22

23   **Abstract**

24

25   Bacteria have evolved macromolecular machineries that secrete effectors and toxins to survive and

26   thrive in diverse environments. The type VI secretion system (T6SS) is a contractile machine that is

27   related to *Myoviridae* phages. The T6SS is composed of a baseplate that contains a spike onto which

28   an inner tube is built, surrounded by a contractile sheath. Unlike phages that are released to and act

29   in the extracellular medium, the T6SS is an intracellular machine inserted in the bacterial membranes

30   by a trans-envelope complex. This membrane complex (MC) comprises three proteins: TssJ, TssL and

31   TssM. We previously reported the low-resolution negative stain electron microscopy structure of the

32   enteroaggregative *Escherichia coli* MC and proposed a rotational 5-fold symmetry with a

33   TssJ:TssL:TssM stoichiometry of 2:2:2. Here, cryo-electron tomography analysis of the T6SS MC

34   confirmed the 5-fold symmetry *in situ* and identified the regions of the structure that insert into the

35   bacterial membranes. A high resolution model obtained by single particle cryo-electron microscopy

36   reveals its global architecture and highlights new features: five additional copies of TssJ, yielding a

37   TssJ:TssL:TssM stoichiometry of 3:2:2, a 11-residue loop in TssM, protruding inside the lumen of the

38   MC and constituting a functionally important periplasmic gate, and hinge regions. Based on these

39   data, we revisit the model on the mechanism of action of the MC during T6SS assembly and function.

40

41

42   **Introduction:**

43   In a competitive environment, the ability to communicate and outcompete neighbours

44   provides bacteria with key advantages to survive. The type VI secretion system (T6SS) is a

45   macromolecular complex involved in the release of toxins that disrupt essential functions in

46   competitor cells (Russell *et al*, 2014). The T6SS is associated with increased survival and

47   pathogenicity in bacteria expressing it (Zhao *et al*, 2018). The T6SS is composed of 13-14 core

48   proteins (Boyer *et al*, 2009), usually encoded in the same locus in the genome (Mougous *et al*, 2006).

49   The T6SS assembles a molecular spring-loaded dagger, which punctures the target cell to secrete

50   fully folded effector proteins into neighbouring bacteria (Russell *et al*, 2011) or eukaryotic hosts

51   (Barker *et al*, 2009). The full assembly consists of the trans-envelope TssJLM membrane complex

52   (MC) (Durand *et al*, 2015) that tethers the TssKFGE-VgrG baseplate (Brunet *et al*, 2015)(No Title),

53   onto which the tail polymerize. This tail comprises the inner tube made of stacks of Hcp hexamers

54   wrapped by the TssBC sheath proteins that polymerize in a helical conformation (Brunet *et al*, 2014;

55   Clemens *et al*, 2015; Kudryashev *et al*, 2015; Chang *et al*, 2017) and tipped by the spike VgrG which

56   can be sharpened by the PAAR protein (Renault *et al*, 2018; Shneider *et al*, 2013). Effectors are either

57   associated within the Hcp lumen, or directly or indirectly bound to the VgrG or PAAR spike

58   (Unterweger *et al*, 2017; Silverman *et al*, 2013; Shneider *et al*, 2013; Flaugnatti *et al*, 2016a; Quentin

59   *et al*, 2018). Upon contact with a neighbouring cell, unknown signals trigger the contraction of the

60   sheath causing the tube and spike to pierce the membranes and secrete the effectors (Basler *et al*,

61   2012).

62   While the baseplate, tube and sheath proteins are conserved among contractile injection

63   systems, the MC is specific to the T6SS. TssJ is an outer membrane lipoprotein (Aschtgen *et al*,

64   2008a) that positions first at the site of assembly, and then recruits TssM and TssL (Durand *et al*,

65   2015). TssM and TssL are two inner membrane proteins that share homology with two accessory

66   subunits associated with T4SSb, IcmF and IcmH/DotU (Aschtgen *et al*, 2012; Ma *et al*, 2009; Durand

67   *et al*, 2012; Logger *et al*, 2016). Not only does the MC anchor the baseplate to the inner membrane,

68   but it would also serves as a channel to allow the passage of the tail tube/spike and maintain the

69   integrity of the attacking cell during the translocation of the inner tube (Durand *et al*, 2015). The

70   different subunits and the MC have been extensively biochemically characterised and several crystal

71   structures of the components are available from various bacterial species (Felisberto-Rodrigues *et al*,

72   2011; Durand *et al*, 2012; Rao *et al*, 2011; Robb *et al*, 2012; Chang & Kim, 2015; Durand *et al*, 2015).

73   We previously reported the negative-stain electron microscopy (EM) structure of the TssJLM complex

74   from enteroaggregative *Escherichia coli* (EAEC). We determined that 10 TssJ lipoproteins are bound

75   to 10 TssM proteins, forming two concentric rings of pillars and arches that span the periplasm. The

76   arches were shown to link to a flexible base composed of the N-terminal part of TssM and 10 copies

77   of TssL (Durand *et al*, 2015). This study also revealed that the EAEC TssJLM complex assembles into a

78   5-fold rotationally symmetric trans-envelope structure. However, the symmetry mismatch between

79   the 5-fold symmetry of the MC and 6-fold symmetry of the baseplate (Nazarov *et al*, 2018) questions

80   whether the purified TssJLM MC reflects the *in vivo* situation. In addition, although most of the

81   available crystal structures can be fitted into this EM structure, we currently lack molecular details on

82   the whole complex, such as the precise location of the membranes, of the trans-membrane helices,

83   and the potential presence of a periplasmic channel.

84   Here, we first present the *in situ* cryo-electron tomography (cryo-ET) structure of the EAEC

85   TssJLM MC. These data confirm the 5-fold symmetry of the complex *in vivo*, and provide information

86   on the location of the inner and outer membranes. We then present the single particle (SPA) cryo-

87   electron microscopy (cryo-EM) structure of the MC that describes the intricate molecular

88   architecture of the periplasmic portion of the complex. This high-resolution cryo-EM structure

89   reveals the presence of five additional copies of TssJ at the tip of the complex, the presence of a

90   periplasmic gate that closes a periplasmic channel. Finally, we demonstrate that the periplasmic gate

91   and the additional TssJ are required for T6SS-dependent activity *in vivo*.

92   **Results**

93   ***Structure of the T6SS MC within the cell envelope***

94   To observe the T6SS MC in its native cellular environment, we performed cryo-ET on bacterial

95   cells (Weiss *et al*, 2017). With the aim to have a sufficient number of particles to obtain an *in situ*

96   structure by subtomogram averaging, we imaged *E. coli* BL21(DE3) cells in which TssJLM were

97   heterologously overexpressed. This strain does not possess T6SS genes, thereby preventing any

98   crosstalk or protein-protein interactions between TssJLM and other natively present T6SS proteins.

99   Since *E. coli* is too thick to be directly imaged by cryo-ET, we pursued three different approaches to

100   tackle sample thickness. The first approach consisted of engineering a minicell-producing skinny

101   strain (Farley et al, 2016) of *E. coli* BL21(DE3), and thereby generating a minicell strain that is

102   compatible with the T7-based expression system. Although this strain produced minicells as small as

103   450 nm in diameter (Fig EV1A), their size still affected the contrast to an extent that did not allow for

104   sub-tomogram averaging. Nevertheless, characteristic inverted Y-shaped particles (side views, Fig

105   EV1B) and star-shaped particles (top views, Fig EV1C) could occasionally be observed in the

106   periplasm of these minicells. In a second approach, tomograms were recorded of cells that were

107   partially lysed and exhibited a high contrast (Fig EV1D, E). These cells, which have previously been

108   described as "ghost cells" due to their transparent appearance, still had mostly intact membranes

109   and conserved their cytoplasmic macromolecular complexes such as ribosomes (Fu et al, 2014). In a

110   third approach, we used a state-of-the-art cryo-sample thinning method called focused ion beam

111   (FIB) milling to thin E. coli BL21(DE3) cells in which TssJLM were heterologously overexpressed (Fig

112   EV1F, G). FIB milling allows to etch through a lawn of bacterial cells and thin them down to under 200

113   nm (Medeiros et al, 2018a, 2018b; Marko et al, 2007). This approach was more native, as it was

114   performed on intact rod-shaped wild-type BL21(DE3) cells. These tomograms had a high contrast and

115   provided great detail. To confirm the relevance of these observations, we carried out control

116   experiments in the native T6SS⁺ EAEC 17-2 strain. TssJLM particles were also readily observed by

117   cryo-ET, both when heterologously overproduced (Fig EV1H, note that the particles could

118   occasionally be found detached from the outer membrane: Fig EV1J) as well as under native

119   conditions, i.e. in wild-type EAEC 17-2 cells (Fig EV1I).

120   Sub-volumes of star-shaped (top views) and inverted Y-shaped (side views) particles were

121   manually picked and subsequently aligned and averaged. The resulting average was similar to the in

122   vitro T6SS MC structure published previously (Durand et al, 2015), with a tip and a core, made of 5

123   pairs of pillars forming a narrow central channel, that splits into 10 arches (Fig 1A-E). Importantly, the

124   5-fold symmetry was evident without applying symmetry (Fig 1A'). As it is the case for the TssJLM MC

125   solved by EM (Durand et al, 2015), the periplasmic core and the arches were well resolved, whereas

126   the inner membrane embedded base and the outer membrane-embedded cap were poorly resolved.

127   The Fourier shell correlation (FSC) curve indicated a resolution of 25 Å at a coefficient of 0.5 (Fig EV2

128   A). The prevalence of top views indicated that the average might be affected by a missing wedge (Fig

129   EV2 B).

130   After aligning and averaging a set of sub-volumes, it can be useful to place the isosurface of

131   the average back in the original tomographic volume to analyze the positions and orientations of the

132   individual aligned particles. In this way, we obtained a clear view of the location of the MC within the

133   cell envelope (Fig 2A, Movie 1 and Fig EV2 C-E, Movie 2). The position of the membranes with respect

134   to the TssJLM highlighted that the tip was embedded in the outer membrane without crossing it,

135   while the MC was anchored in the inner membrane at the lower part of the arches (Fig 2B). In some

136   cases, densities could be seen spanning the inner membrane and extending into the cytoplasm (Fig

137   2C). In what could be an overexpression artefact, TssJLM particles were also found in cytoplasmic

138   membrane invaginations (Fig 2A). Altogether, these data confirmed the 5-fold symmetry of the T6SS

139   TssJLM MC in situ and provided further insights into the position of the inner and outer membranes.

140

Structural analysis of the TssJLM complex by cryo-EM

142   We previously reported the negative stain EM structure of the EAEC TssJLM MC (Durand *et al*,

143 2015). Here, we used the same purification procedure and used SPA cryo-EM to obtain the cryo-EM

144 structure of the 1.7 MDa T6SS MC at 4.9 Å overall resolution. With a 5-fold symmetry imposed, the

145 local resolution ranged between 4.1 Å and 21.7 Å (Figs 3A and EV3A-E). The angular distribution of

146 the particles was good and allowed us to reach a high resolution (Fig EV3 C, F).

147   The 5-fold symmetry is clearly visible in the 2D classes top views and the volume slices of the

148 reconstruction, which retain a 5-pointed star shape (Fig EV3C,G). When no symmetry was applied

149 during the reconstruction, the overall resolution decreased to 7.5 Å but the pentameric nature of the

150 complex was maintained, with only one of the 10 arches displaying weaker density than the others

151 causing the drop in resolution (Fig EV3H, I). This could indicate partial assembly of the complex *in*

152 *vivo* or disassembly during its purification.

153   The overall structure resembles that obtained by negative stain (Fig EV3J(Durand *et al*, 2015)).

154 The architecture of the complex comprises a tip connected to a core region that extends to a base,

155 through a double ring of pillars with arches in proximity to the inner membrane (Fig 3A-B). Several

156 notable features are already evident from the cryo-EM density map of the full complex (Fig 3A). First,

157 the tip region and the base are disordered, and appear to be filled by random densities. Second,

158 cross-sections of the full complex show that the channel, across which tube/spike transport might

159 occur, is closed by a gate at the intersection between arches and pillars, above the inner membrane

160 (Fig 3B-E).

161   To better characterise the flexibility of the base of the complex, we collected tomograms on

162 the same frozen EM grids that were used to collect the SPA dataset (Fig EV4A-C). The base of

163 individual complexes appeared as very heterogeneous, with single arches often pointing in opposite

164 directions, or on the contrary several arches clumping together (Fig EV4A). On the other hand, the

165 core was rigid and resembled a 5-branched star. Moreover, about 20% of the particles possessed

166 only 3 or 4 out of 5 branches (Fig EV4B), indicating that partial assemblies could be stable. The

167 particles were lying in a thin layer of ice (25 nm) and were found at different orientations (Fig EV4C1-

168 2).

169

The structure of the base

171   To try and overcome the inherent flexibility of the complex and better discern different

172 features of the base, we performed a density subtraction of the tip, core and arches followed by a

173   focused refinement of the base with and without symmetry applied. We thus obtained 2D classes

174   and a 3D structure of the base at 17-Å resolution when a C5 symmetry was applied (Figs 3F and

175   EV4E-F). When observing the cross section of the base in the full complex, as indicated by arrows in

176   Fig3B, and in the subtracted structure (Fig EV4E), two 110 Å-wide linear densities are clearly visible,

177   separated by 40 Å. This double layer of density is consistent with the density diagram of a lipid

178   bilayer with the head groups being the most dense at a distance of ~4 nm from each other and fits

179   well a lipid bilayer composed of PE, obtained using the CHARMM-GUI (Jo *et al*, 2007) (Fig EV4E). We

180   conclude that the inner membrane sub-domain of the T6SS MC is filled by a lipid bilayer.

181

An additional TssJ is present in the full complex

183   To focus on the best-resolved region of the cryo-EM map, the base was subtracted from the

184   tip, a 2D classification and a masked 3D refinement was performed to obtain the structure of the

185   core at 4.5 Å (Figs 3G and EV5A-B), with a local resolution ranging from 4 Å to >10 Å (Fig EV 5C). The

186   known crystallographic structure of the C-terminus of TssM (aa. 869-1129) bound to TssJ (PDB 4Y7O)

187   could be easily fitted in the outer and inner pillars, with a correlation of 0.8505 and 0.565

188   respectively, leaving an extra density (Fig EV5D-E). Interestingly, an extra TssJ subunit, TssJ', which

189   was not observed in the low resolution complex (Durand *et al*, 2015) fits in this extra density with a

190   correlation of 0.879 (EV5E-F). We conclude that the T6SS MC comprises 15 TssJ proteins, 3 TssJs for 2

191   TssM (Fig 4A). No additional residues were visible for the N- and C-termini of TssJ (1-21 and 151-155),

192   disordered in both the crystal and the cryo-EM structures. After placing the extra TssJ, we refined the

193   TssM-TssJ crystal structure and the newly fitted TssJ copy against the cryo-EM map to obtain the

194   structure of each TssM and TssJ monomer within the whole MC.

195   TssJ' binds to the MC through previously unknown interfaces. If we consider the TssJ.i, TssJ.o

196   and the TssJ' subunits (Figs 4A-C and EV6A-B) with TssJ.i and TssJ.o being in contact with TssM.i and

197   TssM.o respectively, they sit in the same position as in the crystal structure and in the outer and

198   inner pillars (Fig 4B). By contrast, TssJ' binds to TssM.o and TssJ.i strongly (Fig 4C, Table EV1). In

199   particular, the interaction of TssJ' with TssJ.i is specifically strong, as their contact is mediated not

200   only by hydrogen bonds but also by salt bridges (R31 with E34, and D97 with R33; see Fig EV6C). TssJ'

201   binds to TssM.i via hydrogen bonds only and this interaction is comparable to that between TssJ.i and

202   TssJ.o with TssM.i and TssM.o respectively (surface of interaction 573 Å^2 and -2.6 kcal/mol ΔG) (Fig

203   4B-C, Table EV1).

TssJ' is required for MC assembly and T6SS activity

To gain further information on the function and *in vivo* relevance of TssJ', mutations that specifically impact the TssJ'-TssJ.i interface were engineered onto the chromosome, at the native locus. Two residues, Arg-31 and Asp-97 (Fig EV6C), were targeted as they form a salt bridge with E34 and R33 in TssJ.a, respectively (Table EV 1 and Fig EV6C). The R31E, D97A and D97K substitutions were then tested for their ability to outcompete a fluorescent *E. coli* competitor strain. Although the R31E and D97A did not significantly impact T6SS antibacterial activity, the D97K mutation abolished proper function of the T6SS (Fig 4D). The assembly and stability of the T6SS MC was then assessed by fluorescence microscopy using a chromosomally-encoded and functional fusion protein between TssM and the super-folder GFP ($_{sfGFP}$TssM, Durand *et al*, 2015) (Fig 4E). As previously observed (Durand *et al*, 2015), the $_{sfGFP}$TssM strain forms stable foci. By contrast, cells producing the TssJ D97K variant form small and unstable fluorescent $_{sfGFP}$TssM foci (Fig. 4E). Time-lapse fluorescence microscopy recordings showed that about 90% of the foci observed in the $_{sfGFP}$TssM strain (n = 50) are stable over the 600-sec recording time, in agreement with the previous observation that the EAEC T6SS MC is stable and serves for several contraction/elongation cycles (Durand et al., 2015). By contrast, with a mean lifetime of ~ 107 sec (n = 50) the $_{sfGFP}$TssM fluorescent foci observed in cells producing the TssJ D97K variant are drastically less stable (Fig EV 7A). We then tested whether the TssJ D97K variant promotes sheath assembly, using chromosomally-encoded functional $_{sfGFP}$TssB fusion. Fig. 4F shows that, contrarily to the wild-type parental cells in which dynamic sheaths can be observed, no sheath polymerization occurs in presence of TssJ-D97K (Fig. 4F and EV Fig.7B). Altogether, these results demonstrate that TssJ'-TssJ.i interface is required for the stability of the T6SS MC, sheath formation and T6SS antibacterial activity.

A flexible hinge within the TssM periplasmic domain

We were able to confidently build *de novo* the periplasmic domain of TssM including its N-terminal fragment (residues 579 to 869) that was missing in the crystal structure (Durand *et al*, 2015). This was done in Coot (Emsley *et al*, 2010) by using Phyre2 secondary structure predictions (Kelley *et al*, 2015) and RaptorX evolutionary covariance interaction predictions (Källberg *et al*, 2012) as validation tools (Fig 5A and EV8A-C). The cryo-EM structure of the TssM periplasmic domain slightly differs from the X-ray structure (Fig EV9A). From the C-terminus, helix 869-891 extends to amino-acid 841 with a slight kink at residue Pro-870. The remaining N-terminal fragment forms an α-helical domain comprising 8 helices that snake back and forth to the inner membrane (Fig 5A). The region closest to the membrane was too flexible to be resolved and for an atomic model to be built (Fig EV8B). The cryo-EM pseudoatomic model of the fully assembled TssM-TssJ complex shows it

238   forms a bell shape composed of two rings of pillars that twist around each other (Fig 5A). Within each

239   asymmetric unit, two copies of TssM are present, named TssM.o in the external pillar and TssM.i in

240   the internal pillar. The inner and the outer pillar TssM proteins are superimposable with the

241   exception of a 23° kink located at residue 867 (Fig EV9B). These two TssM subunits interact front-to-

242   back (Fig EV9C) with an area of 1168 Å^2, a binding energy of -9.9 kcal/mol, and a ΔG of -5.2 kcal/mol.

243   Each TssM.i also interacts with two adjacent TssM.i within the inner TssM ring at an angle of 76°,

244   with an area of 1529 Å^2, a binding energy of -12 kcal/mol and a ΔG of -5.32 kcal/mol (Figs EV6A and

245   EV9D). Finally, TssM.o^{+1} also interacts with TssM.i and the two are oriented at 68° from one another

246   (Figs EV6A and EV9E).

247   A poorly-defined density that sits in the core region between TssM.i and TssM.o^{+1}, was

248   attributed to the C-terminus of TssM. We built a small loop that terminates into a helix. (Fig EV9F).

249   This region is disordered in the outer pillar monomer (TssM.o). Additionally, the resolution of the

250   pillars gets worse towards the basal side, and no secondary structure could be identified when we

251   tried to build *de novo* the atomic model of TssM. Despite this high degree of flexibility, we produced

252   a model of the periplasmic region between amino acids 390 and 550 based on a RaptorX contact

253   predictions. This model fits well (correlations of 0.819 and 0.827) into the remaining densities (Fig

254   EV9G). The EM density shows that while they are separated at the level of the arches, the inner and

255   the outer pillar re-join at the level of the inner membrane (Fig EV9G).

256   *The periplasmic TssM gate*

257   The inner pillars of TssM form a channel with a diameter that varies between 2.6 Å and > 20 Å

258   (Fig 5B-C). The site of constriction observed in the cryo-EM density (Figs 3B,E) corresponds to loop

259   776-786 in the atomic model of TssM (Fig 5D). Specifically, residues Gln-779 and Asn-780-781

260   maintain the constriction via polar interactions (Fig 5D). In the external pillar, the same loop interacts

261   with loop 600-625 on the neighbouring pillar, providing further stabilisation of the structure (Fig

262   EV10A). Conservation analysis of the sequence with related proteins predicted by the ConSurf server

263   (Celniker *et al*, 2013), indicated that the sequence of the loop 776-786 is poorly conserved amongst

264   species (Fig EV10B) although the presence of a loop at this position is a conserved feature. As

265   previously proposed (Durand *et al*, 2015), these data suggest that the purified TssJLM MC is in a

266   closed state. Large conformational changes, including modification of the constriction and movement

267   of the inner pillars are therefore required to allow the passage of the tube/spike during sheath

268   contraction.

269

270   *The TssM periplasmic gate is required for MC assembly and T6SS function*

271   To test the function of the periplasmic gate, several mutations were engineered at the *tssM*

272   locus in the wild-type EAEC 17-2 strain and the function of the T6SS was assessed as previously

273   described (Fig 5E-G). To covalently stabilize the contacts between the internal pillars and thus

274   prevent MC opening, Gln779 and Asn780 were substituted with cysteines (Q779C-N780C).

275   Conversely, a constitutively open gate was created by deleting a large portion of the constriction

276   loop (Δ777-783). Antibacterial competition assays showed that the Q779C-N780C variant loses the

277   ability to outcompete competitor cells, whereas the single control mutant Q779C did not (Figure 5E).

278   Deletion of the Δ777-783 loop also impaired the T6SS antibacterial activity (Figure 5E). Fluorescence

279   microscopy recordings further show that $_{sfGFP}$TssM Q779C-N780C and $_{sfGFP}$TssM Δ777-783 do not

280   assemble TssM foci since, in contrast to the parental strain, diffuse fluorescent pattern were

281   observed (Figs 5F and EV11). These results demonstrate that the MC is not properly assembled when

282   the integrity of the periplasmic gate is impacted. As expected, these mutant cells were not able to

283   assemble T6SS sheaths (Figs 5G and EV11).

284   *Discussion*

285   In this study, we report the *in situ* and *in vitro* structures of the T6SS TssJLM MC from EAEC.

286   The cryo-ET structure confirmed the 5-fold symmetry and general architecture *in vivo* while the high-

287   resolution cryo-EM structure provided molecular details about the periplasmic portion of the

288   complex (Fig 1, Fig 3 and Movie 3). As previously defined, the pentameric propeller-like structure

289   composed of 10 pillars intertwined with each other was observed both *in situ* and from purified

290   material (Figs 1 and 3C-E). Cryo-ET analyses allowed to position both the inner and outer

291   membranes. As anticipated based on biochemical experiments showing that TssJ is a periplasmic

292   lipoprotein attached to the outer membrane by an acyl anchor (Aschtgen *et al*, 2008), the tip of the

293   complex is embedded in the outer membrane (Fig 2B). However, neither the predicted detergent cap

294   in the SPA cryo-EM structure nor the cryo-ET data, indicate that TssJLM breaches or crosses the outer

295   membrane (Fig 2, Fig 3A-B). Nevertheless, it has been shown that this region is extracellularly

296   exposed in wild-type EAEC cells (Durand *et al*, 2015). Although the cryo-EM structure demonstrates

297   that the C-terminal region of TssM locates in the periplasm, we propose that the recruitment of

298   specific T6SS components induces MC conformational changes and cell surface exposition of the

299   TssM C-terminus. While our previous study suggested that the inner membrane locates at the level

300   of the arches (Durand *et al*, 2015), the cryo-ET analyses revealed that the inner membrane surrounds

301   the base (Fig 2B). Moreover, some tomograms also revealed the most basal parts of the MC, which

302   cross the inner membrane into the cytoplasm (Fig 2A, C). The *in situ* cryo-ET structure presents an

303   apparent elongation of the tip region compared to the cryo-EM structure (Fig EV12A, B and Movie 3),

304   which could correspond to an additional density associated to the outer membrane or which could

305   alternatively be explained by the missing wedge. Nevertheless, the similarities between both

306   structures allowed the atomic model of TssJ - TssM to be docked into the *in situ* average (Fig EV12C,

307   D), whereas the cryo-EM structure could be placed in a cellular context (Fig EV12E and Movie 3).

308   The base of the complex in this higher resolution structure was not better resolved than in the

309   negative stain structure (Figs 3A, F, and EV3D). This base should comprise 10 copies of the TssM and

310   TssL cytoplasmic domains (Durand *et al*, 2015). TssL forms dimers (Zoued *et al*, 2018; Durand *et al*,

311   2012; Zoued *et al*, 2016) and the crystal structure of its cytoplasmic hook-like domain has been

312   reported from various species including EAEC, *P. aeruginosa* and *V. cholerae* (Durand *et al*, 2012;

313   Robb *et al*, 2012; Chang & Kim, 2015; Wang *et al*, 2018)(Durand *et al*, 2012; Robb *et al*, 2012; Chang

314   & Kim, 2015). The TssM cytoplasmic domain is comprised between the N-terminal transmembrane

315   hairpin and a third transmembrane helix (Ma *et al*, 2009; Logger *et al*, 2016). No high-resolution

316   structure of the TssM cytoplasmic domain is available, although a model has been built based on

317   homology with DPY-30 and NTPases (Logger *et al*, 2016). Unfortunately, due to the poor resolution of

318   the base, we did not succeed to confidently fit the TssL and TssM cytoplasmic domains in this

319   density. Additional assays to improve the resolution such as the use of nanodiscs or amphipols

320   proved to be unsuccessful (Fig EV13A). The flexibility of the TssJLM base, which did not allow for it to

321   be resolved, might be due to the absence of other T6SS cytoplasmic components such as the

322   baseplate. A similar observation was made for the type III secretion system, in which the presence of

323   the cytoplasmic sorting platform orders the IM components (Hu *et al*, 2017). One may hypothesize

324   that this flexibility is essential for the docking of the hexameric baseplate, and to accommodate the

325   five-fold to six-fold symmetry mismatch. One alternative hypothesis is that the disorder at the centre

326   of the base structure is caused by the presence of a lipid bilayer encircled by the TssM and TssL

327   proteins. In the *in vivo* situation, the MC assembles first, before the recruitment of the baseplate

328   (Durand *et al*, 2015; Brunet *et al*, 2015), and hence, one can expect that a lipid bilayer at the

329   entrance of the TssJLM lumen would be present before baseplate docking to prevent the leakage of

330   solutes and proton-motive force.

331   The high-resolution structure of the EAEC TssJLM MC also revealed new interesting and

332   functional features. First, five additional TssJ subunits, called TssJ', were identified in the tip complex.

333   These TssJ' proteins interact with the TssJ proteins of the outer pillars (TssJ.i). Mutations that

334   interfere with TssJ'-TssJ.i interaction impair the functional integrity of the MC and hence inactivated

335   the T6SS (Fig 4D-F). Second, we identified a 11-amino-acid loop in TssM that protrudes from each

336   inner pillar to the centre of the channel, thus creating a constriction that is observed in the density

337   map (Fig 3D, E). Each loop is stabilized by the adjacent loop via Asn/Gln pairings. Such weak

338   interactions could be easily displaced by the VgrG/PAAR spike upon baseplate docking or during

339   firing. Our mutational analyses demonstrate that this constriction is important for TssJLM MC

340   formation and T6SS activity. Periplasmic constrictions are usual features of trans-envelope

341   complexes. The best characterized examples include the OM T2SS and T3SS secretins, and the CsgG

342   curli secretion channel who present one or two periplasmic gates to prevent leakage (Fig EV14A-B)

343   (Yan *et al*, 2017; Spagnuolo *et al*, 2010; Goyal *et al*, 2014). While we do not know the role of this

344   constriction in the T6SS, we propose that these loops may stabilize the MC in its closed conformation

345   during the resting state. The cryo-EM structure defined two hinge regions that exhibit a certain

346   degree of flexibility (Fig EV9B,G). These two hinges result in the formation of the two layers of pillars,

347   with the inner layer obstructing the channel. A large conformational change of these pillars is

348   therefore necessary to open the channel for the passage of the tube/spike complex. Interestingly,

349   with an interaction surface of 1540 Å^2 (ΔG of 6.1 kcal/mol) the TssM inner pillars contacts are

350   considerably less stable than the contacts within the T2SS secretin (interaction surface of 5353.7 Å^2

351   and ΔG of -52.4 kcal/mol). The displacement of the pillars could be controlled by the flexibility of the

352   hinge regions.

353   Based on these data, we propose a model in which the T6SS TssJLM MC is assembled in a

354   closed state. In this conformation, five pillars are oriented toward the centre of the complex to close

355   the complex at the outer membrane and hence to protect the cell from periplasmic leakage or from

356   the entry of toxic compounds. This conformation is further stabilized by the interactions of the TssM

357   protruding loops. The flexibility of the MC cytoplasmic base allows the proper positioning of the

358   TssKFGE-VgrG baseplate, and accommodates the five-to-six symmetry. The docking of the baseplate

359   positions the VgrG/PAAR spike in proximity to the inner membrane. Once in contact with the target

360   cell, a signal transmitted to the baseplate triggers the contraction of the sheath, allowing the passage

361   of the tube/spike complex through the MC. The hinge regions undergo a tectonic conformational

362   change that opens the channel and the tip complex. The MC then returns to the resting, closing state

363   allowing a new cycle to start (Figure 6).

Figures legends

390

Figure 1.   **Subtomogram average of the TssJLM complex *in situ***

A-E. Isosurface of the subtomogram average (in pink) with an applied C5 symmetry and 0.69 nm tomographic slices (A-E) at the indicated heights. The average is shown in side view, whereas the slices represent perpendicular slices. The 5 pairs of pillars formed a narrow central channel and separated into 10 arches towards the base (base not visible at the used threshold). The division of the structure into subparts was adapted from (Durand *et al.*, 2015). Subvolumes were extracted from cryotomograms of ghost cells and FIB-milled intact *E. coli* BL21 cells heterologously expressing TssJLM.

A'. Slice (0.69 nm) through the non-symmetrized average. Note that the C5 symmetry was visible.

400

Figure 2.   **Position of TssJLM in the cell envelope**

A. Slice (9.7 nm) through a cryotomogram of a FIB-milled *E. coli* BL21 cell expressing TssJLM. The average shown in Figure 1 was placed back at the positions and orientations of the individual subvolumes that were used to generate the final average. The zoomed-in area highlights the position of the TssJLM particles within the inner and the outer membrane. Some particles were found in cytoplasmic membrane invaginations, as indicated by white arrows. Scale bar 100 nm.

B. Isosurface of the final average (orange) merged with the isosurface of a second average (with higher threshold; grey mesh). The panel shows the positioning of TssJLM with respect to both inner (IM) and outer membranes (OM). The distances corresponded to the widest and longest dimensions of the TssJLM complex.

C. Cryotomographic slices (9.7 nm) showing side views of TssJLM. In these examples, the basal parts of TssJLM (red arrows) could be seen extending into the cytoplasm. Scale bar 10 nm.

458   **E.** Antibacterial assay. Prey cells (Gfp+ kanR E. coli W3110) were mixed with the indicated attacker

459   cells, spotted onto Sci-1-inducing medium (SIM) agar plates and incubated for 4 h at 37°C. The image

460   of a representative bacterial competition spot is shown on the upper part. The relative fluorescent

461   level (in AU) and the number of recovered E. coli recipient cells are indicated in the lower graph (in

462   log10 of colony forming units (cfu)). The assays were performed from at least three independent

463   cultures, with technical triplicates and a representative technical triplicate is shown. The circles

464   indicate values from technical triplicate, and the average is indicated by the bar. **F.** Fluorescence

465   microscopy recordings showing sfGFPTssM foci in the parental (WT) and TssM mutated strains (TssM

466   Q779C/N780C, TssM Δ777-783). TssM foci containing cells are indicated by arrowheads. Microscopy

467   analyses were performed independently three times, each in technical triplicate, and a

468   representative experiment is shown. Scale bars, 1 μm. **G.** Fluorescence microscopy recordings

469   showing TssBsfGFP sheath in the parental (WT) and TssM mutated strains (TssM Q779C/N780C, TssM

470   Δ777-783). Fluorescent sheath containing cells are indicated by arrowheads. Microscopy analyses

471   were performed independently three times, each in technical triplicate, and a representative

472   experiment is shown. Scale bars, 1 μm.

473

474   **Figure 6. Summary of the Type 6 secretion system cycle of action**

475   The T6SS assembly begins first with the recruitement of the membrane complex (MC) in its resting

476   state (1). The MC recruits the baseplate (BP) and the tail tip complex (TTC) is assembled (2). The

477   recently solved structures of the BP (No Title) and MC (this paper) in the membrane context are

478   shown in the inset. A conformational change leads to the channel opening (3) and release of the

479   toxin onto the VgrG spike by contraction of the TTC (4). Once the secretion has occurred, the TTC is

480   recycled (5) and the MC can return to its resting state (6).

481

482

Materials and methods

Strains and media

Strains used in this study are listed in Table EV2. The E *E. coli* K-12 W3110 bearing the pUA66-*rrnB* vector (Kan[R] and GFP[+], (Zaslaver *et al*, 2006)) was used as recipient for antibacterial competition assays. Strains were routinely grown in lysogeny broth (LB) rich medium or in Sci-1-inducing medium (SIM; M9 minimal medium, glycerol 0.2%, vitamin B1 1 μg.mL^{-1}, casaminoacids 100 mg.mL^{-1}, LB 10%, supplemented or not with bactoagar 1.5%) (Brunet *et al*, 2011) with shaking at 37°C.

Strain construction

tssM and *tssJ* point mutations were engineered at the native locus on the chromosome by allelic replacement using the pKO3 suicide vector (Link *et al*, 1997) into the enteroaggregative *E. coli* 17-2 strain. Briefly, 17-2 WT strain was transformed with a pKO3 plasmid in which a fragment of the *tssM* or *tssJ* gene carrying the point mutations has been cloned (see below). Insertion of the plasmid into the chromosome was selected on chloramphenicol plates at 42°C. Plasmid sequences removal was then selected on 5% sucrose plates without antibiotic and *tssM* point mutation recombinant strains were screened by PCR and confirmed by DNA sequencing (Eurofins,MWG). Chromosomal fluorescent reporter insertions into the enteroaggregative *E. coli* 17-2 strain mutated in *tssM* or *tssJ* was achieved by using a modified one-step inactivation procedure (Datsenko & Wanner, 2000) as previously described (Aschtgen *et al*, 2008b) using plasmid pKOBEG (Chaveroche *et al*, 2000). Briefly, a kanamycin cassette was amplified from plasmid pKD4 using oligonucleotide pairs carrying 5' 50-nucleotide extensions homologous to regions adjacent to the gene to be deleted. After electroporation of 600 ng of column-purified PCR product, kanamycin-resistant clones were selected and verified by colony-PCR. The kanamycin cassette, inserted at the gene locus on the bacterial chromosome, was then excised using plasmid pCP20, leaving an FRT scars. Gene deletions were confirmed by colony-PCR and sequencing.

Fluorescence microscopy, image treatment and analyses

Fluorescence microscopy experiments were performed as described (Brunet *et al*, 2013; Zoued *et al*, 2013). Briefly, cells were grown overnight in LB medium and diluted to A_{600nm} ~ 0.04 in SIM. Exponentially growing cells (A_{600nm} ~ 0.8–1) were harvested, washed in phosphate-buffered saline buffer (PBS), resuspended in PBS to A_{600nm} ~ 50, spotted on a 1.5% agarose pad and covered with a cover slip. Fluorescence micrographs were captured using AxioImager M2 microscope (Zeiss) equipped with an OrcaR2 digital camera (Hamamatsu). For time lapse fluorescence microscopy, images were recorded with a Nikon Eclipse Ti microscope equipped with an Orcaflash 4.0 LT digital

518 camera (Hamamatsu) and a perfect focus system (PFS) to automatically maintain focus so that the

519 point of interest within a specimen is always kept in sharp focus at all times despite mechanical or

520 thermal perturbations. Fluorescence images were acquired with a minimal exposure time to reduce

521 bleaching and phototoxicity effects, typically 200 ms for TssB-sfGFP and 300 ms for sfGFP-TssM. For

522 image treatment, noise and background were reduced using the 'Subtract Background' (20 pixels

523 Rolling Ball) and Band plugins of imageJ (Rasband, 2012). The sfGFP foci were automatically detected

524 using the microbeJ plugin (Ducret *et al*, 2016). Floating bars representing the number of detected

525 foci for each strain were made using GraphPad (https://www.graphpad.com). Microscopy analyses

526 were performed at least three times, each in technical triplicate, and a representative experiment is

527 shown.

528

529 **Interbacterial competition assay**

530 The antibacterial growth competition assay was performed as previously described (Flaugnatti *et al*,

531 2016b). Wild-type *E. coli* K-12 strain W3110 bearing the pUA66-*rrnB* plasmid (conferring kanamycin

532 resistance and constitutive GFP fluorescence (*gfp* gene under the control of the ribosomal *rrnB*

533 promoter, (Gueguen & Cascales, 2013) was used as recipient. Attacker and recipient cells were

534 grown for 16 h in LB medium, diluted in SIM to allow maximal expression of the *sci-1* gene cluster

535 (Brunet *et al*, 2011). Once the culture reached A_{600nm}~ 0.8, cells were harvested and normalized to

536 A_{600nm} = 0.5 in SIM. Attacker and recipient cells were mixed to a 4:1 ratio and 15-µl drops of the

537 mixture were spotted in triplicate onto a pre-warmed dry SIM agar plate. After incubation for 4 h at

538 37°C, the bacterial spots were resuspended in LB and bacterial suspensions were normalized to

539 A_{600nm} = 0.5. For the enumeration of viable prey cells, bacterial suspensions were serially diluted and

540 spotted onto kanamycin LB plates. The assays were performed from at least three independent

541 cultures, with technical triplicates and a representative technical triplicate is shown.

542

543 **Protein preparation:**

544 The expression and purification of the TssJLM complex was carried out as previously described

545 (Durand *et al*, 2015), with the exception that the cryo-EM grids were prepared immediately after the

546 HisTrap Elution. For the amphipole-containing sample, the Strep-Trap elution was incubated with

547 amphipoles A8-35 (Anatrace, USA) and subjected to gel filtration on a superpose 6 (GE Healthcare,

548 UK) to remove residual detergent.

549

550 **Cryo-EM grids preparation and data acquisition**

551 C-flat ™ (CF-2/1-2C) grids were coated with graphene oxide as previously described (Martin *et al*,

552 2016). 3.5 µl of the sample at 0.2 mg.mL-1, was loaded on the copper side and then blotted on the

553   same side for 2s in a Leica EM GP at 80% humidity and 4 ˚C, before being plunge frozen in liquid

554   ethane (-184˚C). Micrographs (Fig EV3B) at a nominal magnification of 120,000 X were collected in a

555   Talos Arctica electron microscope equipped with a Falcon 3EC camera (Thermo Fisher, Waltham, MA,

556   USA) in linear mode and with a pixel size of 1.24 Å. Dose-fractionated movie frames 20/micrograph

557   were acquired for 1 s with a total electron flux of 120 e/Å/s. The defocus range chosen for the

558   automatic collect was 0.7 to 2 μm, which resulted in an actual range between 0.4 to 5 μm.

559   For the amphipoles-containing MC collection, 3019 movies composed of 25 frames at a defocus

560   range between 0.7 and 2μm, were collected at 1.38Å pixel size with a 5s exposure time and 15

561   e/pix/s exposure rate at the Krios 2 at the Diamond eBIC facility.

562

563   **Cryo-EM image processing**

564   The 16,000 movies collected were aligned using MotionCor2, with dose weighting (6 e-/Å^2/frame)

565   and with 5X5 patches applied (Zheng *et al*, 2017). gCTF was used to estimate the CTF parameters

566   (Zhang, 2016) and low quality images were discarded. Relion 2.1 (Scheres, 2012) autopicked 227,527

567   particles and after several rounds of 2D classification in cryosparc (Punjani *et al*, 2017) and a

568   heterogeneous *ab initio* reconstruction (2 classes), 37,435 particles were converted using the script

569   csparc2star.py (Asarnow, 2016) and selected for a final 2D classification in relion 2.1 (Fig EV3C), of

570   which 36,828 particles were selected. An initial unmasked refinement using the *ab initio* model from

571   crysoparc, gave us a resolution of 7.6 Å with 5-fold applied symmetry and a soft mask of 450 Å. This

572   refined structure was used to do a movie refinement with all the frames and a polishing step with

573   RELION2.1. The final masked refinement of the full structure gave a final resolution of 4.9 Å with a C5

574   symmetry applied, and 7.9 Å with no symmetry applied (Fig EV3E, I), The disordered tip and base

575   were subtracted and a masked refinement around the core structure yielded a final resolution of 4.6

576   Å (Fig EV5B). The base focused refinement was also performed on subtracted particles, without the

577   tip and the core regions, to a resolution of 17Å (Fig EV4F). The resolution for all densities except the

578   base, was calculated by masked postprocessing according to the "gold standard" method using 0.143

579   as the FSC value cut-off, or 0.5 for the low resolution reconstruction (Rosenthal & Henderson, 2003)

580   and the local resolution of the core was calculated by relion 2.1 (Fig EV5 C).

581   For figures and to build *de novo* pseudoatomic models in Coot (Emsley *et al*, 2010), the cryo-EM

582   density was initially sharpened using phenix.autosharpen (Terwilliger *et al*, 2018) and later with

583   LocalDeblur (Ramírez-aportela *et al*, 2018). Fitting of density, correlation calculations, molecular

584   graphics and analyses were performed on UCSF Chimera (Pettersen *et al*, 2004). For the amphipoles

585   dataset, 2D classes were calculated from a total of 8637 particles (Fig EV13A).

586

587   **Model building.**

588 Model building proceeded by fitting the PDB 4Y7O (Durand *et al*, 2015) into the density 2 times for

589 each pillar, with the cross correlation being calculated using Chimera (Pettersen *et al*, 2004)(Fig

590 EV5D). The model was manually built in Coot (Emsley *et al*, 2010) using bulky sidechains and

591 secondary structure predictions (Kelley *et al*, 2015) as guides. The de novo structure was validated

592 and the register adjusted using residue contact prediction (Bouvier *et al*, 2018). The map of the co-

593 evolution contacts was aligned with those of the built PDB using the MapAlign software (Ovchinnikov

594 *et al*, 2017). Where discrepancies were observed, the register was modified to fit the predicted

595 contact maps (Fig EV8). The model was then refined using one round of rosetta.refine (Wang *et al*,

596 2016) and phenix.real_space_refine (Afonine *et al*, 2018).

597

598 **Validation of the data**

599 The model was validated as in the protocol in Refmac5 (Murshudov *et al*, 2011). The FSC map to

600 model was calculated with the sharpened map (FSC_{sum}). The model was shaken by 0.5 Å and the FSC

601 map to model was calculated with one Half map (FSC_{work}). This refined model was then used to

602 calculate the FSC map to model with the other Half map (FSC_{free}) (Fig EV15A).

603 The cross correlation between each amino acid in the model and map was also calculated with

604 phenix.real_space_refine (Afonine *et al*, 2018) (Fig EV15B) and the Molprobity score (Chen *et al*,

605 2010). was obtained from the online server (Table EV5) Pore radius calculations were carried out

606 using the HOLE (Smart et al, 1996) plugin in Coot and the protein interfaces were analysed with PISA

607 (Krissinel & Henrick, 2007).

608

609 **Strains, media and chemicals**

610 The strains, plasmids and nucleotides used in this study are listed in Tables EV2 and 3. For the cryoET

611 studies, *E. coli* K-12 BL21(DE3) and enteroaggregative *E. coli* EAEC strain 17-2 were used for protein

612 overexpression before plunge freezing. Strains were routinely grown in LB-Miller or in Sci-1-inducing

613 medium (SIM; M9 minimal medium, glycerol 0.2%, vitamin B1 1 mg ml^{-1}, casaminoacids 100 mg ml^{-1},

614 LB 10%, supplemented or not with bactoagar 1.5%) (Brunet *et al*, 2011) with shaking at 37°C.

615 Plasmids were maintained by the addition of ampicillin (100 mg ml^{-1} for E. coli K-12, 200 mg ml^{-1} for

616 EAEC), kanamycin (50 mg ml^{-1}) or chloramphenicol (30 mg ml^{-1}). Expression of genes from pRSF (in

617 BL21) and pBAD33 (in EAEC) vectors was induced for 2-3h with 1 mM of isopropyl-b-D-thio-

618 galactopyrannoside (IPTG) or 0.3% L-arabinose, respectively.

619

620 **Preparation of frozen-hydrated specimens**

621 Plunge freezing was performed according to (Weiss *et al*, 2017). *E. coli* BL21 or EAEC cells were

622 concentrated by centrifugation to an OD_{600} of 3 - 20 and then mixed with protein A – 10 nm gold

623   conjugate (Cytodiagnostics Inc.). The higher concentrations of cells were used when preparing grids

624   for cryo-focused ion beam (cryo-FIB) milling to form "bacterial lawns" of several layers of bacteria on

625   top of each other. Bacterial lawns were found to be more amenable to cryo-FIB milling then

626   individual cells. A 3 µL droplet of the sample was applied to a carbon-coated EM copper grid (R2/1,

627   Quantifoil) that had been previously glow-discharged for 90 s at -25 mA using a Pelco easiGlow^{TM}

628   (Ted Pella, Inc.). The grid was plunge-frozen in liquid ethane-propane (37 %/63 %) using a Mark IV

629   Vitrobot (Thermo Fisher Scientific). The forceps were mounted in the Vitrobot (27°C, humidity 95%)

630   and the grid was blotted from both sides or only from the backside by installing a Teflon sheet

631   (instead of a filter paper) on the front blotting pad. Grids were stored in liquid nitrogen.

632

633   **Cryo-focused ion beam milling**

634   Cryo-focused ion beam (cryo-FIB) milling was used to prepare samples of plunge-frozen cells that

635   could then be imaged by electron cryotomography (Marko *et al*, 2007). Our cryo-FIB milling workflow

636   has been detailed in (Medeiros *et al*, 2018b). Frozen grids with lawns of *E. coli* BL21 cells

637   overexpressing TssJLM were clipped into modified Autogrids provided by J. Plitzko or a commercial

638   prototype provided by Thermo Fisher. We then transferred the grids into the liquid nitrogen bath of

639   a loading station (Leica Microsystems) and clamped them onto a "40° pre-tilted TEM grid holder"

640   (Leica Microsystems). The holder with grids was shuttled from the loading station to the dual beam

641   instrument using the VCT100 transfer system (Leica Microsystems). The holder was mounted on a

642   custom-built cryo-stage in a Helios NanoLab600i dual beam FIB/SEM instrument (FEI). The stage

643   temperature was maintained below -154°C during loading, milling and unloading procedures. Grid

644   quality was checked by scanning EM (SEM) imaging (5 kV, 21 pA). The samples were then coated with

645   a Platinum (Pt) precursor gas using the Gas Injector System. We adapted a "cold deposition"

646   technique that was published previously (Hayles *et al*, 2007) (needle distance to target of 8 mm,

647   temperature of the precursor gas of 27 °C, and open valve time of 5 s). Lamellae were milled in

648   several steps. We first targeted two rectangular regions to generate a lamella with ~2 µm thickness

649   with the ion beam set to 30 kV and ~400 pA. The current of the ion beam was then gradually reduced

650   until the lamella reached a nominal thickness of 150-400 nm (ion beam set to ~25 pA). Up to 6

651   lamellae were milled per grid. After documentation of the lamellae by SEM imaging, the holder was

652   brought back to the loading station using the VCT100 transfer system. The grids were unloaded and

653   stored in liquid nitrogen.

654

655   **Electron cryomicroscopy and electron cryotomography**

656   *E. coli* BL21 and EAEC cells (overexpressing TssJLM where indicated), cryo-FIB-processed *E. coli* BL21

657   cells overexpressing TssJLM, and purified TssJLM samples were examined by electron

658   cryotomography (cryoET). Images were recorded on a Tecnai Polara TEM (Thermo Fisher Scientific)

659   equipped with post-column GIF 2002 imaging filter and K2 Summit direct electron detector (Gatan),

660   or on a Titan Krios TEM (Thermo Fisher Scientific) equipped with a Quantum LS imaging filter and K2

661   Summit (Gatan). Both microscopes were operated at 300kV and the imaging filters with a 20 eV slit

662   width. The pixel size at the specimen level ranged from 4.93 Å to 4.05 Å. The latter pixel-sized was

663   used for the sub-tomogram average. Tilt series covered an angular range from -60° to +60° with 2°

664   (lamellae, sheath preparations) increments and -10 to -6 μm defocus, or in focus (0 μm defocus)

665   when the data was collected on the Titan Krios with a Volta phase plate (Thermo Fisher Scientific)

666   (Danev & Baumeister, 2016). The total dose of a tilt series was 60-100 e$^-$/Å^2. Tilt series and 2D

667   projection images were acquired automatically using UCSF Tomo (Zheng *et al*, 2007) on the Tecnai

668   Polara and SerialEM (Mastronarde, 2005) on the Titan Krios. Three-dimensional reconstructions and

669   segmentations were generated using the IMOD program suite (Kremer *et al*, 2005).

670

671   **Sub-tomogram averaging**

672   Tomograms used for subtomogram averaging were not CTF-corrected, as most of the particles

673   were extracted from tomograms collected in focus with the Volta phase plate. Individual particles

674   were identified visually in tomograms as 5-branched stars shapes in top and bottom views and as

675   inverted-Y shapes in side views and their longitudinal axes were manually modelled with open

676   contours in 3dmod (Kremer *et al*, 1996). The manual particle picking and first round of sub-

677   tomogram averaging were performed with the PEET software package on tomograms that were

678   binned by 4 (1k reconstructions). Model points, the initial motive list, and the particle rotation axes

679   were generated using the stalkInit program from the PEET package (Nicastro *et al*, 2006). This

680   approach allowed the definition of each structure's longitudinal axis as the particle y-axis. 28474

681   individual particles extracted from cryotomograms of *E. coli* BL21 ghost and FIB-milled cells were

682   averaged using PEET with a box size of 44 pixels in x and z, and 72 pixels in y for the final step on data

683   binned by 2 (2k reconstruction, final pixel size 8.1 Å). A random particle was chosen as a first

684   reference. Missing wedge compensation was activated. The final motive lists obtained after this

685   initial average performed on tomograms that were binned by 4 were then translated and used to

686   perform a new round of sub-tomogram averaging on tomograms that were binned by 2 (2k

687   reconstructions). From individual particles and after analysing the resulting average, C$_5$ symmetry

688   was imposed. The Fourier shell correlation curves were calculated in PEET to estimate resolution. A

689   cylindrical mask centred on the structure's longitudinal axis was applied to the volumes using

690   imodmop (IMOD package) in order to mask neighbouring structures and the membranes during

691   averaging. 3dmod (IMOD package) and UCSF Chimera (Pettersen *et al*, 2004) were used for

692   visualization of the averages. 3dmod was used for generating all the movies, except for the morph

693   and the atomic model visualization in Movie 3 that were generated in UCSF Chimera.
