ABSTRACT

Because lipid bilayers can bend and stretch in ways similar to thin elastic sheets, physical models of bilayer deformation have utilized mechanical constants such as the moduli for bending rigidity (κ_C) and area compressibility (K_A). However, the use of these models to quantify the energetics of membrane deformation associated with protein-membrane interactions and the membrane response to stress is often hampered by the shortage of experimental data suitable for the estimation of the mechanical constants of various lipid mixtures. While computational tools such as Molecular Dynamics (MD) simulations can provide alternative means to estimate K_A values, current approaches suffer significant technical limitations. Here, we present a novel computational framework that allows for a direct estimation of K_A values for individual bilayer leaflets. The theory is based on the concept of elasticity and derives K_A from real-space analysis of local thickness fluctuations sampled in MD simulations. We explore and validate the model on a large set of single and multicomponent bilayers of different lipid composition and sizes, simulated at different temperatures. The calculated bilayer compressibility moduli agree with values estimated previously from experiments and those obtained from a standard computational method based on a series of constrained tension simulations. We further validate our framework in a comparison with an existing polymer brush model (PBM) and confirm the PBM's predicted linear relationship with proportionality coefficient of 24 using elastic parameters calculated from the simulation trajectories. The robustness of the results that emerge from the new method allows us to revisit the origins of the bilayer mechanical (compressible) thickness and in particular, its dependence on acyl chain unsaturation and the presence of cholesterol.

INTRODUCTION

Cells exhibit a wide variety of morphologies ranging from discoid or spherical shapes (e.g. erythrocytes and staphylococcus bacteria, respectively), to branched formations with multiple highly curved and flat elongated segments (e.g. nerve axons in the brain, microvilli in the intestines and rod cells in the retina of the eye). A cell's ability to take on distinct shapes is directly dependent on the flexibility of its bounding plasma membrane (PM), and thus maintaining a certain level of flexibility of the PM is essential to both cell and human physiology. A prominent example of the consequences of deficits in PM flexibility is sickle cell anemia, a disease characterized by a drastic change in the shape and stiffness of red blood cells that leads to their accumulation on vessel walls and blockage of blood flow [1-6].

The PM is composed of two layers, or leaflets, composed of a mixture of various types of amphiphilic lipid molecules, each type with its own set of structural and thermodynamic properties. Despite this complexity, the PM's flexibility has been successfully modeled quantitatively as a simple elastic sheet with characteristic bending and compressibility constants [7]. While measurements of PM's elastic properties have been performed directly on live cells, the interpretation of such measurements is still challenging due to the complexity and non-uniformity of the cellular membrane environment [8, 9]. Instead, experiments on less complex, compositionally symmetric model membranes have been utilized to characterize the bilayer's bending rigidity (κ_C) and area compressibility (K_A) moduli as a function of lipid composition. These mechanical constants quantify, respectively, the energetic cost associated with bending the membrane and stretching/compressing its area, and have thus been used to make successful predictions about biological phenomena, e.g., of the changes in shape of closed lipid vesicles under stress [10-12]. Since the proper function and organization of transmembrane proteins are often regulated by membrane deformations near the protein (e.g. local bilayer bending and thinning or thickening), K_A and κ_C also appear as important parameters in theoretical models quantifying the energetics of protein-membrane interaction [13-15]. All these approaches directly link the elastic properties of membranes to bilayer shape and the sorting of both lipids (e.g., into distinct lipid domains) and proteins (e.g., into local clusters or oligomers) on the surface of a heterogeneous membrane such as the PM.

Various methods exist for measuring κ_C both *in vitro* and *in silico* [16-18], but the equally important compressibility modulus K_A is less well studied. It quantifies the response of membrane area to tension, which under physiological conditions may arise from various perturbations, such as changes in osmolarity across the membrane or the addition of lipids or other molecules to only one of the membrane's leaflets. Several experimental approaches have been developed to measure K_A in model membranes, and these methods rely on extracting the compressibility modulus from a relationship between systematically varied tension and the resulting bilayer area expansion. Perhaps the most commonly used technique utilizing this approach is the micropipette aspiration of giant unilamellar vesicles (GUVs), which has supplied the largest set of bilayer K_A data available currently [19-21]. The procedure involves imaging a single GUV while applying incremental amounts of suction pressure to it with a micropipette. The tension exerted on the bilayer is calculated directly from the applied pressure while the resulting changes in the bilayer area are inferred from geometrical considerations of the corresponding changes in GUV shape. In an alternative approach, pressure is applied to extruded unilamellar vesicles through osmotic imbalance between the vesicles' interior and exterior due to solutes such as salt or sugar [22-24]. The ensuing trends in the bilayer structure are monitored from the vesicle diameter measured with techniques such as light scattering or electron microscopy. NMR alone

[25] or in combination with X-ray diffraction [26] have also been used to measure K_A of bilayers at low hydration by relating changes in bilayer area to changes in the osmotic pressure of a polymer (e.g. polyethylene glycol) solution. Unfortunately, experimental data on the behavior of many lipids, including lipid mixtures, is still scarce and the availability of the resources needed to make the measurements is often limited. In that respect, a combination of rigorous physics-based simulation and well-calibrated computational tools holds great promise for enabling an otherwise impossible elasticity-based analysis of membrane systems that remain elusive to experimental methods.

With the feasibility of more extensive molecular dynamics (MD) simulations, the area compressibility modulus has been estimated from trajectories of (on average) flat lipid bilayer patches. The classical computational approach is based on the same principle as the experimental methods, i.e., that for small changes in area per lipid (A_{lip}), tension is linear with direct area expansion. To calculate the bilayer K_A , a series of constrained-area (or tension) simulations is performed and the value emerges from the slope of the best-fit line through the data of $\ln(A_{lip})$ vs surface tension. While the estimated moduli are typically in good agreement with experimental estimates, the analysis of one lipid composition requires multiple simulations, which makes this approach very expensive computationally. An alternative computational strategy that circumvents this requirement uses the equilibrium thermal fluctuations of the bilayer at constant zero tension instead. In this spirit, K_A is estimated from a single simulation trajectory utilizing the equilibrium expression $K_A = \langle A_{box} \rangle / \langle \delta A_{box}^2 \rangle k_B T$, where A_{box} represents the lateral area of the simulation box, k_B is the Boltzmann constant, T is temperature and $\langle \cdot \rangle$ denotes ensemble average (see Methods section below). Since the analysis is directly related to the fluctuations in the simulation box, the modulus exhibits a strong dependency on the thermodynamic phase behavior of the bilayer (which is directly related to the relaxation rate of its lateral area), system size, and the corresponding length of the simulation trajectory. Importantly, no existing computational or experimental methods allow for calculation of K_A of individual bilayer leaflets, which is a prerequisite for the quantification of the energy of local leaflet distortions in an asymmetric bilayer.

Here, we report a novel computational methodology that overcomes the aforementioned shortcomings in the calculation of area compressibility, and obtains the K_A moduli of a bilayer and of each of its leaflets from a single MD trajectory. Like the existing methods, we take advantage of thermal fluctuations, but express the compressibility modulus as a function of leaflet thickness instead of bilayer area. Following our recent success in calculating each leaflet's bending rigidity from real-space analysis of local splay fluctuations [18], we base our method for K_A estimation on sampling the leaflet thickness locally, and estimate the corresponding probability distribution and potential of mean force (PMF) profile as a function of changes in thickness. Finally, the K_A is extracted from a quadratic fit of a small region of the PMF around the global minimum, according to the elastic energy of stretching (see Methods). We show that for a large set of single and multicomponent bilayers, the compressibility moduli we calculate with the new method are in excellent agreement with the ones reported from experiments *in vitro*, or calculated with alternative computational approaches. We find that the K_A values obtained with our framework are less sensitive to bilayer size and simulation length due to the local nature of the analysis. We further validate our approach by reproducing the linear relationship between bilayer thickness, K_A and κ_C in the polymer brush model (PBM) [20], using mechanical constants calculated from the simulation trajectories. This analysis lets us revisit the definition of the bilayer mechanical thickness and clarify observed discrepancies reported in the literature with respect to PBM's predictions [17, 27, 28].

METHODS

Here, we present the theoretical framework and details of the new method for the calculation of the area compressibility moduli of a bilayer and each of its leaflets, based on the analysis of trajectories from molecular dynamics simulations. We begin by reviewing the calculation of bilayer compressibility from area fluctuations, and then expand the formulation to the calculation of individual local leaflet moduli. Since the use of area in the latter presents certain practical challenges as outlined below, we then re-express the theory in terms of local leaflet thicknesses and provide a detailed methodological description of our new computational framework.

Calculation of bilayer compressibility from area fluctuations. Following Helfrich's formalism [29], we treat the bilayer as a two-dimensional elastic sheet with mechanical constants describing its modes of deformation. For small equilibrium fluctuations around the free energy minimum, each deformation mode is associated with an elastic energy that is approximated by a quadratic function of the relevant deformation. For changes in area, the elastic energy E of stretching/compressing a bilayer patch with equilibrium area a_0 is given as:

$$E = \frac{1}{2} K_A a_0 \left(\frac{a - a_0}{a_0} \right)^2, \quad (1)$$

where a is the deformed area and K_A is the bilayer area compressibility modulus. Assuming that bilayer area stretching/compression are independent degrees of freedom in the context of the full energy functional describing bilayer mechanics (cf. bending or tilt), K_A can be obtained from the bilayer's thermally excited area fluctuations [30]. Specifically, from the equipartition theorem, $\langle E \rangle = (1/2)k_B T$ where k_B is Boltzmann constant and T is temperature, it follows that:

$$K_A = \frac{a_0}{\langle (a - a_0)^2 \rangle} k_B T. \quad (2)$$

This is the expression commonly used to obtain K_A from MD simulations of a bilayer by sampling fluctuations in the lateral area of the simulation box A_{box} [17, 30, 31]. Since E is the energy of a deformed state described by $\Delta a/a_0 = (a - a_0)/a_0$, from statistical mechanics it also follows that the probability of this state can be written as:

$$p(\Delta a/a_0) = C e^{-\frac{E}{k_B T}} \quad (3)$$

where C is a constant. Rearrangement of Eq. 3 leads to an alternative equality from which K_A can be calculated provided the probability distribution of the deformed states is known:

$$\ln p\left(\frac{\Delta a}{a_0}\right) = -\frac{1}{2k_B T} K_A a_0 \left(\frac{\Delta a}{a_0}\right)^2 + \ln C, \quad (4)$$

which can be written as:

$$-\frac{2k_B T}{a_0} \ln p\left(\frac{\Delta a}{a_0}\right) = K_A \left(\frac{\Delta a}{a_0}\right)^2 + C'. \quad (5)$$

While both Eqs. 2 and 5 are equivalent upon sufficient sampling of area fluctuations, Eq. 2 in which K_A is inversely proportional to the mean square area fluctuations, is more sensitive to outliers and deviations from the elastic regime (see Eqs. 12-13 and discussion afterwards) when used for K_A estimation. In contrast, Eq. 5 relies on the distribution of deformations around the mean and can thus provide a more robust approximation of the area compressibility modulus.

Leaflet compressibility calculated from area fluctuations. The area compressibility modulus of a bilayer quantifies the total energy of membrane deformation and can be used to infer the energetics of deforming individual bilayer leaflets in *symmetric* bilayers whose two leaflets are assumed to behave in the same way. However, in an *asymmetric* membrane, the two leaflets can have very different lipid compositions with potentially different energetic costs for stretching/compression that cannot be simply inferred from the elastic properties of the bilayer. To enable the analysis of these more general (and physiologically relevant) systems, we sought a formulation that would yield the area compressibility modulus of each leaflet of the membrane independently. Specifically, the goal was to obtain leaflet compressibility from area fluctuations in the spirit of the above-described theory (Eqs. 2-5).

Globally (e.g. considering the entire simulated bilayer patch), the area fluctuations of the two leaflets are identical and equal to the area fluctuations of the whole bilayer. Therefore, the apparent leaflet compressibility moduli calculated from area fluctuations at that scale would always appear the same, masking any potential differences in the inherent mechanical properties of the leaflets. In order to extract these differences and find the effective local leaflet moduli, we perform the analysis on a length scale much smaller than the global bilayer area. In particular, we view each leaflet as a collection of more than one parallel elastic blocks that are made of the same material (i.e. have the same compressibility modulus). Within a leaflet, it is assumed that all blocks have the same average area (e.g. the average area of a lipid) but can have different instantaneous areas and their area fluctuations are weakly coupled. Due to its elastic nature, the deformation energy of a block has the same form as Eq. 1 and its compressibility modulus (which is the effective local leaflet modulus) can be obtained accordingly from its area fluctuations through Eq. 2 or Eq. 5.

In order to relate the effective local leaflet moduli to the bilayer's compressibility, we express the energy of bilayer stretching/compression as a function of the stretching/compression of the individual leaflet blocks. If we denote the instantaneous global areas of the two leaflets with A_x and A_y and the instantaneous and average local areas of their elastic blocks with a_{xi} , a_{yi} and a_{x0} , a_{y0} respectively (i being the identity of the block), the second order approximation of the bilayer energy can be written as:

$$\begin{aligned}
 E = & \sum_i K_A^x a_{x0} \left(\frac{a_{xi} - a_{x0}}{a_{x0}} \right)^2 + \sum_i K_A^y a_{y0} \left(\frac{a_{yi} - a_{y0}}{a_{y0}} \right)^2 \\
 & + \sum_{i,j} K_{xx} a_{x0} \left(\frac{a_{xi} - a_{x0}}{a_{x0}} \right) \left(\frac{a_{xj} - a_{x0}}{a_{x0}} \right) \\
 & + \sum_{i,j} K_{yy} a_{y0} \left(\frac{a_{yi} - a_{y0}}{a_{y0}} \right) \left(\frac{a_{yj} - a_{y0}}{a_{y0}} \right) \\
 & + \sum_{i,j} K_{xy} \sqrt{a_{x0} a_{y0}} \left(\frac{a_{xi} - a_{x0}}{a_{x0}} \right) \left(\frac{a_{yj} - a_{y0}}{a_{y0}} \right).
 \end{aligned} \tag{6}$$

The first two terms in Eq. 6 represent summations over the deformation energies of the individual elastic blocks in the two leaflets, the next two terms are the corresponding inter-block correlations within each leaflet, and the last term quantifies the correlations between blocks from different leaflets. Each term has its characteristic modulus, and K_A^x and K_A^y in particular are the effective local leaflet compressibility moduli.

Since the bilayer area A is $A = A_x = A_y = (A_x + A_y)/2$, $A_x = \sum_i a_{xi}$ and $A_y = \sum_i a_{yi}$, we can express the variance of A as a sum over variances and covariances of the local areas:

$$\sigma^2(A) = \frac{\sum_i \sigma^2(a_{xi}) + \sum_i \sigma^2(a_{yi}) + \sum_{ij} \sigma^2(a_{xi}, a_{xj}) + \sum_{ij} \sigma^2(a_{yi}, a_{yj}) + W}{2}, \quad (7)$$

where $W = \sum_{ij} \sigma^2(a_{xi}, a_{yj})$. Since the global areas of the two leaflets are constrained to be the same, their variances are the same and consequently, the sum of the interleaflet correlations is 0, i.e. $W = 0$.

In addition, $\sigma^2(a_{xi}) = a_{x0} \sigma^2\left(\frac{a_{xi} - a_{x0}}{a_{x0}}\right)$ and at the same time $\sigma^2(a_{xi}) = 1/K_A^x$ (as in the second order approximation of the energy the multivariate Boltzmann distribution becomes the multivariate normal distribution). If n denotes the number of blocks, Eq. 7 then simplifies to:

$$\frac{1}{K_A} = \frac{1}{2} \left(\frac{1}{K_A^x} + \frac{1}{K_A^y} \right) + Q, \quad (8)$$

where Q is the average sum of the inter-block correlations within each leaflet:

$$Q = \frac{\sum_{ij} \sigma^2(a_{xi}, a_{xj}) + \sum_{ij} \sigma^2(a_{yi}, a_{yj})}{2n}. \quad (9)$$

While these inter-block correlations within a leaflet can generally deviate from 0, when the local areas (elastic blocks) are small the correlations can be both positive and negative (representing the fact that the blocks can undergo stretching/compression deformations in two dimensions) and we find that they cancel each other out in the respective sums (see section S.1 in SM). As a result, we assume $Q \approx 0$ and arrive at the final relationship between the bilayer K_A and the local compressibility moduli, K_A^x and K_A^y , of the two leaflets:

$$\frac{1}{K_A} = \frac{1}{2} \left(\frac{1}{K_A^x} + \frac{1}{K_A^y} \right). \quad (10)$$

Note that the derivation above assumes that the two leaflets have the same number of elastic blocks, however Eq. 10 holds even in the general case when these numbers are different (as for membranes with asymmetric lipid composition; see section S.1 in SM for the extended derivation).

It is important to note that in our formulation a local leaflet K_A in a symmetric bilayer has the same magnitude as the bilayer K_A and therefore should be treated differently from the *global* leaflet

compressibility moduli often referred to in the literature as 1/2 the bilayer K_A [32]. The latter are based on a model in which the global area changes in the two leaflets are the same due to the constraints on the bilayer geometry, but are uncoupled, and thus the elastic energy (and consequently, the K_A) of deforming each leaflet is half the energy (K_A) of deforming the bilayer. In contrast, K_A^x and K_A^y capture the *local* properties of the leaflets, which are affected by the global constraint on area only indirectly and thus reveal features that are more specific of the leaflets themselves. From Eqs. 6-10 it further follows that the harmonic mean of the local leaflet moduli gives the bilayer K_A , which as we show in Results quantitatively matches experimentally measured bilayer moduli for various membrane systems.

Leaflet compressibility calculated from thickness fluctuations. The theoretical formulation presented in the previous section allows the calculation of an effective local leaflet compressibility modulus from area fluctuations. To capture the individual leaflet properties when calculating K_A^L (where L can be x or y), given the outlined considerations (e.g. the cancelation of the Q term in Eq. 8), we chose to analyze the fluctuations of the smallest local unit area that is characteristic for leaflet L , that is the average area per lipid in the leaflet. In this way, the two leaflets in a symmetric bilayer will have the same local unit area, as expected, while in an asymmetric bilayer they may be different. We thus seek a local description of instantaneous leaflet area that would allow for ample sampling of area fluctuations, while treating each leaflet independently from the other leaflet.

Since the definition and calculation of local leaflet areas is rather challenging [30, 33], we assume volume conservation to relate deformations in local area to deformations in local thickness, and then estimate the coefficients from thickness fluctuations. Specifically, let a^L and t^L be the instantaneous local area and thickness of a leaflet, and a_0^L and t_0^L are their corresponding equilibrium values. Assuming that $a_0^L t_0^L = a^L t^L = V$ where V is a constant, we can express the energy of stretching/compressing leaflet L , E^L , as a function of *characteristic* changes in thickness instead of *relative* changes in area:

$$E^L = \frac{1}{2} K_A^L a_0^L \left(\frac{a^L - a_0^L}{a_0^L} \right)^2 = \frac{1}{2} K_A^L a_0^L \left(\frac{V/t^L - V/t_0^L}{V/t_0^L} \right)^2 = \frac{1}{2} K_A^L a_0^L \left(\frac{t_0^L - t^L}{t^L} \right)^2. \quad (11)$$

Consequently, Eqns. 2 and 5 become:

$$K_A^L = \frac{1}{a_0^L \langle (t^L - t_0^L)^2 / (t^L)^2 \rangle} k_B T \quad (12)$$

$$-\frac{2k_B T}{a_0^L} \ln p \left(\frac{t_0^L - t^L}{t^L} \right) = K_a^L \left(\frac{t_0^L - t^L}{t^L} \right)^2 + C'. \quad (13)$$

While both Eqns. 12 and 13 can be used to obtain K_A^L in theory, practical (numerical) considerations render Eq. 13 more suitable (see section S.2 in SM for comparison between the two approaches). Our formal framework is therefore centered on extracting K_A^L from Eq. 13 through the following steps:

1. Calculate local leaflet thicknesses at different chain depths within the bilayer.
2. From all possible definitions of leaflet thickness, identify the one that is suitable for the calculation of K_A^L .
3. Use Eq. 13 to obtain K_A^L .

In the following, we present details of the above three stages in our algorithm.

1. *Calculating local leaflet thicknesses from simulations.* Over the course of a simulation trajectory, the thickness of each bilayer leaflet is laterally inhomogeneous and fluctuates around its equilibrium value t_0^L as a result of thermal motions. To construct the probability distribution of thickness changes in Eq. 13, $p(\Delta t/t^L)$, by sampling local fluctuations, we take a grid-based approach and calculate the leaflet thickness at different grid points on the leaflet surface. In a continuum representation, a leaflet can be viewed as a stack of layers with each layer being a surface made of a particular lipid atom (ζ), e.g. a phosphate surface ($\zeta = P$), a first glycerol carbon surface ($\zeta = C1$ using CHARMM36 atom naming scheme), a first sn-1 carbon surface ($\zeta = C2I$), a first sn-2 carbon surface ($\zeta = C3I$) and so on (see Fig. S1). To calculate the leaflet thickness at a grid point (x, y) we first find the height of each of these surfaces at this grid point by performing interpolation on the corresponding atomic z-coordinates as follows:

$$h_{\zeta,(x,y)} = \frac{\sum_i \frac{z_{\zeta,i}}{d_{i,(x,y)}^n}}{\sum_i \frac{1}{d_{i,(x,y)}^n}}, \quad (14)$$

where $h_{\zeta,(x,y)}$ is the height of the ζ -surface (i.e. the surface made of atom type ζ at grid point (x, y)), $z_{\zeta,i}$ is the z-coordinate of atom i , $d_{i,(x,y)}$ is the 2D distance between atom i and (x, y) , n is interpolation order, and the summations are done over all leaflet atoms i of type ζ (note that the atoms on individual lipid chains have unique atom names, thus each lipid has at most one atom of type ζ). Since a lipid can have multiple chains and the heights in Eq. 14 are calculated separately for each carbon atom on each chain, we simplify the analysis by averaging the corresponding surface heights across all lipid chains:

$$h_{\zeta,(x,y)} = \frac{1}{N_{sn}} \sum_{ch=1}^{N_{sn}} h_{\zeta(ch),(x,y)} \quad (15)$$

where $h_{\zeta(ch),(x,y)}$ is the height of the surface calculated from the ζ carbon on the ch chain, and N_{sn} is the number of lipid chains. Eq. 15 can also be extended to lipids whose chains have different lengths (see Section S.3 in SM). While this approach works well for most bilayers, we found that for lipids like SAPE (see Simulation details below for lipid name abbreviations) which has one fully saturated and one highly-unsaturated chain, this averaging can become problematic for the subsequent analysis that is based on correlations of the resulting heights (described in the next section). Empirically, we found that the problem is alleviated when prior to the averaging in Eq. 15, each double bond and its preceding carbon are represented by a single data point with an instantaneous height equal to the average interpolated height across the 3 carbons. Thus, each double bond effectively reduces the unsaturated chain length (or the number of surfaces defining the unsaturated chain) by 2 carbons. As this procedure is more general and at the same time does not affect the results for the bilayers for which Eq. 15 can be applied, it was integrated in the methodological framework.

The leaflet thickness at the level of the ζ -surface, denoted τ_{ζ} , is defined as the difference between the height of the ζ -surface and the height of the lowest-situated surface at the grid point (usually, the surface of the terminal methyl carbons):

$$\tau_{\zeta,(x,y)} = h_{\zeta,(x,y)} - \min h_{(x,y)}. \quad (16)$$

The interpolation order n in Eq. 14 determines the contribution to $h_{\zeta,(x,y)}$ of the atoms closest to (x, y) relative to those that are further apart, i.e., the higher the n , the larger the effect from nearby atoms, and the lower the n , the larger the effect from all atoms. Hence, n is related to the effective number of atoms (lipids) that are being averaged, and consequently to the equilibrium area a_0^L in Eq. 13 (i.e. the area whose thickness fluctuations are effectively being analyzed).

Since atoms are weighted differently in the interpolation, we estimate a_0^L by first using the denominator in Eq. 14 to approximate the *effective* number of lipids being averaged, and then multiplying this number by the average area per lipid in the leaflet, A_{lip}^L . When $n = 2$ the denominator in Eq. 14 is approximately 1, conveniently setting $a_0^L \sim A_{lip}^L$, and we therefore use $n = 2$ and $a_0^L = A_{lip}^L$ in the subsequent analysis (see Section S.4 in the SM for the derivation, and Fig. S2 for a demonstration of the invariability of the results with n). As described in the SM (Section S.5), the interpolated thicknesses (Eq. 16) preserve the product of local area and thickness (i.e. the assumption underlying Eq. 11), which further establishes their suitability for the calculation of K_A^L .

2. Identifying the relevant thickness for fluctuations analysis. The first step of the method described above allows us to calculate local thicknesses at different surfaces (i.e. different depths) within the leaflet. Naturally, surfaces at heights near the water/hydrocarbon interface fluctuate less due to interfacial tension, while those further down into the leaflet fluctuate more, due to the increased fluidity of the lipid chains around the bilayer midplane. The height (and consequently thickness) fluctuations in a leaflet therefore fall roughly into two categories: ones that are relatively suppressed, and ones that are dominated by relatively unconstrained motion of the lipid chains. The former would tend to overestimate K_A^L while the latter would tend to underestimate it. The fluctuations of the surface lying at the intersection of these two regimes will thus be the most suitable from the elasticity considerations to obtain a reliable estimate of K_A^L . We term the thickness at the level of this surface the *relevant thickness for K_A^L* and proceed to identify its location within a bilayer leaflet.

The location of the atomic surface corresponding to the relevant thickness may differ in different membranes due to various degrees of bilayer fluidity. We have therefore developed a general algorithm for identifying the surface relevant for K_A^L calculations for an arbitrary lipid membrane. Specifically, we examine the correlation between the height fluctuations of a particular surface ζ and those of a reference surface (*RS*) close to the water-hydrocarbon interface (in our case, the *RS* is the surface of the first acyl chain carbon atom that is not connected to oxygen). Fig. 1 shows a typical behavior of this correlation, $r(\zeta) = r(h_{RS}, h_\zeta)$, (here, for the top leaflet of a DPPC bilayer) as the distance, $d(\zeta)$, between a surface ζ and the reference surface increases ($d(\zeta) = |\overline{h_{RS}} - \overline{h_\zeta}|$; where \overline{h} denotes median of the distribution of local heights). At small $d(\zeta)$, the correlation drops slowly and linearly with distance (Fig. 1, red solid line), implying a regime of suppressed thickness fluctuations (i.e. fluctuations of the atoms in this segment of the chain are strongly coupled to one another). At larger $d(\zeta)$ distances, the $r(\zeta)$ vs. $d(\zeta)$ profile strongly deviates from the initial linear behavior as $d(\zeta)$ increases more slowly while $r(\zeta)$ decreases more rapidly, characteristic of the more fluid region of the bilayer in which the lipid chains exhibit greater flexibility and intercalate with the chains of the opposing leaflet. Given the two well-defined regimes, we choose the first point outside of the linear regime (Fig. 1, yellow dashed line) to represent the leaflet whose thickness fluctuations can be used to extract K_A^L . We identify this surface ζ_s following the algorithm outlined on the right hand side box in Fig. 1. For DPPC the surface ζ_s is at the 10th carbon (shown in yellow in Figs. 1 and S1). Interestingly, for this and all other bilayers that we examined, ζ_s appears to be located right around the region within

the leaflet where the density of the opposing leaflet vanishes (i.e. just outside the interleaflet interdigitation zone, see Fig. S3).

3. *Calculating K_A^L from local thickness fluctuations.* Having identified ζ_s , we calculate the local thickness τ_{ζ_s} at every grid point in every frame of the trajectory and estimate its probability distribution using kernel density estimation (Fig. 2A). From this distribution, we estimate t_0 (defined here and throughout as the most probable thickness, i.e. at the peak of the distribution), and the left hand side of Eq. 13, i.e. the Potential of Mean Force (PMF), as shown on Fig. 2B. The characteristic asymmetric shape of the PMF is consistent with the free energy vs. area per molecule profile predicted by Ben-Shaul from theoretical considerations of lipid chain packing [34] and arises from the relative ease of deforming the membrane upon thickness contraction (area expansion, increase in entropy) compared to thickness expansion (area contraction, decrease in entropy). To find the leaflet compressibility, we identify a small region around t_0 (typically $\leq 7\%$ of t_0) where the PMF is closest to a normal distribution. We then fit a quadratic function to the PMF in this region and obtain K_A^L from the quadratic coefficient in the best fit (see Section S.6 in SM for a step-by-step outline of the procedure). Errors are calculated with a two-dimensional bootstrapping approach over both time and space as described in Section S.7 in SM.

Simulation details. Table S1 lists information for all simulated bilayers. The following lipid names are abbreviated as shown in the parenthesis: 1,2-dilauroyl-*sn*-glycero-3-phosphocholine (DLPC, di12:0), 1,2-dimyristoyl-*sn*-glycero-3-phosphocholine (DMPC, di14:0), 1,2-palmitoyl-*sn*-glycero-3-phosphocholine (DPPC, di16:0), 1,2-dilinoleoyl-*sn*-glycero-3-phosphocholine (DLiPC, di18:2), 1,2-dioleoyl-*sn*-glycero-3-phosphocholine (DOPC, di18:1(cis)), 1-stearoyl-2-oleoyl-*sn*-glycero-3-phosphocholine (SOPC, 18:0,18:1), 1,2-dielaidoyl-*sn*-glycero-3-phosphocholine (DEPC, di18:1(trans)), 1-palmitoyl-2-oleoyl-*sn*-glycero-3-phosphocholine (POPC, 16:0,18:1), 1-palmitoyl-2-oleoyl-*sn*-glycero-3-phosphoethanolamine (POPE, 16:0,18:1), 1-stearoyl-2-diarachidonoyl-*sn*-glycero-3-phosphoethanolamine (SAPE, 18:0,20:4), 1,2-dioleoyl-*sn*-glycero-3-phospho-(1'-*rac*-glycerol) (DOPG, di18:1(cis)), 1',3'-bis[1,2-dioleoyl-*sn*-glycero-3-phospho]-*sn*-glycerol (TOCL, tetra18:1), N-palmitoyl-D-*erythro*-sphingosylphosphorylcholine (PSM), cholesterol (Chol). As indicated in Table S1, some of the bilayers were taken from Ref. [18]. All remaining bilayers were constructed with CHARMM-GUI [35-37] and simulated with NAMD [38] using the CHARMM36 force field [39, 40]. Initial equilibration was carried out with CHARMM-GUI's protocols. Following equilibration, the simulations were performed with a 10-12 Å cutoff for non-bonded and short-range electrostatic interactions, and Particle Mesh Ewald with grid spacing of 1 Å for long-range electrostatics. Vdw force switching was turned on. Temperature was controlled with a Langevin thermostat while constant pressure was maintained with NAMD's Langevin piston Nose-Hoover method with a 200 fs period and 50 fs decay. All simulations were run with a time step of 2 fs, *rigidbonds* set to all, and both atomic coordinates and velocities were output every 20 ps.

Analysis of simulations and method implementation. All bilayer properties were estimated from the last segments of the trajectories over which the lateral area of the simulation box was considered converged, as determined with a method based on maximizing the number of effectively uncorrelated data points [41]. Table S1 lists the total simulation time for each system and the length of the trajectory segments used for the analysis. All trajectories were centered prior to analysis, such that the mean z position of the terminal methyl carbons on all lipids was set to 0.

The interpolated heights, as described in Step 1 of the calculation of leaflet compressibility from thickness fluctuations, were calculated for each leaflet with a modified version of VMD's MEMBPLUGIN [42] and sampled on an $8 \times 8 \text{ \AA}^2$ square grid. All subsequent analysis (outlined in Section S.6 in SM) was performed with MATLAB. Number density profiles were calculated with the Density Profile tool in VMD [43] and acyl chain order parameter profiles were obtained with in-house Tcl and MATLAB scripts. All code for calculation of the area compressibility moduli is available upon request.

Lateral pressure profile calculation. Lateral pressure profiles were calculated from the last ~ 100 ns of the centered simulation trajectories. The calculation was done with NAMD using stored instantaneous atomic coordinates and velocities. Each system was divided into slabs of approximately 0.8 \AA thickness. The total lateral pressure was the sum of the independently obtained Ewald and non-Ewald pressure contributions. The x, y and z dimensions of the grid size used for calculating the Ewald contribution were all equal and less than half the z dimension of the simulation box. Due to the known limitations of the Harasima algorithm with PME electrostatics implemented in NAMD for the discretized pressure calculation, the normal component of the pressure tensor in each slab, p_N , was set to $p_N = L_N^{-1} \int dz p_L(z)$ where L_N is the length of the simulation box in the direction of the bilayer normal, and $p_L(z)$ is the lateral (or tangential) pressure in slab z [44, 45]. The total pressure in slab z was then calculated as $p(z) = p_L(z) - p_N$.

Treatment of Chol-containing membranes. At relatively small mole fractions (up to 0.3-0.35) of cholesterol (Chol) in the bilayers, the expected effect of Chol on the bilayer structural properties (average area and volume per lipid) is mainly a *condensing* effect on the non-Chol lipids [33, 46]. It is reasonable, therefore, to assume that Chol's effect on the area compressibility modulus at such small Chol mole fractions will be indirect and captured in the K_A calculated from the non-Chol components only, as detailed in Section S.3 in the SM. However, as shown (see, for example, Ref. [46]), at higher mole fractions (above 0.35) the distribution of Chol's tilt angles becomes narrower and moves closer to zero, indicating that its motion is more restricted and the molecule is more parallel to the bilayer normal. In this regime Chol is likely to contribute directly to the leaflet compressibility (i.e. compression of the bilayer would involve compression of the Chol molecules themselves), and its effect needs to be considered explicitly. This is achieved by assuming that the ratio of the area compressibility calculated by considering only the non-Chol components ($K_a^{L(nonCh)}$) and all components (K_a^L) is the same as the fraction (s_f) of the surface area occupied by the non-Chol lipids, i.e. $K_a^{L(nonCh)}/K_a^L = s_f$ (where $s_f = \chi_{nonCh} a_0^{L(nonCh)}/a_0^L$). From here $K_a^L = K_a^{L(nonCh)}/s_f$. This correction to K_a^L is used only for bilayers with Chol mole fractions > 0.35 , and is found to produce a gradual increase in the bilayer compressibility modulus, consistent with experimental measurements (see Fig. 3 and discussion below).

RESULTS AND DISCUSSION

Validation of the new method for quantifying compressibility moduli from local thickness fluctuations (LTF). The canonical method for calculating bilayer area compressibility from MD simulations involves performing a series of NP γ T simulations (e.g., [30]). In each simulation a non-zero tension γ is applied in the x-y plane and the bilayer K_A is obtained by analyzing the linear

relationship between the applied tension and the resulting area expansion [30]. Since this methodology directly mimics the micropipette aspiration technique [47], it is expected to reproduce closely the experimental results provided that the properties of the simulated bilayers are correctly captured by the underlying force field. Table 1 shows the calculated moduli from NP γ T simulations of several single-component lipid membranes and the corresponding experimental measurements (see also Table S2). There is indeed a very good agreement between the two, verifying that the simulations are well-converged and able to reproduce the known values of K_A using standard techniques. Therefore, these and other single and multicomponent symmetric bilayers served as controls for the validation of our new LTF method.

Tables 1 and 2 list the compressibility moduli for each leaflet and for the bilayer obtained from LTF analysis of the equilibrated trajectories (see Table S1 for a detailed description of all simulated bilayers). The bilayer K_A 's obtained from the LTF method are in excellent agreement with those measured experimentally or obtained from NP γ T simulations (Table 1), indicating that our new approach reproduces the accuracy of existing methods when applied to symmetric bilayers. We note, however, that while the confidence intervals associated with the linear fits from the NP γ T simulations are large, the LTF errors calculated with a 2D bootstrapping algorithm (as described in Section S.7 in SM) are much smaller and comparable to the experimental uncertainties. (The experimental uncertainty for POPC is notably larger than the rest because the measurement was obtained with a different infrared (IR) linear dichroism-based method [48].)

Table 1 also lists the corresponding compressibility moduli calculated from the same equilibrated portions of the trajectories, but from lateral bilayer area fluctuations using Eq. 2. While these values are also in reasonable agreement with published results from the same method [17, 37], there is a large variability among the resulting K_A 's. For example, for PSM simulated at 48-55°C, Lee et al. [37] calculated a value of 456 ± 65 mN/m, which is similar to the one we obtained from the bilayer area fluctuation analysis (499 ± 42 mN/m), but Venable et al. [17] reported 310-350 mN/m, which is very similar to the moduli we obtained from NP γ T simulations and with the LTF method. This variability seems more likely for high-melting lipids (PSM, DMPC, DPPC) whose dynamics 5-10°C above their melting temperatures are generally slower compared to low-melting temperature lipids, suggesting that the underlying reason for the divergent results is likely an insufficient sampling of the lateral area fluctuations. Indeed, in the analysis of box fluctuations each frame of the simulation trajectory represents a single data point, which makes proper sampling highly dependent on the length of the simulation and the size of the bilayer patch (the latter is closely related to the amplitude of the fluctuations [49]). To illustrate this point, we compare in Table 1 the K_A 's for DOPC and DEPC (two fluid bilayers of the same size) calculated from either the full equilibrated trajectories of 517 and 680 ns respectively, or only from the last 100 ns of the simulation runs. The K_A moduli obtained with bilayer area fluctuation analysis vary from 246 ± 20 mN/m to 313 ± 33 mN/m for DOPC and from 204 ± 18 mN/m to 321 ± 53 mN/m for DEPC, whereas those calculated with the LTF method do not show such variability. The reproducibility of the LTF moduli can also be seen from the analysis of replica simulations of DOPC, i.e. systems with identical size and lipid composition that were constructed and simulated independently from one another (Table 1).

For bilayers with up to 200 lipids, the results from our method are only weakly dependent on bilayer size: For POPC membranes with 128 and 200 lipids, we calculated K_A 's of 245 ± 22 and 208 ± 20 mN/m respectively (Table 1). For a larger POPC bilayer with 416 lipids, the K_A was 185 ± 18 mN/m, which may indicate a potential challenge for the analysis of larger systems, although the result is within

the error of one of the smaller bilayers. Notably, since larger size of the simulated systems generally leads to larger undulations [49], the results might be affected by the assumption inherent in our method that the bilayer normal is the same throughout the bilayer surface (along the z axis of the simulation box). Because thicknesses are calculated by interpolation on the z positions of all atoms in the leaflet (see Methods), using the LTF method with the single bilayer normal assumption would tend to underestimate the apparent K_A when large-scale undulations are present in the system. It is feasible to introduce local normals in the LTF formulation, but this would result in more complex numerical calculations. Instead, we sought to circumvent the problem by constraining the radius of interpolation, R_{int} . We reasoned that because large-scale bilayer undulations are known to appear on length scales larger than the bilayer thickness (t_{pp}), setting R_{int} to a length slightly larger than t_{pp} could help alleviate the size dependence of K_A . Indeed, using R_{int} that is 10% larger than t_{pp} produced a bilayer K_A of 241 ± 23 mN/m for the larger POPC bilayer with 416 lipids, the same as calculated for the smaller systems.

Table 1 shows that the bilayer K_A varied between 230 and 260 mN/m for most single-component bilayers we studied. One exception is PSM, which is characterized by a somewhat higher compressibility of 312 ± 29 mN/m. Interestingly, we found tetra-oleoyl cardiolipin (TOCL) to have a compressibility modulus of 231 ± 11 mN/m, in contrast to a previously reported modulus of 342 mN/m obtained from a rather poor linear fit of tension versus area expansion in a set of constrained tension simulations (Fig. 4 in Ref. [50]). The similarity of TOCL's compressibility to that of a DOPG membrane (233 ± 19 mN/m) is particularly interesting because TOCL's bending rigidity modulus was found to be twice that of DOPG [18]. (Note that chemically, TOCL resembles 2 DOPG lipids with linked headgroups).

Application of the LTF method to mixed lipid systems. Interestingly, we found that binary mixtures of 30 mol% POPS with 70 mol% POPC or POPE at 20 and 25°C (respectively) have higher K_A 's compared to most single-component bilayers. This is consistent with the combination of their large phosphate-to-phosphate thicknesses (40.1 and 42.8 Å) and small areas per lipid (60.9 and 55 Å²). Similarly, when increasing amounts of DMPC are added to POPC at 25°C, the bilayer K_A increases gradually: from 210 ± 22 for 10 mol% DMPC to 262 ± 24 for 75 mol% DMPC, which is accompanied by a systematic decrease in the average bilayer thickness (from 38.6 to 36.6 Å) and area per lipid (from 63.8 to 61.4 Å²). Indeed, as shown in Fig. S4, we found a strong correlation (0.965) between the bilayer K_A and the ratio of bilayer thickness to area per lipid for all fluid multi-component bilayers we studied, with the exception of the 8:2 DPPC/Chol membrane which is under gel-like conditions (see Table 2).

Chol has a large effect on membrane compressibility (see Refs. in Table 2) and this is captured successfully by the LTF analysis as shown by the good agreement with experimental data (see Table 2 and Fig. 3). Indeed, the addition of Chol to DOPC at low concentrations (10 mol%) has a negligible effect on K_A , but from approximately 20 mol% and higher, the K_A value starts to increase gradually (see Fig. 3 and the discussion on the effect of Chol on bilayer mechanical thickness below). In agreement with results from experiments, we also find that Chol has a larger effect on the compressibility of POPC compared to DOPC: at 30 mol% Chol, POPC/Chol has a K_A of 757 ± 87 mN/m while DOPC/Chol has a K_A of 465 ± 57 mN/m. Interestingly, the large K_A of the highly ordered 8:2 DPPC/Chol bilayer at 25°C (3126 ± 281 mN/m) is similar to the one reported for a 1:1 SM/Chol bilayer at 15°C (3327 ± 276 mN/m) [21].

Compression-bending relationship and the role of chain unsaturation. Another aspect of the validation of our method relates to the reproducibility of known relationships among the mechanical properties of the membrane. One basic principle of the mechanical properties of elastic sheets is that the compression (K_A) and bending (κ_C) moduli are related to one another through the sheet's thickness t_{el} up to some constant C , i.e., $K_A = C\kappa_C/t_{el}^2$. Since the elastic moduli of a lipid bilayer are calculated by assuming that the bilayer behaves as an elastic sheet, we tested whether the same compression-bending relationship holds for our systems. Using experimentally measured K_A , κ_C and phosphate-to-phosphate thickness of a number of phosphatidylcholine bilayers, this relation was initially demonstrated using *in vitro* data by treating each leaflet as a collection of freely jointed polymer chains [20]. The proposed simple model is referred to as the *polymer brush model* (PBM), which derives a proportionality constant C of 24 and thus gives:

$$K_A \approx \frac{24\kappa_C}{t_m^2} \rightarrow \sqrt{\frac{\kappa_C}{K_A}} \approx t_m \sqrt{\frac{1}{24}} \quad (17)$$

where t_m is the *mechanical* thickness of the bilayer (i.e. the “deformable” thickness corresponding to t_{el} in the above elastic sheet analogy). Since bilayer thickness is often measured as the average distance between the phosphate atoms of the two leaflets (t_{pp}), t_m can be expressed as $t_{pp} - t_{inc}$ where t_{inc} is some incompressible part within the length of the membrane. Notably, if t_{pp} is the true mechanical thickness of the bilayer, then $t_{inc} = 0$ and in a plot of t_{pp} vs $\sqrt{\kappa_C/K_A}$, according to Eq. 17 above, all data points would lie on a line with slope $\sqrt{1/24}$ and x -intercept 0. However, t_{inc} was found to be non-zero [20] and equal to 10 Å, implying that t_m was 10 Å shorter than t_{pp} . This difference was proposed to reflect the fact that the deformable thickness of a bilayer is limited to its hydrocarbon thickness, and since 5 Å represents the approximate vertical separation between the phosphorus atoms from the hydrocarbon acyl chains on either side of the bilayer, t_m is 10 Å shorter than t_{pp} , explaining the non-zero t_{inc} . The only bilayers described as deviating from this behavior were polyunsaturated membranes [20], which appeared to have shorter mechanical thicknesses than expected.

We were able to test the relation between compression and bending and the applicability of PBM to the membrane systems we studied by taking advantage of the ability to calculate all three bilayer properties: bending rigidity [18], area compressibility and phosphate-to-phosphate thickness (Table S3) from our trajectories. Fig. 4A shows the results for all single-component PC bilayers together with the data for the binary mixtures of PC and Chol. Notably, the relationship between bending, compression and thickness could be explained with the PBM model (each dotted line has a slope of $\sqrt{1/24}$) for all single-component bilayers. However, based on the results in Fig. 4A the membranes can be roughly divided into 2 categories with different mechanical thicknesses (x -intercepts): PC lipids with fully saturated acyl chains for which $t_m \approx t_{pp}$ (DLPC, DMPC, DPPC shown in blue) and lipids with 1 or more double bonds for which $t_m \approx t_{pp} - 10\text{Å}$ (POPC, SOPC, DEPC, DOPC, DLiPC shown in red in Fig. 4). We find that the data in Fig. 4A cannot be explained by the rationale for t_{inc} given in Ref. [20], because the distance between the phosphates and the hydrocarbon chains on either side of the bilayer, proposed to be the origin of t_{inc} , is independent of the saturation of the lipid chains (e.g. the average distance between the phosphates and the first carbons on the acyl chains is 4.7 Å for DPPC, 5.0 Å for POPC, 4.6 Å for DOPC and 4.6 Å for DLiPC). Instead, our result suggests an alternative model in which the double bonds are the ones responsible for reducing the deformable thickness.

To evaluate this alternative model, we tested if double bonds lead to relatively incompressible regions in the bilayer and decrease t_m by increasing t_{inc} . We first examined how pressure was distributed in tension-free bilayers with varying degrees of saturation (Fig. S5) and analyzed the pressure profile as a function of the average number of atoms in equal volume segments along the membrane normal. If the segments of the membrane each behaved like non-interacting ideal gasses, the pressure P can be expressed as a linear function of the number of atoms n , where the slope is proportional to the usual state variables:

$$P = \left(\frac{RT}{V}\right)n. \quad (18)$$

However, when pressure is plotted as a function of n for the saturated lipid bilayer DPPC, we find that P is inversely proportional to n (Fig. S6, row 1). This result can be rationalized by utilizing the van der Waals equation of state,

$$\left(P + \frac{n^2a}{V^2}\right)(V - nb) = nRT, \quad (19)$$

where a describes attractive interactions between atoms in the gas and b describes the *excluded volume* (i.e. the volume occupied by the atoms that is excluded from the total volume) [51]. Eq. 19 can thus be rewritten as:

$$P = \left(\frac{RT}{V - nb}\right)n - \frac{n^2a}{V^2}, \quad (20)$$

which reveals a strictly negative component that is a function of n and of the strength of the attractive interactions a . Thus, the negative relationship between P and n that is seen for DPPC can be explained by the inter- and intra- molecular bonds present in the bilayer. However, when analyzing membranes with varying degrees of unsaturation, we find that upon adding double bonds, a regime of positive slope occurs (Fig. S6, rows 2-4). This observation can be explained by the dominance of the first term in Eq. 20 due to the increase in excluded volume caused by the presence of double bonds, which limit the space that can be sampled by the lipid chains. Indeed, a comparison between the van der Waal's constants for ethylene (C_2H_4 $b = 0.05821$ L/mol), ethane (C_2H_6 $b = 0.06499$ L/mol) and hydrogen (H_2 $b = 0.02651$ L/mol) [51, 52] clearly shows that a double bond increases the b term (i.e. $b_{C_2H_4} > b_{C_2H_6} - b_{H_2}$). Further comparison of the corresponding a terms (C_2H_4 $a = 4.612$ bar L²/mol², C_2H_6 $a = 5.570$ bar L²/mol², H_2 $a = 0.2453$ bar L²/mol²) suggests that a double bond also decreases the attractive interactions between atoms (i.e. $a_{C_2H_4} < a_{C_2H_6} - a_{H_2}$), which would further contribute to the dominance of the first term in Eq. 20.

To investigate the expected change in compressibility due to the additional double bonds we interpreted the data in Fig. S5 in the context of the compressibility factor which is defined as:

$$Z = \frac{PV}{nRT}. \quad (21)$$

When $Z > 1$, the volume is greater than expected for a given pressure due to its incompressibility. When combined with Eq. 20, the compressibility factor becomes a function of the excluded volume and the interaction between atoms,

$$Z = \frac{V}{V - nb} - \frac{an}{RTV}. \quad (22)$$

In the regime in which the excluded volume term dominates (i.e. when there are double bonds present), Z becomes large and positive, indicating the membrane is less compressible. This analysis thus confirms that the addition of double bonds to lipid chains leads to relatively incompressible regions that decrease t_m by increasing t_{inc} .

Motivated by the effect of the double bonds on the chain order parameter profile of the lipids, we used a simple heuristic approach to approximate the length of the perturbed region around the double bonds, t_{DB} , for the unsaturated PC bilayers from Fig. 4A: namely, the perturbed region extends 4 carbons above and below the midpoint of all double bonds for DOPC and DLiPC, and 2 carbons above and below the midpoint of the double bonds for POPC, SOPC and DEPC (see Fig. S7 and Table S3). Remarkably, after subtracting t_{DB} from t_{pp} and replotting the data in Fig. 4B, all data points moved to the line with x -intercept at 0, confirming our hypothesis regarding the nature and source of the incompressibility, and suggesting that the bilayer mechanical thickness for unsaturated lipids can be defined as the phosphate-to-phosphate thickness *excluding* the regions around the double bonds. We note that this result explains as well the observation in Ref. [20] that polyunsaturated bilayers have shorter mechanical thicknesses, since the perturbed region around their double bonds would be larger and consequently, t_m would be smaller.

Although DLiPC (di18:2 PC) has two more double bonds per molecule than DOPC (di18:1 PC), we find that both DLiPC and DOPC bilayers have similar mechanical thicknesses. This result is consistent with the nearly identical chain stress distributions in monolayers of these two lipids, predicted by Cantor [53]. As illustrated by the analysis in Ref. [53], the effect of the double bonds on monolayer properties (and very likely, bilayer properties) depends on both the number and the location of the double bonds.

Note that in the validation of the PBM described in Ref. [20], the mechanical thickness of DMPC was found to be 10 Å shorter than t_{pp} , like the rest of the examined bilayers. However, the reported DMPC's bending rigidity modulus measured by micropipette aspiration (13.2 kT) was much lower than the one obtained with flicker spectroscopy (31.1 kT, [54]) and also with our computational method (34.7 kT, [18]). The low value of κ_C reported in Ref. [20] is most likely due to the difficulties of applying the micropipette aspiration technique to higher melting temperature lipids as discussed in Ref. [18]. If a higher κ_C had been used instead in the PBM analysis, DMPC's mechanical thickness would likely have been predicted to be much closer to t_{pp} , consistent with the data in Fig. 4.

The effect of cholesterol on bilayer mechanical thickness. As illustrated by the analysis above, the effective mechanical thickness of a bilayer, t_m^{eff} , can be expressed as the phosphate-to-phosphate distance excluding the length of any region that resists compression. In this respect, it is interesting to investigate the behavior of lipid bilayers containing cholesterol, as the sterol contains a rigid and relatively incompressible set of rings [46]. Fig. 4A shows the mechanical properties of various lipid mixtures with cholesterol, including a set of DOPC/Chol bilayers with varying amounts of Chol tested against PBM. Most of these bilayers exhibit a larger deviation from either of the dotted lines, indicating a larger t_{inc} than the non-Chol membranes. To determine t_{inc} for the DOPC/Chol and POPC/Chol membranes, we first used the same heuristic approach as for the unsaturated lipids described above and

calculated $t_m^{DB} = t_{pp} - 2t_{DB}$. With this definition, all DOPC/Chol data points from Fig. 4A shifted to the line with an x-intercept at 0, but for the POPC/Chol bilayer t_m^{eff} was shorter than t_m^{DB} (Fig. S8A). Given the larger effect of Chol on POPC compared to DOPC and the relatively incompressible and rigid nature of the sterol ring structure as discussed above, we reasoned that in the POPC/Chol membrane t_{inc} would be better approximated by the length of cholesterol's ring region, t_{Chol} . To test this hypothesis, we calculated t_{Chol} as the average distance between the C3 and C17 atoms of Chol (using CHARMM36 notation) projected onto the z -axis, and found it to be 8.4 Å (Table S3). Remarkably, plotted as a function of $t_m^{Ch} = (t_{pp} - 2t_{Chol})$, the PBM data-point for POPC/Chol fell on the line with x-intercept at 0 (Fig. S8B), indicating that $t_m^{Ch} \approx t_m^{\text{eff}}$.

We then tested how well t_m^{Ch} approximates t_m^{eff} in the DOPC/Chol mixtures. In light of the results in Fig. 3 showing that Chol has an effect on the bilayer K_A only at 20 mol% or higher, we expected that $t_{inc} \approx 2t_{Chol}$ for these Chol bilayers but not for the 9:1 DOPC/Chol membrane. Indeed, as shown in Fig. S8B, $t_m^{\text{eff}} \approx t_m^{Ch}$ for the 20-50% DOPC/Chol mixtures, and $t_m^{\text{eff}} > t_m^{Ch}$ for the 10% DOPC/Chol bilayer.

Three different regimes are required to describe the effect of Chol on the structural properties of bilayers, corresponding to low, intermediate, and high cholesterol mole fractions [46, 55]. The results presented above and summarized in Figs. 3 and 4 suggest that this is also the case for the Chol effects on bilayer mechanical thickness and compressibility. Thus, our analysis shows that at 10 mol%, Chol does not have an effect on either t_m^{eff} or K_A ; at 20 and 30 mol% Chol affects t_m^{eff} and increases K_A indirectly through its condensing effect on DOPC; and at 40 and 50 mol% Chol affects t_m^{eff} and increases K_A directly, i.e. its contribution to K_A must be considered explicitly (Fig. 3). These regimes are consistent with the reduction in the translational and rotational entropy for Chol with increasing concentration: at low mole fractions Chol adopts relatively large tilt angles with respect to the bilayer normal, and thus relatively random orientations (large tilt angles result in larger degeneracy of rotational states [18, 56]). This increased orientational freedom can alleviate any potential stress from compressing the bilayer's thickness. At higher concentrations, Chol's conformational freedom gradually decreases, as Chol molecules tend to align parallel to the bilayer normal [56]. Bilayer compression under such conditions likely involves compression of the Chol molecules.

We also investigated the applicability of the PBM to a fully saturated DPPC/Chol bilayer with 20 mol% Chol. The bilayer was simulated at 25°C and is in a very ordered gel-like state as indicated by its small area per lipid and large elastic moduli (Tables 2, S1, S3). The PBM comparison for this system, shown in Fig. 4A, indicates that the mechanical thickness of the membrane is significantly smaller than t_{pp} . Interestingly, we found that for this bilayer the Chol tail was more rigid than in the other membranes (Fig. S9A), and comparable in its tilt distribution to the ring body of Chol in the 7:3 DOPC/Chol bilayer (Fig. S9B), suggesting that it was harder to compress, and that the mechanical thickness of the membrane could exclude the sterol tail as well due to the high order in the system. Indeed, considering in the calculations the full length of Chol, including its ring and tail regions, we were able to successfully recover t_m^{eff} of the DPPC/Chol bilayer (Fig. 4B). Both Chol concentration and the temperature determine the thermodynamic phase behavior of the bilayer and thereby the degree of Chol's conformational freedom. Therefore, it remains to be investigated whether Chol affects the mechanical properties of other fully saturated lipids in a similar way, and how the observed relationships vary with temperature.

Revised definition of bilayer mechanical thickness clarifies conflicting reports on PBM's applicability. As illustrated by our analysis, the effect of double bonds and cholesterol on bilayer's mechanical thickness has not been systematically characterized before. Therefore, we sought to examine the relation of our findings to published observations from both *in vitro* and *in silico* work. We found that our results resolve some contradictory reports in the literature regarding the validity of PBM for different bilayers. Indeed, since PBM was first introduced, the model has been experimentally tested in a number of studies by assuming that $t_m = t_{pp} - 10 \text{ \AA}$, yielding conflicting results [17, 27, 28]. In 2008 Pan et al. found a good agreement between their results and PBM's predictions for DOPC [27] but in 2009 they reported that the theory was incapable of describing the relationship between the mechanical constants in cholesterol-containing bilayers [28]. In a comprehensive review of bilayer mechanical properties from MD simulations published more recently, Venable et al. found a relatively good agreement between the simulation results and PBM for POPC and DOPC but there was a bigger deviation for DMPC and DPPC (see Fig. 11 in Ref. [17]). These conflicting observations can be consolidated in light of our finding that the presence of cholesterol and/or acyl chain unsaturation can affect the mechanical thickness of the bilayers. Not surprisingly, PBM was successfully applied to lipids with 1 or 2 double bonded tails such as DOPC and POPC both in the experimental and computational studies, since for those lipids t_m can indeed be approximated by $t_{pp} - 10 \text{ \AA}$. However, according to our analysis, the incompressible body of cholesterol has length of about 8.3 \AA , effectively decreasing t_m by an additional 6 \AA (3 \AA from each leaflet), i.e. $t_m \approx t_{pp} - 16 \text{ \AA}$. Thus, if the hydrocarbon thickness $2D_C$ (used as a proxy to $t_{pp} - 10 \text{ \AA}$) in Eq. 6 in Ref. [28] is substituted with $(2D_C - 6 \text{ \AA})$, the ratio between predicted and actual κ_C for SOPC and DOPC in the presence of 30 mol% cholesterol becomes 1.0 and 1.36, respectively, indicating a good agreement with the theory contrary to the stated conclusion in Ref. [50]. Similarly, since DMPC and DPPC are fully saturated and hence $t_m \approx t_{pp}$, the use of $t_{pp} - 10 \text{ \AA}$ for their mechanical thickness in Ref. [17] explains the larger deviation of their calculated bending moduli from PBM's predictions.

Together, all these results are consistent with the notion that bilayer mechanical thickness depends on lipid composition and cannot be simply taken as the bilayer hydrocarbon thickness. Our analysis illustrates a simple but general principle of bilayer mechanics whereas the assumption for elastic material behavior holds only for the regions within the membrane that are equally compressible. In particular, the presence of both acyl chain unsaturation and cholesterol produce non-uniform compressibility in the membrane hydrocarbon core that needs to be taken into account when quantifying the deformable membrane thickness.

CONCLUSION AND SUMMARY

We have presented a new computational framework for calculating area compressibility moduli of lipid bilayers and their individual leaflets from all-atom MD simulations that is based on sampling local thickness fluctuations from one sufficiently converged MD simulation. The method alleviates a number of limitations of existing computational approaches, and yields elastic moduli that are in agreement with available experimental data for both single and multi-component bilayers composed of saturated, unsaturated lipids and cholesterol and simulated at different temperatures. Importantly, because it is free from sampling of global lateral bilayer fluctuations, our method is uniquely capable of analyzing the area compressibility of bilayers under tension (i.e. simulated in an NPAT ensemble). It should also allow, in principle, future applications for the calculation of the spatial variability in leaflet compressibility moduli in the presence of transmembrane inclusions.

Notably, the presented data show that the mechanical properties of the simulated bilayers, and the relation between specific parameters representing their properties, are consistent with an elastic sheet model and consonant with a polymer brush model (PBM). However, we showed that the application of the PBM requires a significant modification of the canonical definition of the membrane mechanical thickness as simply the hydrocarbon region of the bilayer. We demonstrated the specific considerations that are necessary to determine the appropriate mechanical thickness needed to calculate unknown elastic moduli. These include the quantitative accounting for acyl chain unsaturation and cholesterol concentration, both of which introduce relatively incompressible regions within the bilayer that decrease the effective mechanical thickness.

While all of the bilayers we have examined have the same lipid composition and the same number of lipids in their two leaflets, the physical model underlying Eq. 10 is general enough to allow for analysis of the great variety of compositionally asymmetric bilayers that are physiologically relevant, as their local leaflet K_A -s could be different. This aspect of the method continues to be the subject of our ongoing computational studies. Systematic experimental measurements of the compressibility moduli of asymmetric bilayers, especially ones whose leaflets are expected to have significantly different mechanical properties, would greatly benefit the validation and/or refinement of the theoretical predictions from the harmonic mean relationship between the bilayer K_A and the local leaflet moduli (Eq. 10).

Author Contributions

MD, GK, ML and HW designed the research and wrote the manuscript. MD performed all simulations and computational analysis.

ACKNOWLEDGMENT

We thank Daniel Harries and Alex Sodt for insightful discussions. The work was supported by NIH Grants P01 DA012408 and U54 GM087519. The extensive computational work used the following resources: the Extreme Science and Engineering Discovery Environment (XSEDE, accounts TG-MCB120008 and TG-MCB130010), which is supported by National Science Foundation grant number ACI-1053575; an allocation at the National Energy Research Scientific Computing Center (NERSC, repository m1710) supported by the Office of Science of the U.S. Department of Energy under Contract No. DE-AC02-05CH11231; and the computational resources of the David A. Cofrin Center for Biomedical Information in the HRH Prince Alwaleed Bin Talal Bin Abdulaziz Alsaud Institute for Computational Biomedicine at Weill Cornell Medical College.

Table 1. Area compressibility of compositionally symmetric single component bilayers calculated with different methods: local thickness fluctuations (LTF), constrained tension (NP γ T) simulations and box (i.e. bilayer) area fluctuations. Where available, experimentally measured moduli are shown (Exp) with references to the respective literature sources. All moduli are given in units of mN/m. The LTF bilayer K_A was calculated with Eq. 10. LTF errors for the leaflets were calculated with a 2-dimensional bootstrap method as described in Section S.7 in SM and propagated to obtain the error on the bilayer K_A . The 95% confidence interval for the values obtained from a linear fit of tension versus area expansion in NP γ T simulations (Table S2) are shown in brackets. For lipid name abbreviations see Simulation details section in the text.

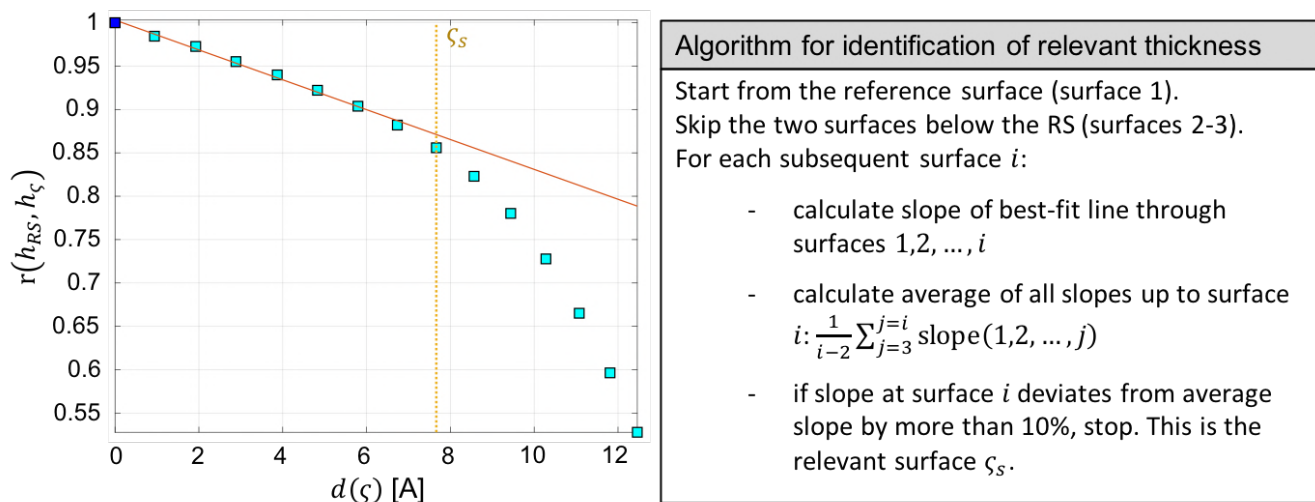

Figure 1. Identification of relevant thickness for calculation of K_A^L . Left, the correlation of the height fluctuations of a surface ζ with the height fluctuations of a *reference surface* RS (first acyl chain carbon atom not attached to oxygen, shown in blue here and in Fig. S1) is plotted as a function of distance from RS for the top leaflet of a DPPC membrane. Right, outline of the algorithm used to identify the relevant surface ζ_s from the data (denoted by a yellow dotted line on the plot). The solid red line shows the corresponding best-fit line through all points preceding ζ_s . A sample representation of the relevant surface can be seen in yellow in Fig. S1.

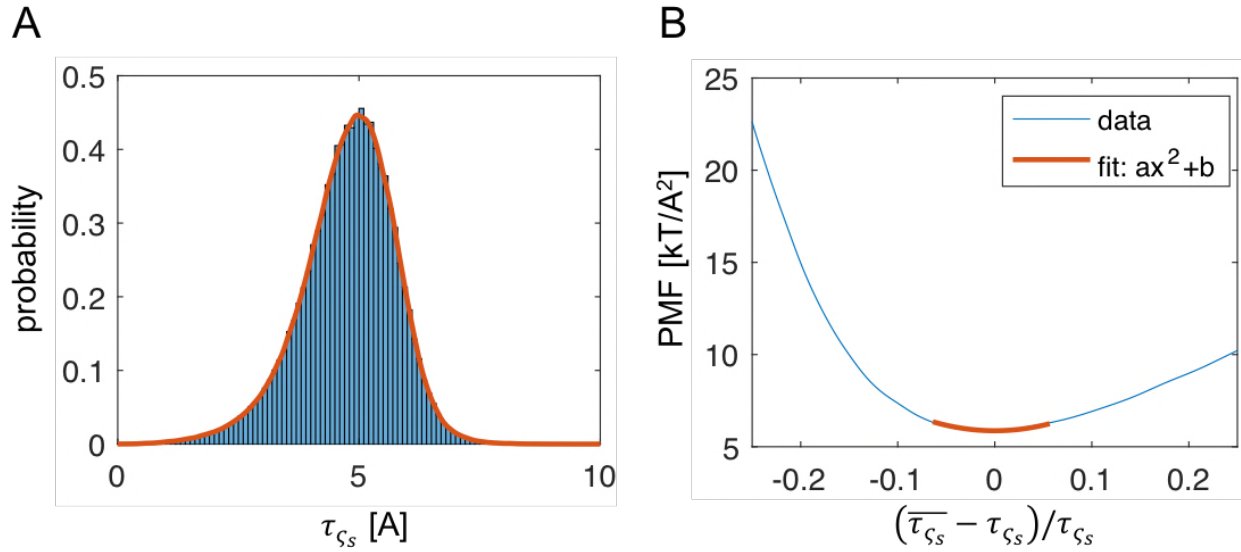

Figure 2. Calculation of K_A^L from local thickness fluctuations. A, Probability distribution of the relevant thickness, τ_{cs} , constructed from the time evolution of the local interpolated thicknesses for the top leaflet of a DPPC bilayer (blue). The distribution is smoothed for subsequent analysis by using a kernel density (red). B, The left-hand side of Eq. 16 is plotted as a function of characteristic changes in the local thickness. The PMF in the region of thicknesses within 6% of the mean thickness is fit to a function of the form $y \sim ax^2 + b$ (see text for details). K_A^L is obtained from the quadratic coefficient $a = 238$ mN/m of the best fit (shown in red).

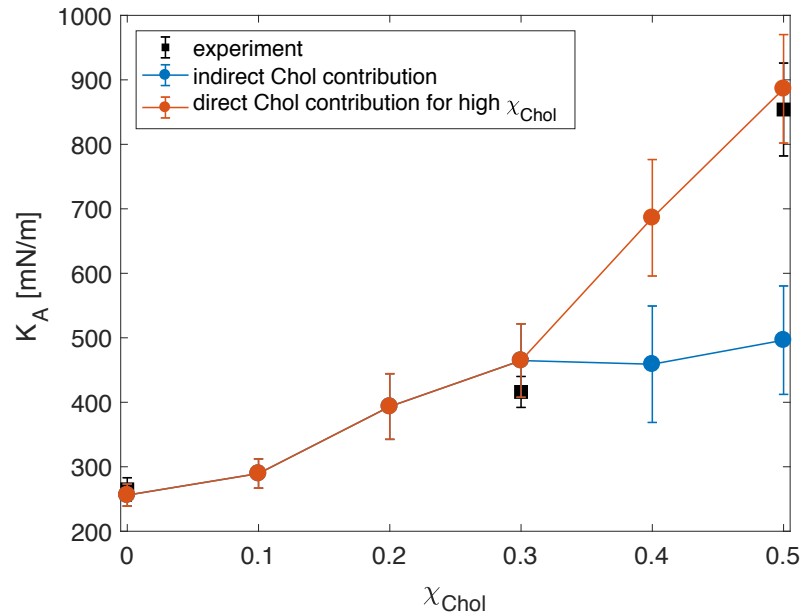

Figure 3. Bilayer area compressibility for DOPC/Chol mixtures with increasing amount of cholesterol. The bilayer K_A was calculated either by considering only the non-Chol lipids for all Chol mole fractions χ_{Chol} (blue symbols) or the non-Chol lipids for $\chi_{Chol} \leq 0.3$ and the direct contribution of Chol to the bilayer compressibility for $\chi_{Chol} > 0.3$ (red symbols, see Simulations analysis and method implementation section for details). Experimentally determined compressibility moduli are shown in black. The red and blue lines are guides to the eye to the respective data points.

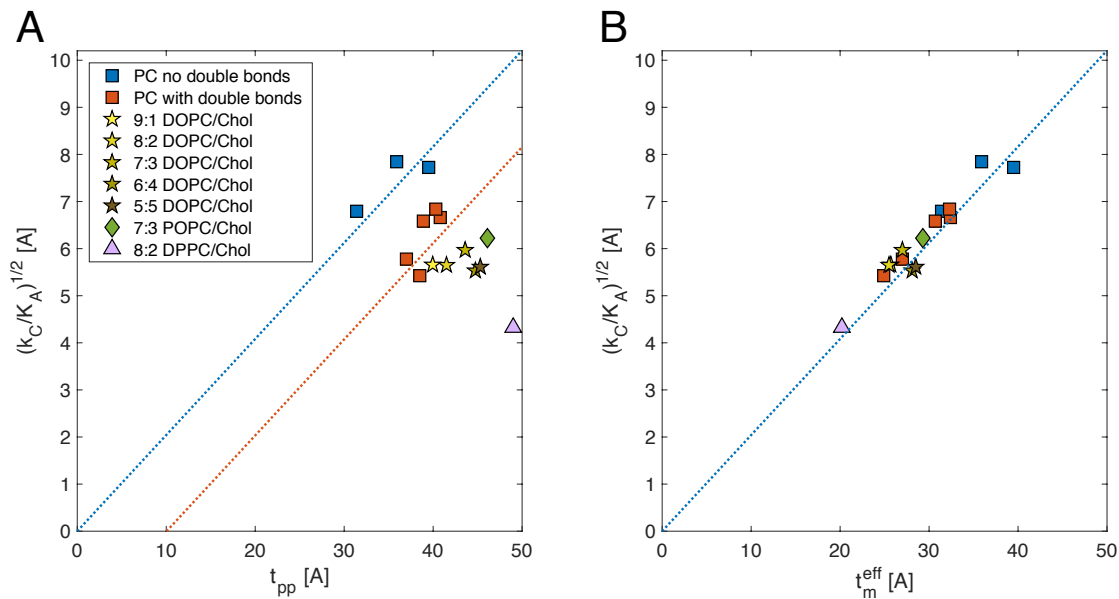

Figure 4. Application of the polymer brush model (PBM) to simulated bilayers suggests a new definition of bilayer mechanical thickness. A, The ratio of the bilayer bending rigidity (calculated from real-space analysis of splay fluctuations [18]) and area compressibility (calculated with the LTF method) from Eq. 17 is shown as a function of phosphate-to-phosphate distance, t_{pp} for all single-component fully saturated (blue) and unsaturated (red) PC bilayers (Table 1) and binary mixtures of PC and Chol (yellow, Table 2). All dotted lines have been drawn with PBM's slope of $\sqrt{1/24}$, and different x -intercepts. A non-zero x -intercept indicates a deviation of the bilayer mechanical thickness, t_m , from t_{pp} as explained in the text. B, The ratio of the mechanical constants of the same bilayers in (A) are plotted against the *effective* mechanical thickness of the bilayers t_m^{eff} , which is assumed to equal to: 1) t_{pp} for all fully saturated PCs, 2) the difference between t_{pp} and the length of the region around the double bonds for single-component unsaturated PCs and 9:1 DOPC/Chol, 3) the difference between t_{pp} and the length of cholesterol's ring body for all remaining binary mixtures of DOPC and Chol, and POPC and Chol, and 4) the difference between t_{pp} and the full length of cholesterol for DPPC/Chol (Table S3). See text for more details.
