plot of microglial densities (microglia / mm^2) in the pons of COVID-19 subjects with (n=5, red) and without (n=16, black) Alzheimer's Disease neuropathological changes (p>0.05), and of COVID-19 subjects treated (n=10, red) and not treated (n=13, black) with intensive oxygen therapy (p>0.05). **B)** Welch one-way ANOVA between anatomical compartments (T, tegmentum; P, pes) between COVID-19 subjects (n=23, red) and controls (n=18, black) reveals no statistically significant differences either at the level of the medullary tegmentum (p=0.55) and pes (p=0.98). **C)** Anatomical heatmap of activated microglia within the pons in COVID-19. **D)** Welch one-way ANOVA of microglial densities per counting fields (FOV) reveals statistically significant differences between FOV1 (dorsal pons, including locus coeruleus) with other pontine counting fields. **E-F)** TMEM119 immunoperoxidase staining of comparable regions of the pons in COVID-19 subjects (above) and controls (below).

Figure 6. A) Welch corrected T-test plot of microglial densities (microglia / mm^2) in the midbrain of COVID-19 subjects with (n=5, red) and without (n=16, black) Alzheimer's Disease neuropathological changes (p>0.05), and of COVID-19 subjects treated (n=10, red) and not treated (n=11, black) with intensive oxygen therapy (p>0.05). **B)** Welch one-way ANOVA between anatomical compartments (TG, tegmentum; TC, tectum; P, pes) between COVID-19 subjects with (n=5, red) and without (n=18) viral tropism (RT-PCR/IHC+ versus RT-PCR/IHC-) reveals statistically significant differences at the level of the midbrain tegmentum (p=0.0074), but not other anatomical districts. **C)** Anatomical heatmap of activated microglia within the medulla oblongata in COVID-19. **D)** Welch one-way ANOVA of microglial densities per counting fields (FOV) reveals statistically significant differences between FOVs of the Tegmentum (T; FOV1-2) when compared to FOVs of the Pes (P; FOV5-6), suggesting for a localized pattern of microgliosis comprising the preacqueductal tegmentum and the substantia nigra.   **E)** Welch one-way ANOVA between anatomical compartments (TG, tegmentum; TC, tectum; P, pes) between COVID-19 subjects (n=23, red) and controls (n=18, black) reveals statistically significant differences between all anatomical districts of the midbrain (p<0.0001). **F-G)** TMEM119 immunoperoxidase staining of comparable regions of the midbrain in COVID-19 subjects (above) and controls (below). Inset: perineuronal microglia in the substantia nigra. COVID-19 subjects often present distinct microglial nodules.

Figure 7. Topographical localization of SARS-CoV-2 Viral Protein Immunoreactivities (Triangles, Right Half) and Microglial Nodules (Asterisks, Left Half) throughout the brainstem. **A)** At the level of the Mesencephalon, Immunoreactivities are found mainly within the boundaries of the substantia nigra, with the exception of Subject #3, which also presented immunoreactive neurons within the Interstitial Nucleus of Cajal; Microglial

nodules were confined mainly within the boundaries of the tegmentum, and were not detected neither within the pes nor the tectum. **A1)** SARS-CoV-2 Spike Protein IHC at the level of the Substantia Nigra reveals immunoreactive neurons (mean of 2 immunoreactivities per mm^2) with well-marked processes (black arrows); negative neurons can also be found nearby (white arrows). **A2)** SARS-CoV-2 Nucleocapsid Protein IHC reveals a similar pattern of immunoreactive neurons and axons throughout the substantia nigra. **B)** At the level of the pons, Subject #3 presented immunoreactive neurons (mean of 5 immunoreactivities per mm^2) within the basilary nuclei, while microglial nodules were found both within the basis, as well as the dorsal pons in proximity to the facial nucleus. **B1)** SARS-CoV-2 Spike Protein IHC at the level of the pons in Subject #3, displaying immunoreactive neurons (black arrows) within the basilary nuclei of the pons; non-reactive cells can also be appreciated (white arrows) **C)** At the level of the upper medulla oblongata, immunoreactivities were found at the level of the dorsal motor nucleus of the vagus, solitary tract nucleus and nucleus ambiguus; microglial nodules were prominent within the Vagal Trigone and Area Postrema, but were also found within the reticular formation and the inferior olivary complex. **C1-2)** SARS-CoV-2 Spike Protein IHC at the level of the solitary tract nucleus and nucleus ambiguus; immunoreactive neurons can be seen within the anatomical boundaries of these nuclei (black arrows), along with non-reactive cells (white arrows). Inset of a single reactive neuron within the solitary tract nucleus, Spike Protein immunohistochemistry. **D)** At the level of the Lower Medulla Oblongata, Immunoreactivities were found at the level of the spinal trigeminal nucleus and medullary reticular formation. Microglial nodules were found within the medullary reticular formation. **D1)** SARS-CoV-2 Spike Protein IHC at the level of the medullary reticular formation in the lower medulla (black arrows); non-reactive cells are indicated with a white arrow. **E-I)** Double label N and S Protein (red) and Beta-III Tubulin (green) fluorescent immunohistochemistry in COVID-19 subjects (E-H) and controls (I). Distinct immunoreactive neurons and neurites can be appreciated in both the medulla (dorsal motor nucleus of the vagus) and midbrain (substantia nigra) (E-G). Juxtavascular immunoreactive neurons in proximity to an immunoreactive vessel in the midbrain of COVID-19 subject #9 (H, inset). Control subjects present no viral protein immunoreactivity (I). **L-M)** N and S protein IHC, real time RT-PCR Cycle Thresholds for SARS-CoV-2 N Gene and RNAseP quality control in our COVID-19 cohort at the level of the medulla (L) and midbrain (M).

Figure 8. Double label N Protein (red) and Tyrosine Hydroxylase (green) fluorescent immunohistochemistry at the level of the substantia nigra in the midbrain. **A-C)** in COVID-19, Both TH+ and TH- neurons display N protein immunoreactivity. **D-E)** in COVID-19 subjects with negative RT-PCR/IHC (D) as well as non-COVID controls (E) no N protein staining was detected.

#9	71	F	40	Y	3	NA	NA	Diffuse hypoxic/ischaemic damage	Moderate to severe	No	Acute respiratory failure, septic shock, peritonitis
#10	46	F	15	N	4	No signs	No signs	Diffuse hypoxic/ischaemic damage	No detectable microscopical changes	No	Respiratory insufficiency, multiorgan failure, cervical neoplasia
#11	75	F	20	Y	5	Chronic Ischaemic Vascular disease, Cerebral atrophy	NA	Vascular dementia, ischaemic vascular disease, diffuse hypoxic/ischaemic damage	Moderate	No	Pneumonia, acute respiratory failure, candidosis
#12	80	F	8	Y	4	Cerebral atrophy	Cognitive decline, Alzheimer type	AD neuropathological changes, diffuse hypoxic/ischaemic damage	Moderate	No	Pentalobar pneumonia, respiratory insufficiency
#13	81	F	NA	Y	3	NA	NA	Diffuse hypoxic/ischaemic damage	Mild	No	Pneumonia, acute respiratory failure
#14	63	F	NA	N	3	No signs	No signs	Diffuse hypoxic/ischaemic damage	Mild	No	Ischaemic heart disease
#15	70	M	38	Y	5	Chronic ischaemic vascular disease	NA	Ischaemic vascular disease, diffuse hypoxic/ischaemic damage	Moderate	No	Bilateral pneumonia, respiratory insufficiency.
#16	81	M	10	Y	4	Cerebral atrophy	Cognitive decline, Alzheimer type	Mixed AD neuropathological changes and Lewy Body pathology, diffuse hypoxic/ischaemic damage	Moderate	No	Pneumonia, respiratory insufficiency
#17	75	M	58	Y	6	Cerebral atrophy	NA	Vascular dementia, ischaemic vascular disease, diffuse hypoxic/ischaemic damage	Moderate	No	Pneumonia, respiratory insufficiency.

| #18 | 87 | M | 30 | Y | 6 | Cerebral atrophy | Cognitive decline | AD neuropathological changes, diffuse hypoxic/ischaemic damage | Moderate | No | Pneumonia, multiorgan failure. |

Table 2. Clinical data of the Control Group
